3. The two ANS divisions exert cooperative effects on the external genitalia.
4. Roles unique to the sympathetic division are regulating blood pressure and body temperature, shunting blood in the vascular system, stimulating renin release, and metabolic effects.
5. Activation of the sympathetic division can cause widespread, long-lasting mobilization of the fight-or-flight response. Parasympathetic effects are highly localized and short-lived.

14.8 The hypothalamus oversees ANS activity (pp. 547–548)

1. Autonomic function is controlled at several levels: (1) The spinal cord and brain stem (particularly medullary) centers mediate reflex activity. (2) Hypothalamic integration centers interact with both higher and lower centers to orchestrate autonomic, somatic, and endocrine responses. (3) Cortical centers influence autonomic function via connections with the limbic system.

14.9 Most ANS disorders involve abnormalities in smooth muscle control (p. 548)

1. Most autonomic disorders reflect problems with smooth muscle control. Abnormalities in vascular control, such as hypertension, Raynaud's disease, and autonomic dysreflexia, are devastating.

Developmental Aspects of the ANS (pp. 548–549)

1. Preganglionic neurons develop from the neural tube; postganglionic neurons develop from the embryonic neural crest.
2. The efficiency of the autonomic nervous system declines in old age, as reflected by decreased gland secretion, reduced gastrointestinal motility, and slower sympathetic vasomotor responses to changes in position.

REVIEW QUESTIONS

To access additional practice questions using your smartphone, tablet, or computer: MasteringA&P® > Study Area > Practice Tests & Quizzes

Level 1 Remember/Understand

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. All of the following characterize the ANS except **(a)** a two-neuron efferent chain, **(b)** presence of neuron cell bodies in the CNS, **(c)** presence of neuron cell bodies in the ganglia, **(d)** innervation of skeletal muscles.
2. Relate each of the following terms or phrases to either the sympathetic **(S)** or parasympathetic **(P)** division of the autonomic nervous system:
   ____**(1)** short preganglionic, long postganglionic fibers
   ____**(2)** intramural ganglia
   ____**(3)** craniosacral part
   ____**(4)** adrenergic fibers
   ____**(5)** cervical ganglia
   ____**(6)** otic and ciliary ganglia
   ____**(7)** generally short-duration action
   ____**(8)** increases heart rate and blood pressure
   ____**(9)** increases gastric motility and secretion of lacrimal, salivary, and digestive juices
   ____**(10)** innervates blood vessels
   ____**(11)** most active when you are relaxing in a hammock
   ____**(12)** active when you are running in the Boston Marathon
3. The white rami communicantes contain what kind of fibers? **(a)** preganglionic parasympathetic, **(b)** postganglionic parasympathetic, **(c)** preganglionic sympathetic, **(d)** postganglionic sympathetic.
4. Collateral sympathetic ganglia are involved with innervating **(a)** abdominal organs, **(b)** thoracic organs, **(c)** head, **(d)** arrector pili, **(e)** all of these.

5. Which ANS fibers release acetylcholine? Which release norepinephrine?
6. Where are the cell bodies of visceral sensory neurons?

Level 2 Apply/Analyze

7. Briefly explain why the following terms are sometimes used to refer to the autonomic nervous system: involuntary nervous system and emotional-visceral system.
8. Describe the anatomical relationship of the white and gray rami communicantes to the spinal nerve, and indicate the kind of fibers found in each ramus type.
9. Indicate the results of sympathetic activation of the following structures: sweat glands, eye pupils, adrenal medullae, heart, bronchioles of the lungs, liver, blood vessels of vigorously working skeletal muscles, blood vessels of digestive viscera, salivary glands.
10. Which of the effects listed in response to question 9 would be reversed by parasympathetic activity?
11. Describe the meaning and importance of sympathetic tone and parasympathetic tone.
12. Describe the importance of the hypothalamus in controlling the autonomic nervous system.
13. Tiffany, a 21-year-old college student, is having trouble sleeping, cries frequently, and has recurrent thoughts of suicide. An antidepressant is prescribed. Like many such drugs, this antidepressant has anticholinergic side effects. What side effects might Tiffany experience in the first week of treatment?
14. As the aroma of freshly brewed coffee drifted by dozing Henry's nose, his mouth started to water and his stomach began to rumble. Explain his reactions in terms of ANS activity.

14

Level 3 Evaluate/Synthesize

15. Mr. Johnson suffers from urinary retention and a hypoactive urinary bladder. Bethanechol, a drug that mimics acetylcholine's autonomic effects, is prescribed to manage his problem. First explain the rationale for prescribing bethanechol, and then predict which of the following adverse effects Mr. Johnson might experience while taking this drug (select all that apply): dizziness, low blood pressure, deficient tear formation, wheezing, increased mucus production in bronchi, deficient salivation, diarrhea, cramping, excessive sweating, undesirable erection of penis.
16. A 32-year-old woman complains of intermittent aching pains in the medial two fingers of both hands. During such episodes, the fingers become blanched and then blue. Her history is taken, and it is noted that she is a heavy smoker. The physician advises her that she must stop smoking and states that she will not prescribe any medication until the patient has discontinued smoking for a month. What is this patient's condition, and why was she told to stop smoking?

CLINICAL CASE STUDY

10-Year-Old Boy with Spinal Injury

On arrival at Holyoke Hospital, Jimmy Chin, a 10-year-old boy, is immobilized on a rigid stretcher so that he is unable to move his head or trunk. The paramedics report that he was awake and alert after his accident at the skateboard park, but crying and complaining that he couldn't get up and that he had a "wicked headache." He has severe bruises on his upper back and head, and lacerations of his back and scalp. His blood pressure is low, body temperature is below normal, lower limbs are paralyzed, and he is insensitive to painful stimuli below the nipples. Although still alert on arrival, Jimmy soon begins to drift in and out of unconsciousness.

Jimmy is immediately scheduled for a CT scan, and an operating room is reserved.

Relative to Jimmy's condition:

1. Why were his head and torso immobilized for transport to the hospital?
2. What do his worsening neurological signs (drowsiness, incoherence, etc.) probably indicate? Relate this to the type of surgery that will be performed.
3. Assuming that Jimmy's sensory and motor deficits are due to a spinal cord injury, at what level do you expect to find a spinal cord lesion?
4. ✚ NCLEX-STYLE Based on your understanding of the anatomy of the nervous system, what functions is Jimmy most likely to lose?
   a. Conscious control of bladder and bowel
   b. Visceral reflexes involving digestion
   c. Reflex control of heart rate
   d. Ability to have an erection

Two days after his surgery, Jimmy is alert and his MRI scan shows no residual brain injury, but does show pronounced swelling and damage to the spinal cord at T_4. On physical examination, Jimmy shows no reflex activity below the level of the spinal cord injury. His blood pressure is still low.

5. Why are there no reflexes in his lower limbs and abdomen? Why is his blood pressure low?
6. Over the next few days, his reflexes return in his lower limbs and become exaggerated. He is incontinent. Why is Jimmy hyperreflexive and incontinent?

On one occasion, Jimmy complains of a massive headache and his blood pressure is far above normal. On examination, he is sweating intensely above the nipples but has cold, clammy skin below the nipples and his heart rate is very slow.

7. ✚ NCLEX-STYLE Which of the following names his condition and best describes what the nurse should assess for?
   a. This condition is called spinal shock, and the nurse should assess for lack of responses below the level of spinal cord injury.
   b. This condition is called Raynaud's disease, and the nurse should check for blanched fingers and toes.
   c. This condition is called autonomic neuropathy, and the nurse should check for sluggish pupil reactions and impaired sweating.
   d. This condition is called autonomic dysreflexia, and the nurse should assess for an overfilled visceral organ or a painful stimulus to his skin.
8. How does Jimmy's excessively high blood pressure put him at risk?

15 The Special Senses

In this chapter, you will learn that

The special senses are vision, smell, taste, hearing, and equilibrium

by exploring

- **Part 1 The Eye and Vision** — by asking
  - 15.1 What are the structures of the eye?
  - 15.2 How does the eye focus light?
  - 15.3 How does the retina detect light?
  - 15.4 How is visual information relayed and processed?
- **Part 2 The Chemical Senses: Smell and Taste** — looking closer at
  - 15.5 The olfactory epithelium and the sense of smell
  - 15.6 Taste buds and the sense of taste
- **Part 3 The Ear: Hearing and Balance** — by asking
  - 15.7 What is the structure of the ear? — and exploring
    - Hearing — by asking
      - 15.8 How does the cochlea detect sound? — and
        - 15.9 How is sound information relayed and processed?
    - Equilibrium — by asking
      - 15.10 How do the semicircular canals and vestibule help maintain equilibrium? — then asking
        - 15.11 What happens when things go wrong?

and finally, exploring

Developmental Aspects of the Special Senses

People are responsive creatures. The aroma of freshly baked bread makes our mouths water. A sudden clap of thunder makes us jump. These stimuli and many others continually greet us and are interpreted by our nervous systems.

When people are asked to list the senses, they usually come up with five: vision, taste, smell, hearing, and touch. Actually, touch reflects the combined activity of the general senses that we considered in Chapter 13. The remaining senses—*vision, taste, smell, hearing,* and *equilibrium*—are called **special senses**. Most of us tend to forget the sense of equilibrium, whose receptors are housed in the ear along with the organ of hearing.

In contrast to the widely distributed general receptors (most of which are modified nerve endings of sensory neurons), the **special sensory receptors** are distinct *receptor cells*. These receptor cells are highly localized in the head, either housed within complex sensory organs (eyes and ears) or in distinct epithelial structures (taste buds and olfactory epithelium).

While we discuss each special sense individually, keep in mind that our perceptions of sensory inputs overlap. What we finally experience—our "feel" of the world—is a blending of stimulus effects.

PART 1

THE EYE AND VISION

Vision is our dominant sense: Some 70% of all the sensory receptors in the body are in the eyes, and nearly half of the cerebral cortex is involved in some aspect of visual processing.

15

15.1 The eye has three layers, a lens, and humors, and is surrounded by accessory structures

Learning Outcomes

- **Describe the structure and function of accessory eye structures, eye layers, the lens, and humors of the eye.**
- **Outline the causes and consequences of cataracts and glaucoma.**

The adult **eye** is a sphere with a diameter of about 2.5 cm (1 inch). Only the anterior one-sixth of the eye's surface is visible (**Figure 15.1a**). The rest is enclosed and protected by a cushion of fat and the walls of the bony orbit. The fat pad occupies nearly all of the orbit not occupied by the eye itself. Before turning our attention to the eye itself, let's consider the accessory structures that protect it or aid its function.

Accessory Structures of the Eye

The **accessory structures** of the eye include the eyebrows, eyelids, conjunctiva, lacrimal apparatus, and extrinsic eye muscles.

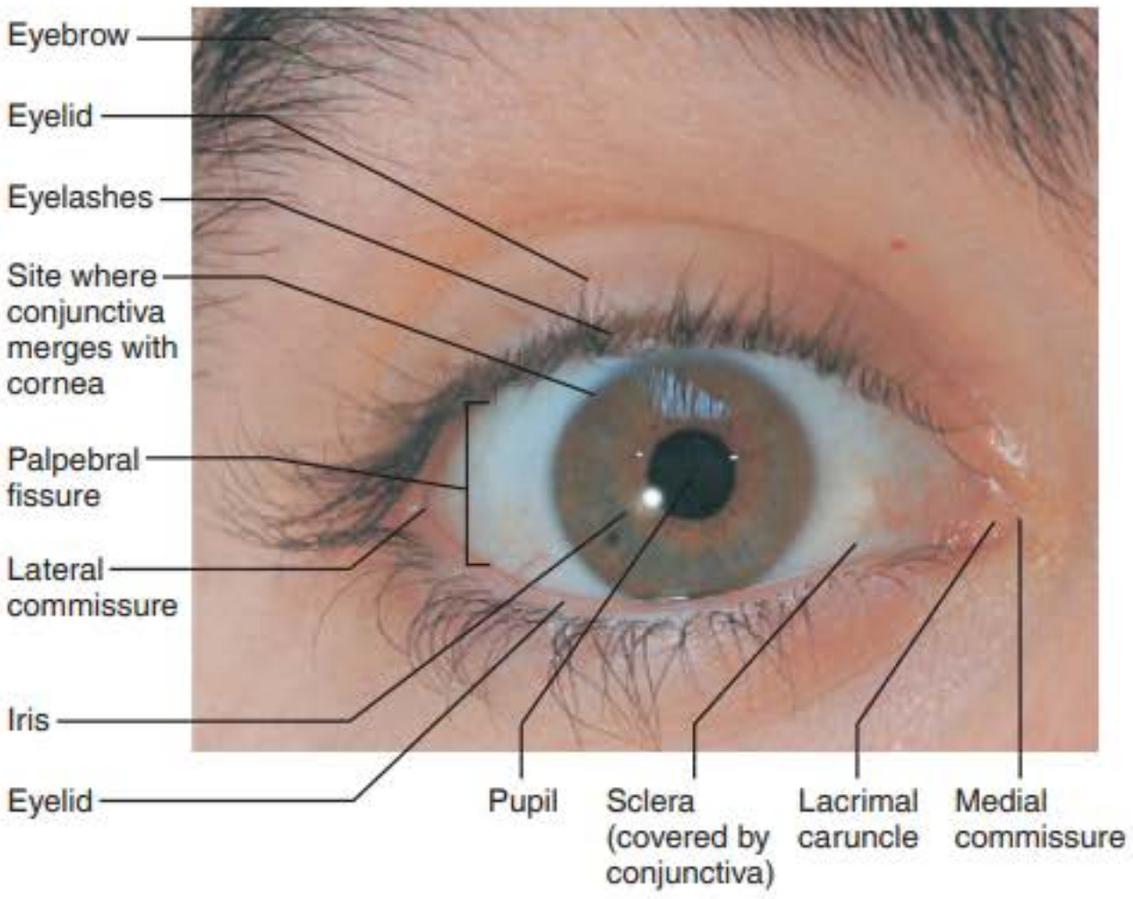
Eyebrows

The **eyebrows** are short, coarse hairs that overlie the supraorbital margins of the skull (Figure 15.1). They help shade the eyes from sunlight and prevent perspiration trickling down the forehead from reaching the eyes.

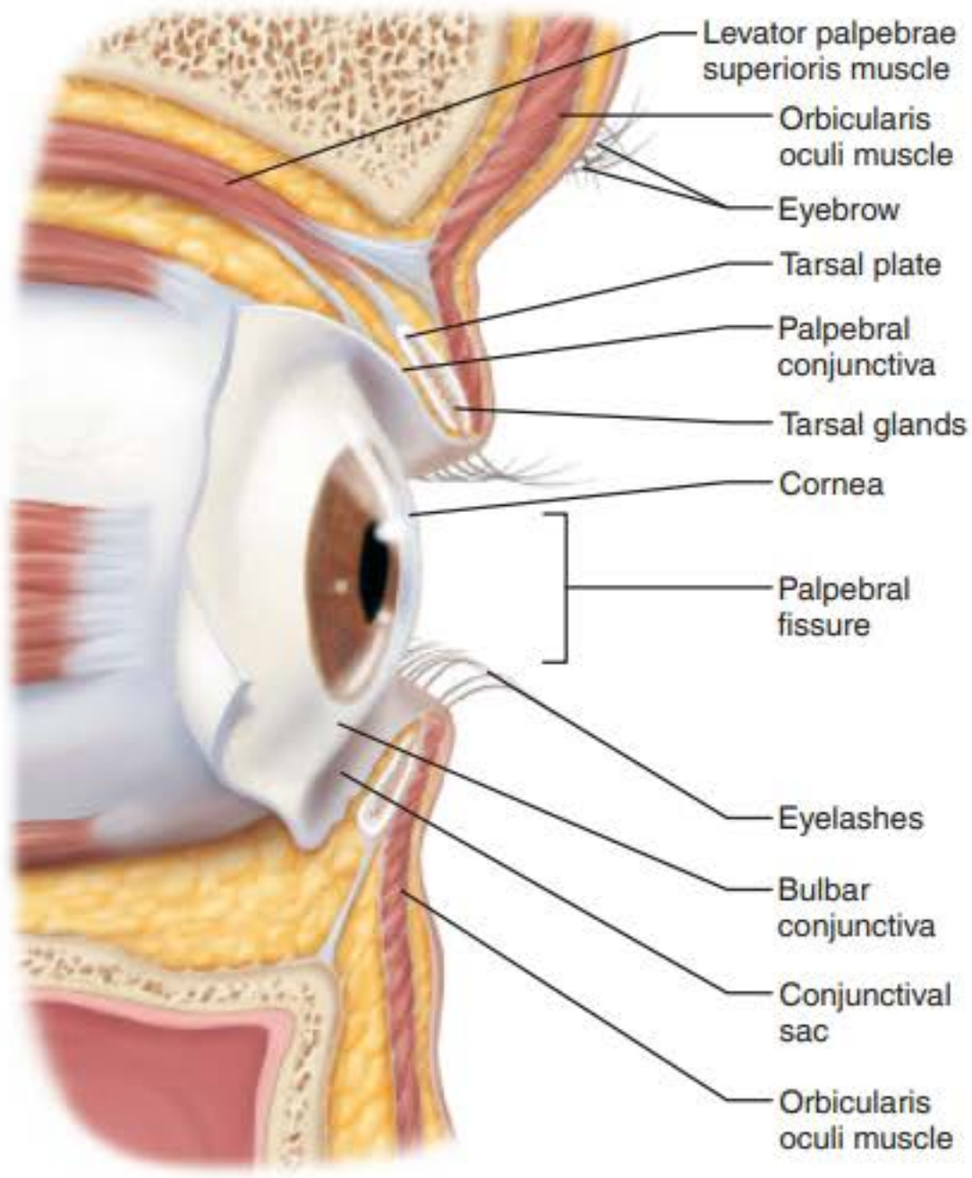
Eyelids

Anteriorly, the eyes are protected by the **eyelids** or **palpebrae** (pal′pĕ-bre). The eyelids are separated by the **palpebral fissure** ("eyelid slit") and meet at the medial and lateral angles of the eye—the **medial** and **lateral commissures** (*canthi*) (Figure 15.1a).

The medial commissure sports a fleshy elevation called the **lacrimal caruncle** (kar′ung-kl; "a bit of flesh"). The caruncle contains sebaceous and sweat glands and produces the whitish, oily secretion (fancifully called the Sandman's eye-sand) that sometimes collects at the medial commissure, especially during sleep. In most Asian



(a) Surface anatomy of the right eye



(b) **Lateral view;** some structures shown in sagittal section

Figure 15.1 The eye and accessory structures.

peoples, a vertical fold of skin called the *epicanthic fold* commonly appears on both sides of the nose and sometimes covers the medial commissure.

The eyelids are thin, skin-covered folds supported internally by connective tissue sheets called **tarsal plates** (Figure 15.1b). The tarsal plates also anchor the **orbicularis oculi** and **levator palpebrae superioris** muscles that run within the eyelid. The orbicularis muscle encircles the eye, and the eye closes when it contracts. The upper eyelid is much more mobile, mainly because of the levator palpebrae superioris muscle, which raises that eyelid to open the eye.

The eyelid muscles are activated reflexively to cause blinking every 3–7 seconds and to protect the eye from foreign objects. Each time we blink, accessory structure secretions (oil, mucus, and saline solution) spread across the eyeball surface, keeping the eyes moist.

Projecting from the free margin of each eyelid are the **eyelashes**. The follicles of the eyelash hairs are richly innervated by nerve endings (hair follicle receptors), and anything that touches the eyelashes (even a puff of air) triggers reflex blinking.

Several types of glands are associated with the eyelids. The **tarsal glands** are embedded in the tarsal plates (Figure 15.1b), and their ducts open at the eyelid edge just posterior to the eyelashes. These modified sebaceous glands produce an oily secretion that lubricates the eyelid and the eye and prevents the eyelids from sticking together. A number of smaller, more typical sebaceous glands are associated with the eyelash follicles. Modified sweat glands called ciliary glands lie between the hair follicles (*cilium* = eyelash).

HOMEOSTATIC IMBALANCE 15.1 CLINICAL

Obstructed tarsal glands may cause a firm, usually painless bump called a *chalazion* (kah-la′ze-on; "swelling"). A **sty** is a painful inflammation of the sebaceous glands at the base of the eyelashes.

Conjunctiva

The **conjunctiva** (kon″junk-ti′vah; "joined together") is a transparent mucous membrane. It lines the eyelids as the **palpebral conjunctiva** and folds back over the anterior surface of the eyeball as the **bulbar conjunctiva** (Figure 15.1b). The bulbar conjunctiva covers only the white of the eye, not the cornea. The bulbar conjunctiva is very thin, and blood vessels are clearly visible beneath it. (They are even more visible in irritated "bloodshot" eyes.)

When the eye is closed, a slitlike space occurs between the conjunctiva-covered eyeball and eyelids. This so-called **conjunctival sac** is where a contact lens lies, and eye medications are often administered into its inferior recess. The major function of the conjunctiva is to produce a lubricating mucus that prevents the eyes from drying out.

HOMEOSTATIC IMBALANCE 15.2 CLINICAL

Inflammation of the conjunctiva, called *conjunctivitis*, results in reddened, irritated eyes. *Pinkeye*, a conjunctival infection caused by bacteria or viruses, is highly contagious.

Lacrimal Apparatus

The **lacrimal apparatus** (lak′rĭ-mal; "tear") consists of the lacrimal gland and the ducts that drain lacrimal secretions into the nasal cavity (**Figure 15.2**). The **lacrimal gland** lies in the orbit above the lateral end of the eye and is visible through the conjunctiva when the lid is everted. It continually releases a dilute saline solution called **lacrimal secretion**—or, more commonly, **tears**—into the superior part of the conjunctival sac through several small excretory ducts.

Blinking spreads the tears downward and across the eyeball to the medial commissure, where they enter the paired **lacrimal canaliculi** via two tiny openings called **lacrimal puncta** (literally, "prick points"), visible as tiny red dots on the medial margin of each eyelid. From the lacrimal canaliculi, the tears drain into the **lacrimal sac** and then into the **nasolacrimal duct**, which empties into the nasal cavity at the inferior nasal meatus.

Lacrimal fluid contains mucus, antibodies, and **lysozyme**, an enzyme that destroys bacteria. As a result, it cleanses and protects the eye surface as it moistens and lubricates it. When lacrimal secretion increases substantially, tears spill over the eyelids and fill the nasal cavities, causing congestion and the "sniffles." This spillover (tearing) happens when the eyes are irritated or when we are emotionally upset. In the case of eye irritation, enhanced tearing washes away or dilutes the irritating substance. The importance of emotionally induced tears is poorly understood.

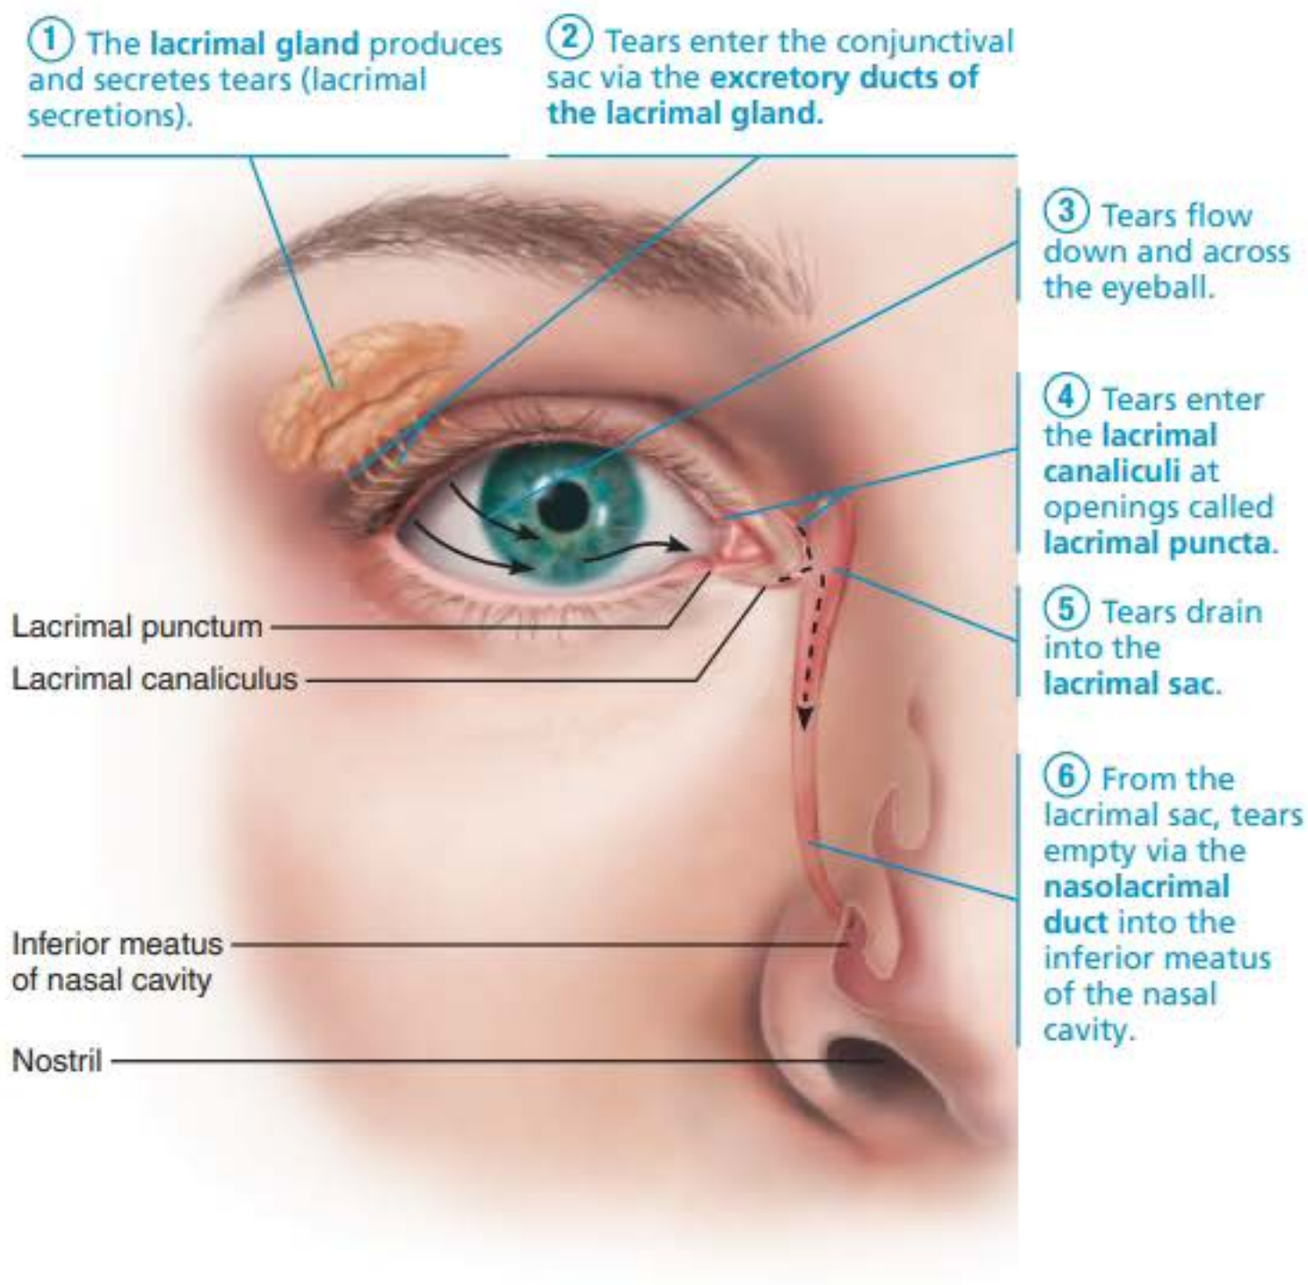


Figure 15.2 The lacrimal apparatus. Arrows indicate the flow of lacrimal fluid (tears) from the lacrimal gland to the nasal cavity.

HOMEOSTATIC IMBALANCE 15.3 — CLINICAL

Because the nasal cavity mucosa is continuous with that of the lacrimal duct system, a cold or nasal inflammation often causes the lacrimal mucosa to swell. This swelling constricts the ducts and prevents tears from draining, causing "watery" eyes.

Extrinsic Eye Muscles

How do our eyes move? Six straplike **extrinsic eye muscles** control the movement of each eyeball. These muscles originate from the walls of the orbit and insert into the outer surface of the eyeball (**Figure 15.3**). They allow the eyes to follow a moving object, help maintain the shape of the eyeball, and hold it in the orbit.

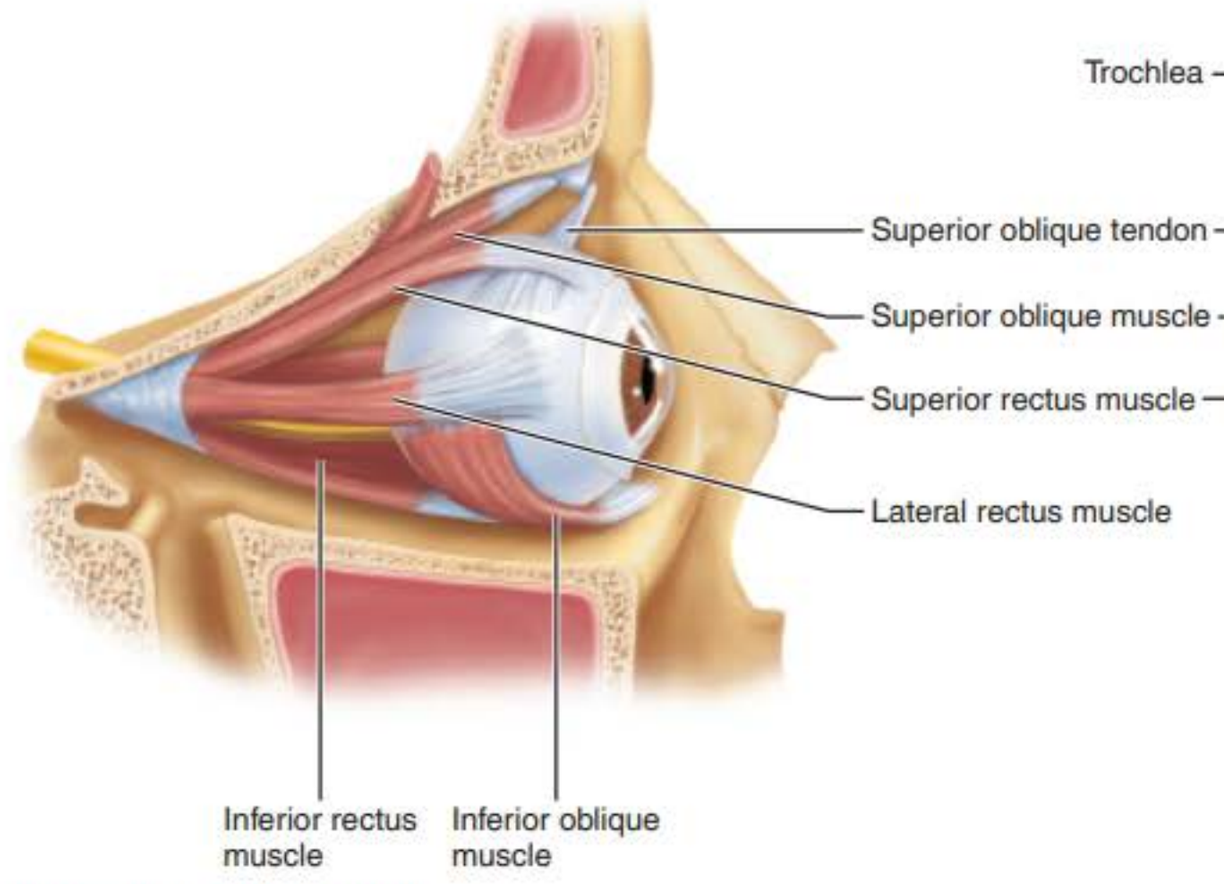
The four *rectus muscles* originate from the **common tendinous ring** (annular ring) at the back of the orbit and run straight to their insertion on the eyeball. Their locations and the movements that they promote are clearly indicated by their names: **superior, inferior, lateral**, and **medial rectus muscles**.

The actions of the two *oblique muscles* are less easy to deduce because they take rather strange paths through the orbit. They move the eye in the vertical plane when the eyeball is already turned medially by the rectus muscles. The **superior oblique muscle** originates in common with the rectus muscles, runs along the medial wall of the orbit, and then makes a right-angle turn and passes through a fibrocartilaginous loop called the **trochlea** (trok′le-ah; "pulley") suspended from the frontal bone before inserting on the superolateral aspect of the eyeball. It rotates the eye downward and somewhat laterally.

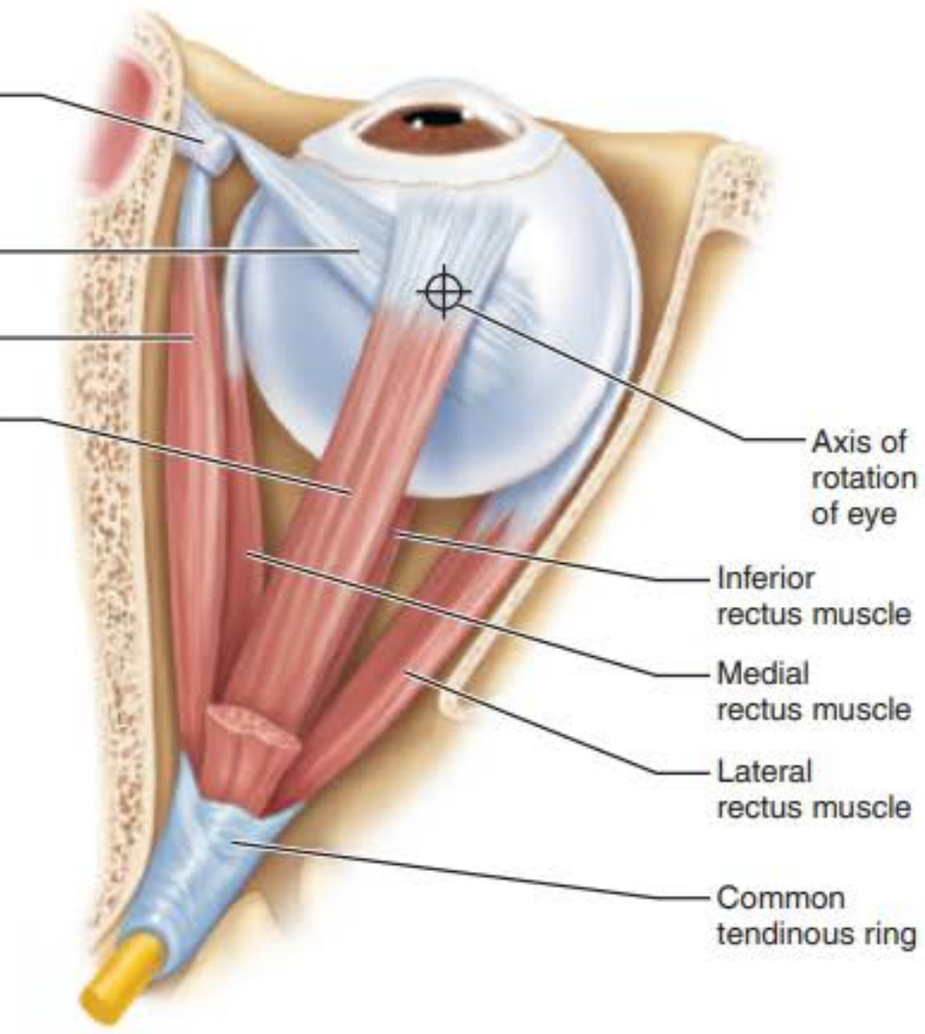
The **inferior oblique muscle** originates from the medial orbit surface and runs laterally and obliquely to insert on the inferolateral eye surface. It rotates the eye up and laterally.

The four rectus muscles would seem to provide all of the eye movements we require—medial, lateral, superior, and inferior—so why the two oblique muscles? The simplest answer is that the superior and inferior recti cannot elevate or depress the eye *without also turning it medially* because they approach the eye from a posteromedial direction. For an eye to be *directly* elevated or depressed, the lateral pull of the oblique muscles is necessary to cancel the medial pull of the superior and inferior recti.

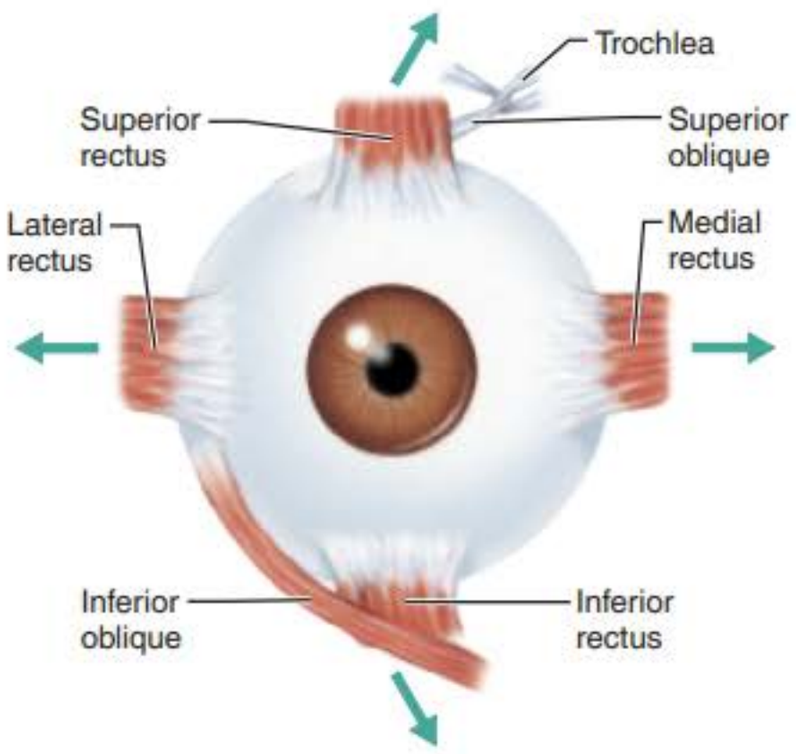
Except for the lateral rectus and superior oblique muscles, which are innervated respectively by the *abducens* and *trochlear nerves*, the *oculomotor nerves* serve all extrinsic eye muscles.



(a) Lateral view of the right eye



(b) Superior view of the right eye



(c) Anterior view of the right eye

Muscle	Action	Controlling cranial nerve
Lateral rectus	Moves eye laterally	VI (abducens)
Medial rectus	Moves eye medially	III (oculomotor)
Superior rectus	Elevates eye and turns it medially	III (oculomotor)
Inferior rectus	Depresses eye and turns it medially	III (oculomotor)
Inferior oblique	Elevates eye and turns it laterally	III (oculomotor)
Superior oblique	Depresses eye and turns it laterally	IV (trochlear)

(d) Summary of muscle actions and innervating cranial nerves

15

Figure 15.3 Extrinsic eye muscles.

Figure 15.3d summarizes the actions and nerve supply of these muscles. Table 13.2 (◀ pp. 501, 503) illustrates the courses of the associated cranial nerves.

The extrinsic eye muscles are among the most precisely and rapidly controlled skeletal muscles in the entire body. This precision reflects their high axon-to-muscle-fiber ratio: The motor units of these muscles contain only 8 to 12 muscle cells and in some cases as few as two or three.

HOMEOSTATIC IMBALANCE 15.4 CLINICAL

When movements of the external muscles of the two eyes are not perfectly coordinated, a person cannot properly focus the images of the same area of the visual field from each eye and so sees two images instead of one. This condition is called **diplopia** (dĭ-plo′pe-ah), or *double vision*. It can result from paralysis or weakness of certain extrinsic muscles, or neurological disorders.

Congenital weakness of the external eye muscles may cause **strabismus** (strah-biz′mus; "squinting"), in which the affected eye rotates medially or laterally. To compensate, the eyes may alternate in focusing on objects. In other cases, only the controllable eye is used, and the brain begins to disregard inputs from the deviant eye, which (unless treated early) can then become functionally blind.

In addition to the extrinsic eye muscles, the eye also contains **intrinsic eye muscles**—the ciliary body and the iris—that are controlled by the autonomic nervous system. We will discuss these muscles shortly.

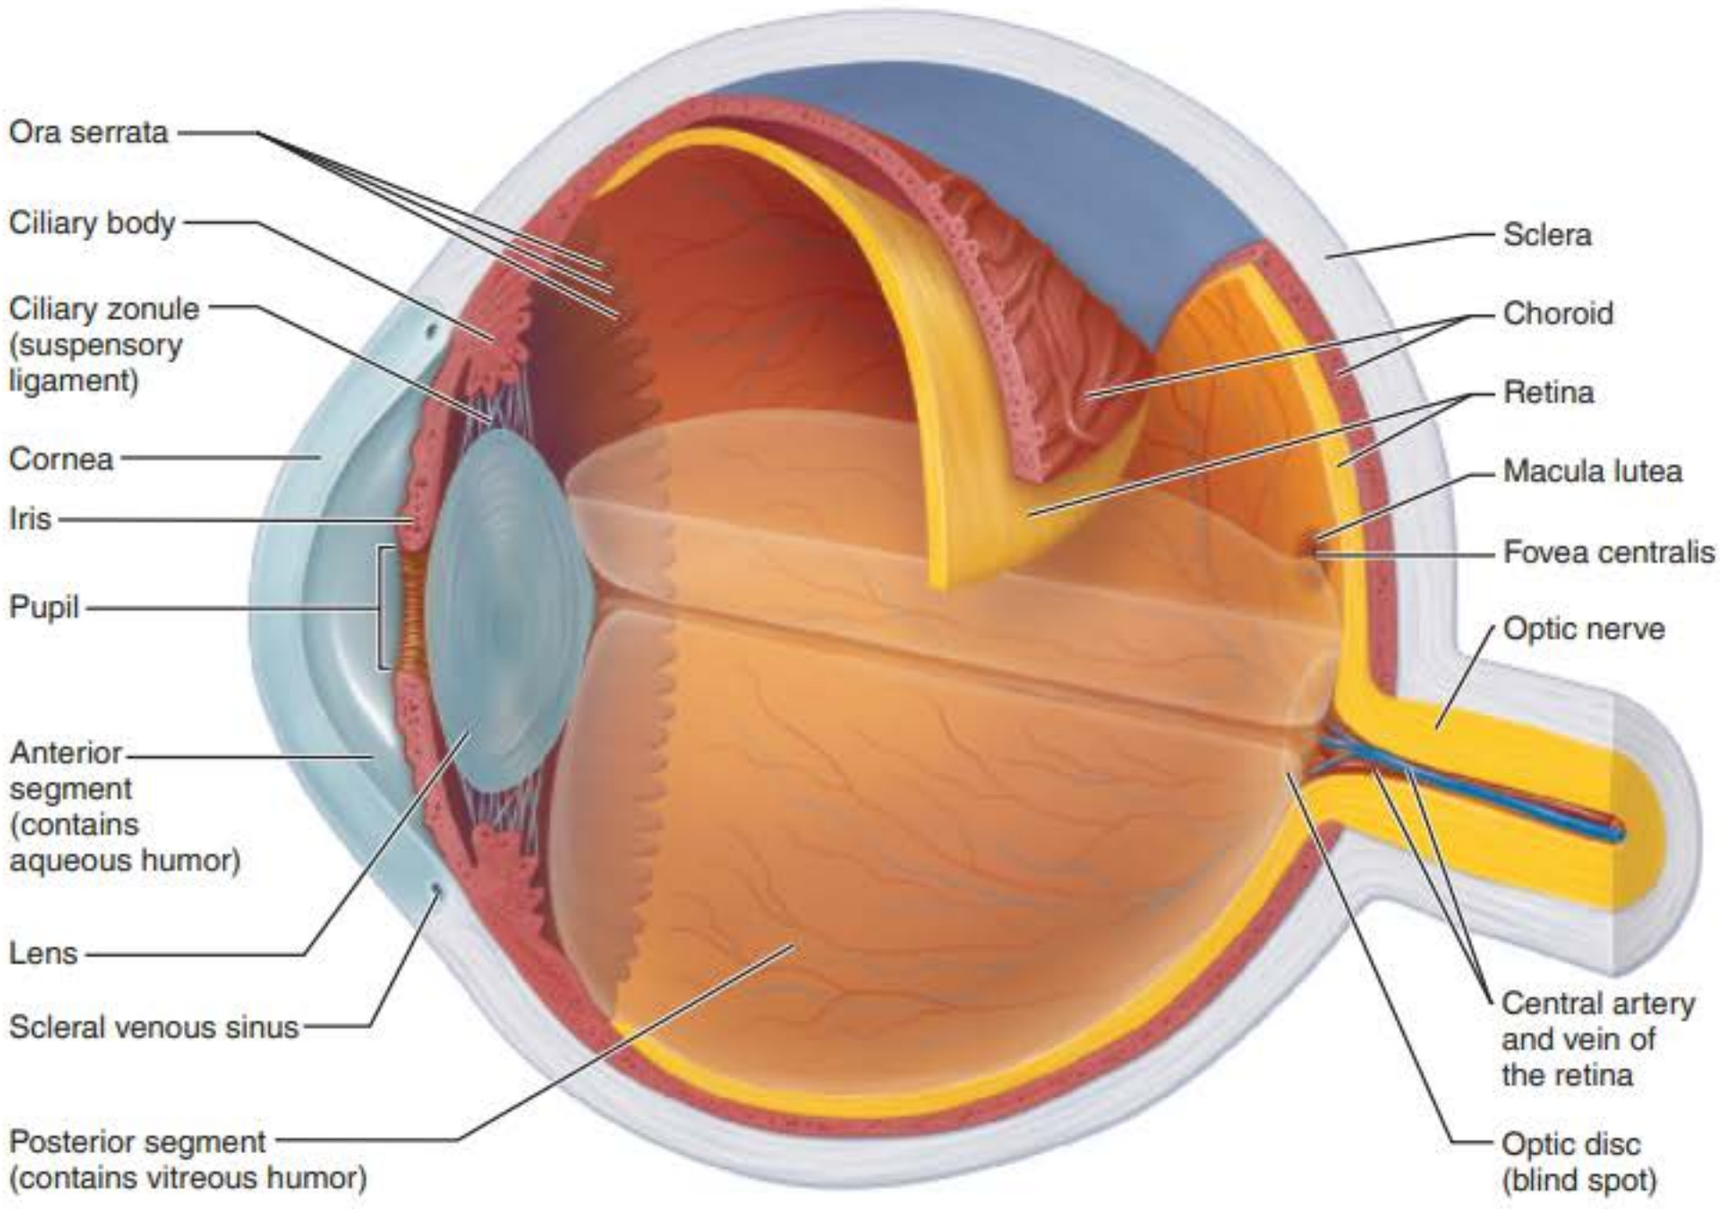
Structure of the Eyeball

The eye itself, commonly called the **eyeball**, is a slightly irregular hollow sphere (**Figure 15.4**). Its wall is composed of three layers: the fibrous, vascular, and inner layers. Its internal cavity is filled with fluids called *humors* that help to maintain its shape. The lens, the adjustable focusing apparatus of the eye, is supported vertically within the eyeball, and divides it into *anterior* and *posterior segments*.

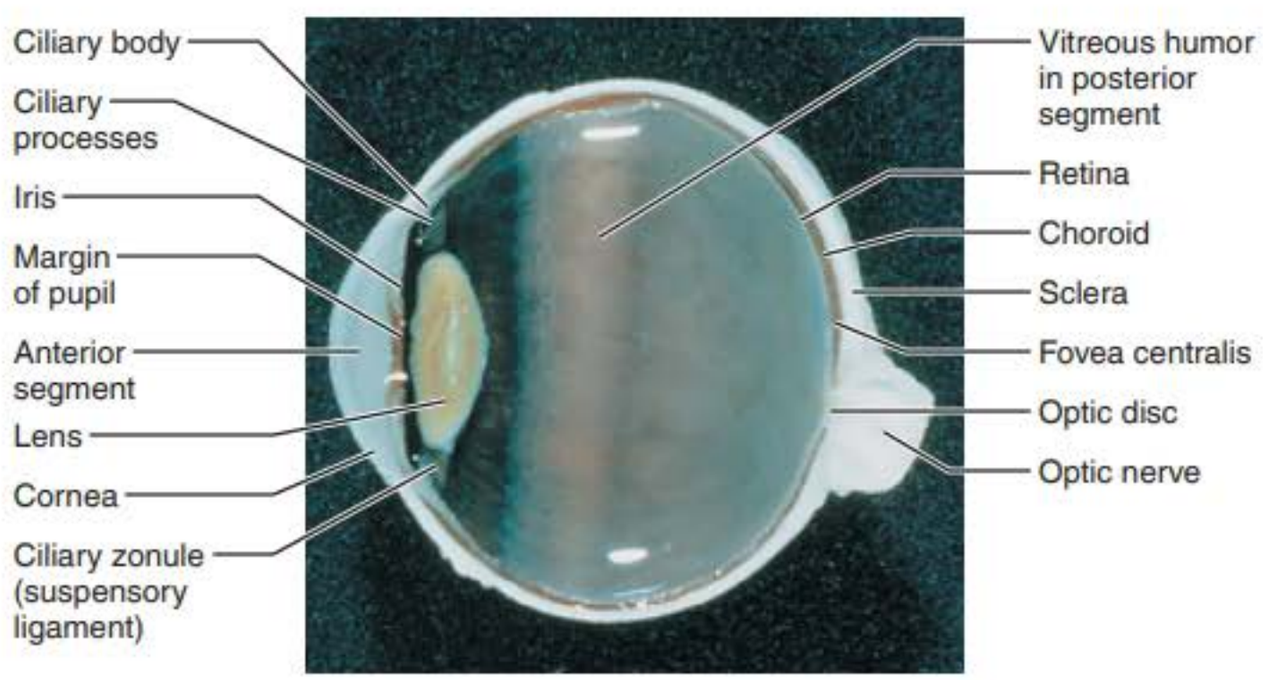
Fibrous Layer

The outermost coat of the eyeball, the **fibrous layer**, is composed of dense avascular connective tissue. It has two obviously different regions: the sclera and the cornea.

Sclera The **sclera** (skler′ah; "hard"), forming the posterior portion and the bulk of the fibrous layer, is glistening white and opaque. Seen anteriorly as the "white of the eye," the tough, tendonlike sclera protects and shapes the eyeball and provides a



(a) Diagrammatic view. The vitreous humor is illustrated only in the bottom part of the eyeball.



(b) Photograph of the human eye.

Figure 15.4 Internal structure of the eye (sagittal section).

sturdy anchoring site for the extrinsic eye muscles. Posteriorly, where the sclera is pierced by the optic nerve (cranial nerve II), it is continuous with the dura mater of the brain.

Cornea The anterior sixth of the fibrous layer is modified to form the transparent **cornea**, which bulges anteriorly from its junction with the sclera. The crystal-clear cornea forms a window that lets light enter the eye, and is a major part of the light-bending apparatus of the eye.

Epithelial sheets cover both faces of the cornea:

- The external sheet, a stratified squamous epithelium that protects the cornea from abrasion, merges with the bulbar conjunctiva at the corneoscleral junction. Epithelial cells that continually renew the cornea are located here.
- The deep *corneal endothelium*, composed of simple squamous epithelium, lines the inner face of the cornea. Its cells have active sodium pumps that maintain the clarity of the cornea by keeping its water content low.

The cornea is well supplied with nerve endings, most of which are pain receptors. (This is why some people can't tolerate contact lenses.) When the cornea is touched, blinking and increased tearing occur reflexively. Even so, the cornea is the most exposed part of the eye and is vulnerable to damage from dust, slivers, and the like. Luckily, its capacity for regeneration and repair is extraordinary.

The cornea has no blood vessels and so it is beyond the reach of the immune system. As a result, the cornea is the only tissue in the body that can be transplanted from one person to another with little risk of rejection.

Vascular Layer

The **vascular layer** forms the middle coat of the eyeball. Also called the *uvea* (u′ve-ah; "grape"), this pigmented layer has three regions: choroid, ciliary body, and iris (Figure 15.4).

Choroid The **choroid** is a blood vessel–rich, dark brown membrane (*choroid* = membrane) that forms the posterior five-sixths of the vascular layer. Its blood vessels nourish all eye layers. Its brown pigment, produced by melanocytes, helps absorb light, preventing it from scattering and reflecting within the eye (which would cause visual confusion). The choroid has a posterior opening where the optic nerve leaves the eye.

Ciliary Body Anteriorly, the choroid becomes the **ciliary body**, a thickened ring of tissue that encircles the lens and has three parts:

- **Ciliary muscles. Ciliary muscles** make up most of the ciliary body and consist of interlacing smooth muscle bundles that control lens shape.
- **Ciliary processes.** Near the lens, the posterior surface of the ciliary body has radiating folds called **ciliary processes**, which secrete the fluid that fills the cavity of the anterior segment of the eyeball.
- **Ciliary zonule.** The **ciliary zonule** (*suspensory ligament*) extends from the ciliary processes to the lens. This halo of fine fibers encircles the circumference of the lens and helps hold it in its upright position. It also transmits tension from the ciliary muscle to the lens.

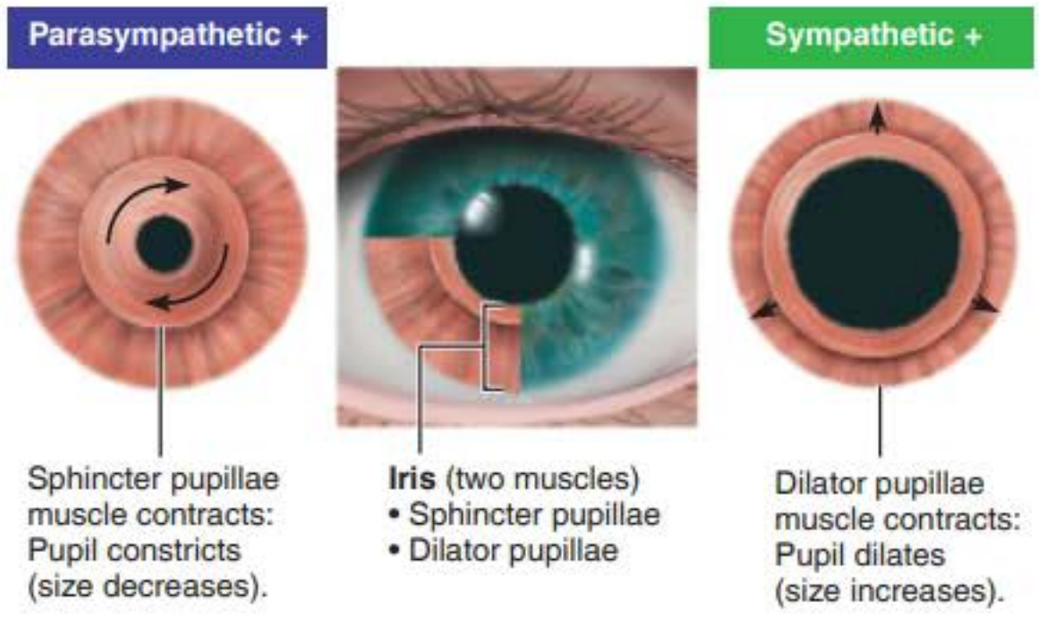


Figure 15.5 Pupil constriction and dilation.
(+ means activation.)

Iris The **iris**, the colored part of the eye, is the most anterior portion of the vascular layer. Shaped like a flattened doughnut, it lies between the cornea and the lens and is continuous with the ciliary body posteriorly. Its round central opening, the **pupil**, allows light to enter the eye. The iris is made up of two smooth muscle layers with bunches of sticky elastic fibers that congeal into a random pattern before birth. Its muscle fibers allow it to act as a reflexively activated diaphragm to vary pupil size (**Figure 15.5**). In close vision and bright light, the *sphincter pupillae* (circular muscles) contracts and the pupil constricts. In distant vision and dim light, the *dilator pupillae* (radial muscles) contracts and the pupil dilates, allowing more light to enter. Sympathetic fibers control pupillary dilation, and parasympathetic fibers control constriction.

Changes in pupil size may also reflect our interests and emotional reactions. Our pupils often dilate when we see something that appeals to us, when we feel fear, and during problem solving. (Computing your taxes should make your pupils get bigger and bigger.) On the other hand, boredom or viewing something unpleasant causes pupils to constrict.

Although irises come in different colors (*iris* = rainbow), they contain only brown pigment. When they have a lot of pigment, the eyes appear brown or black. If the amount of pigment is small and restricted to the posterior surface of the iris, the unpigmented parts simply scatter the shorter wavelengths of light and the eyes appear blue, green, or gray. Most newborn babies' eyes are slate gray or blue because their iris pigment is not yet developed.

Inner Layer (Retina)

The innermost layer of the eyeball is the delicate **retina** (ret′ĭ-nah), which develops from an extension of the brain. It contains (1) millions of photoreceptors that transduce (convert) light energy, (2) other neurons involved in processing responses to light, and (3) glia. The retina consists of two layers: an outer

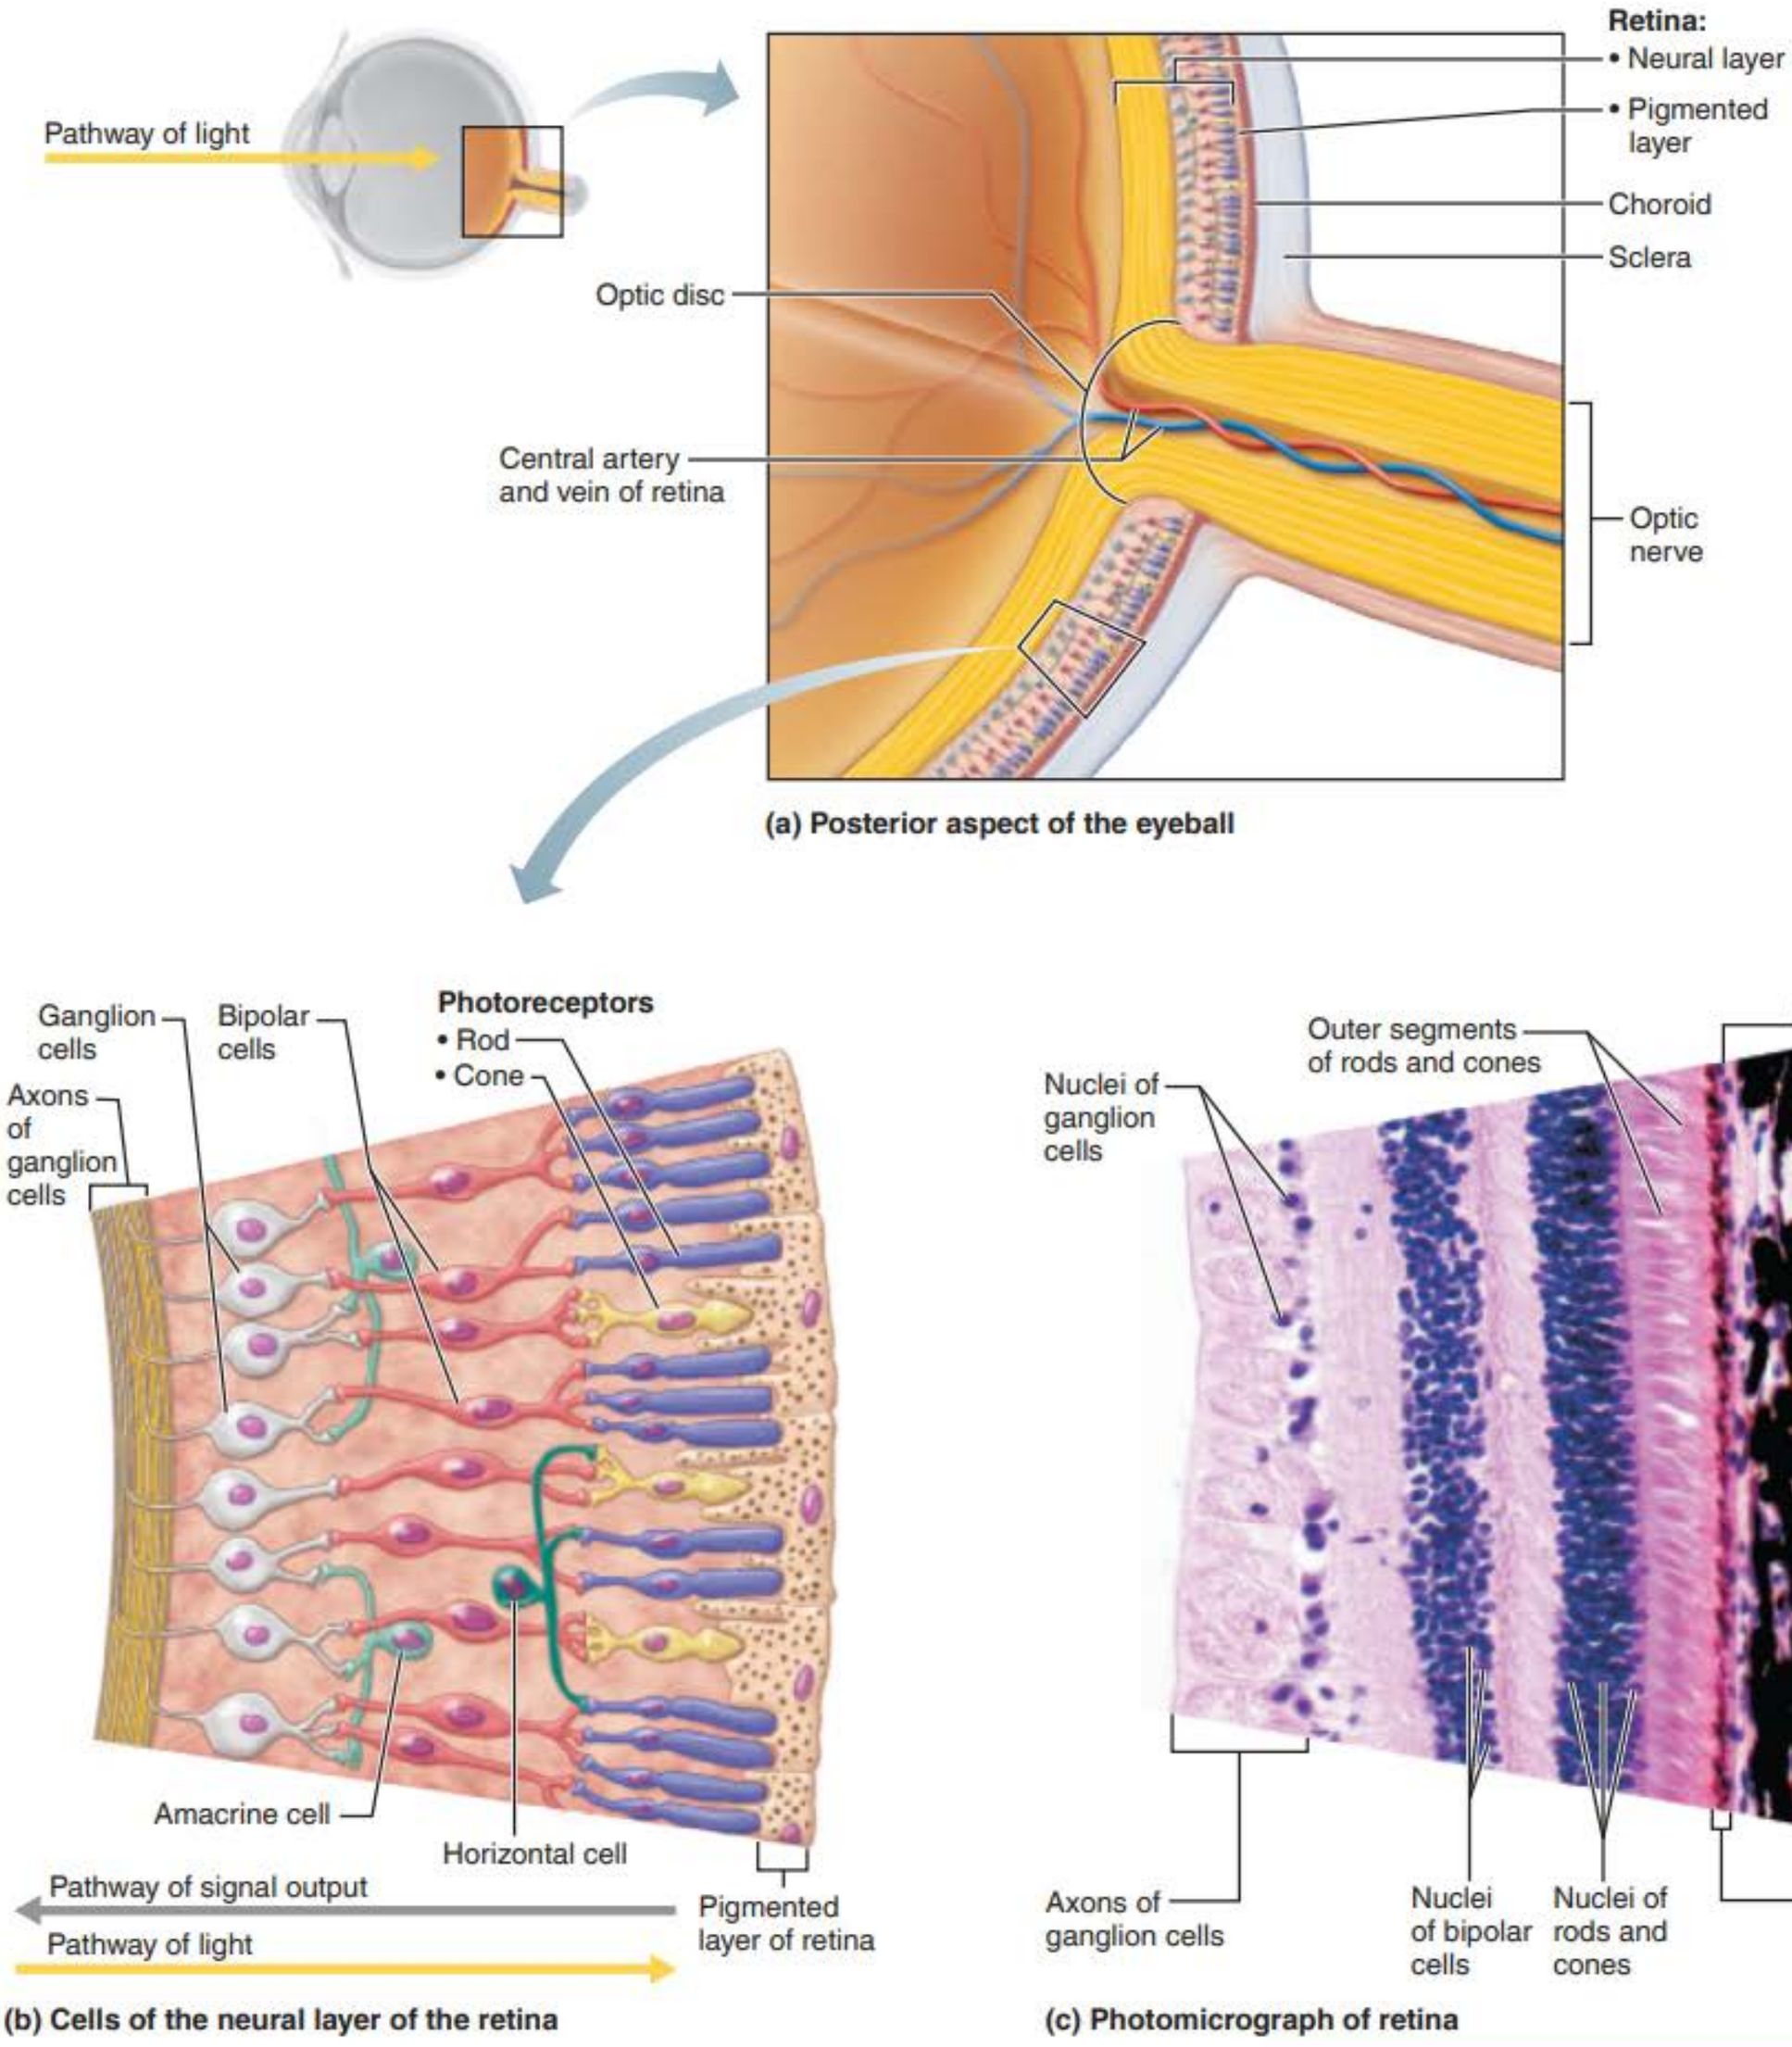

Figure 15.6 Microscopic anatomy of the retina. (a) The axons of the ganglion cells form the optic nerve, which leaves the back of the eyeball at the optic disc. **(b)** Light (indicated by the yellow arrow) passes through the retina to excite the photoreceptor cells (rods and cones). Information (output signals; gray arrow) flows in the opposite direction via bipolar and ganglion cells. **(c)** Photomicrograph (145×).

Practice Histology questions: MasteringA&P® > Study Area > Lab Tools > PAL

pigmented layer and an inner *neural layer* (**Figure 15.6**). Although the pigmented and neural layers are very close together, they are not fused. Only the neural layer of the retina plays a direct role in vision.

Pigmented Layer of the Retina The outer **pigmented layer**, a single-cell-thick lining, is next to the choroid, and extends anteriorly to cover the ciliary body and the posterior face of the iris. These pigment cells, like those of the choroid, absorb light and prevent it from scattering in the eye. They also act as phagocytes participating in photoreceptor cell renewal (described on p. 569), and store vitamin A needed by the photoreceptor cells.

Neural Layer of the Retina The transparent inner **neural layer** extends anteriorly to the posterior margin of the ciliary body. This junction is called the **ora serrata**, literally, the saw-toothed margin (see Figure 15.4).

From posterior to anterior, the neural layer is composed of three main types of neurons: **photoreceptors**, **bipolar cells**, and **ganglion cells** (Figure 15.6). Signals are produced in response to light and spread from the photoreceptors (next to the pigmented layer) to the bipolar cells and then to the innermost ganglion cells, where action potentials are generated. The ganglion cell axons make a right-angle turn at the inner face of the retina, then leave the posterior aspect of the eye as the thick optic nerve. The retina also contains other types of neurons—horizontal cells and amacrine cells—which play a role in visual processing (see p. 575).

The **optic disc**, where the optic nerve exits the eye, is a weak spot in the **fundus** (posterior wall) of the eye because it is not reinforced by the sclera. The optic disc is also called the **blind spot** because it lacks photoreceptors, so light focused on it cannot be seen. We do not usually notice these gaps in our vision because the brain uses a sophisticated process called *filling in* to deal with absence of input.

The quarter-billion photoreceptors found in the neural layer are of two types: rods and cones.

- **Rods** are our dim-light and peripheral vision receptors. They are more numerous and far more sensitive to light than cones, but they do not provide sharp images or color vision. This is why colors disappear and the edges of objects appear fuzzy in dim light and at the edges of our visual field.
- **Cones**, in contrast, are our vision receptors for bright light and provide high-resolution color vision.

Lateral to the blind spot of each eye is an oval region called the **macula lutea** (mak′u-lah lu′te-ah; "yellow spot") with a minute (0.4 mm) pit in its center called the **fovea centralis** (see Figure 15.4). In this region, the retinal structures next to the vitreous humor are displaced to the sides. This allows light to pass almost directly to the photoreceptors rather than through several retinal layers, greatly enhancing visual acuity (the ability to resolve detail). The fovea contains only cones, the macula contains mostly cones, and from the edge of the macula toward the retina periphery, cone density declines gradually. The retina periphery contains mostly rods, which decrease in density from there to the macula.

Only the foveae have a sufficient cone density to provide detailed color vision, so anything we wish to view critically is focused on the foveae. Because each fovea is only about the size of the head of a pin, only a thousandth of the entire visual field is in *hard focus* (foveal focus) at a given moment. Consequently, for us to visually comprehend a scene that is rapidly changing (as when we drive in traffic), our eyes must flick rapidly back and forth to provide the foveae with images of different parts of the visual field.

The neural layer of the retina receives its blood supply from two sources. Vessels in the choroid supply the outer third (containing photoreceptors). The inner two-thirds is served by the **central artery** and **central vein of the retina**, which enter and leave the eye through the center of the optic nerve (see Figure 15.4a). Radiating outward from the optic disc, these vessels give rise to a rich vascular network. This is the only place where small blood vessels are visible in a living person (**Figure 15.7**). Physicians may observe these tiny vessels with an ophthalmoscope for signs of hypertension, diabetes, and other vascular diseases.

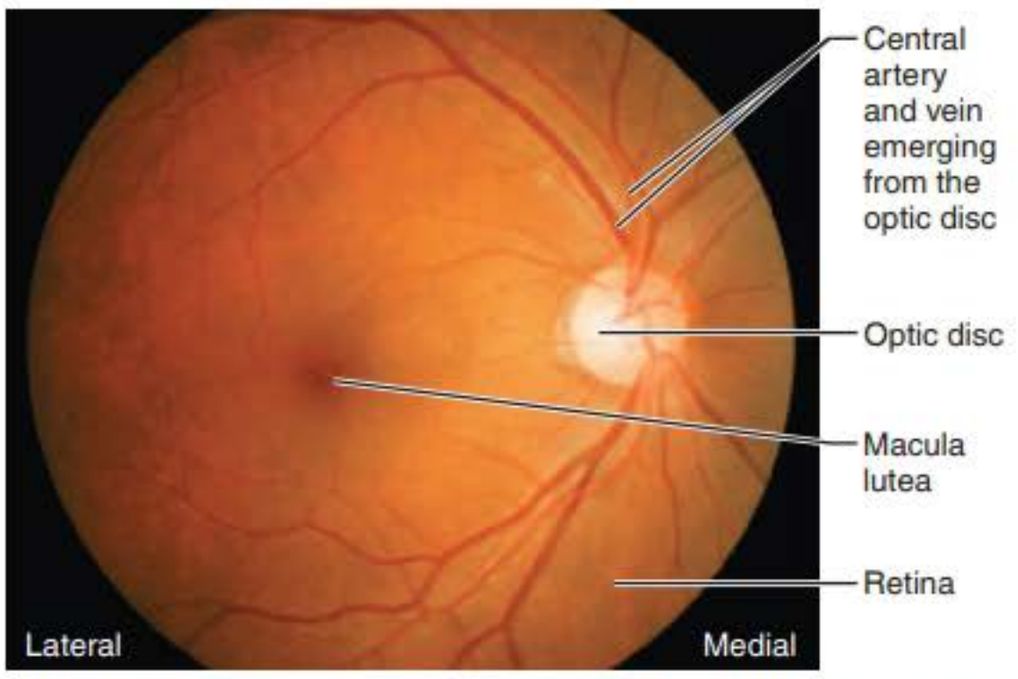

Figure 15.7 Part of the posterior wall (fundus) of the right eye as seen with an ophthalmoscope.

HOMEOSTATIC IMBALANCE 15.5 CLINICAL

The pattern of vascularization of the retina makes it susceptible to *retinal detachment*. This condition, in which the pigmented and neural layers separate (detach) and allow the jellylike vitreous humor to seep between them, can cause permanent blindness because it deprives the photoreceptors of nutrients.

Retinal detachment may happen when the retina is torn during a traumatic blow to the head or when the head stops moving suddenly and then jerks in the opposite direction (as in bungee jumping). The symptom that victims most often describe is "a curtain being drawn across the eye," but some people see soot-like spots or light flashes. If diagnosed early, it is often possible to reattach the retina with a laser before photoreceptors are permanently damaged.

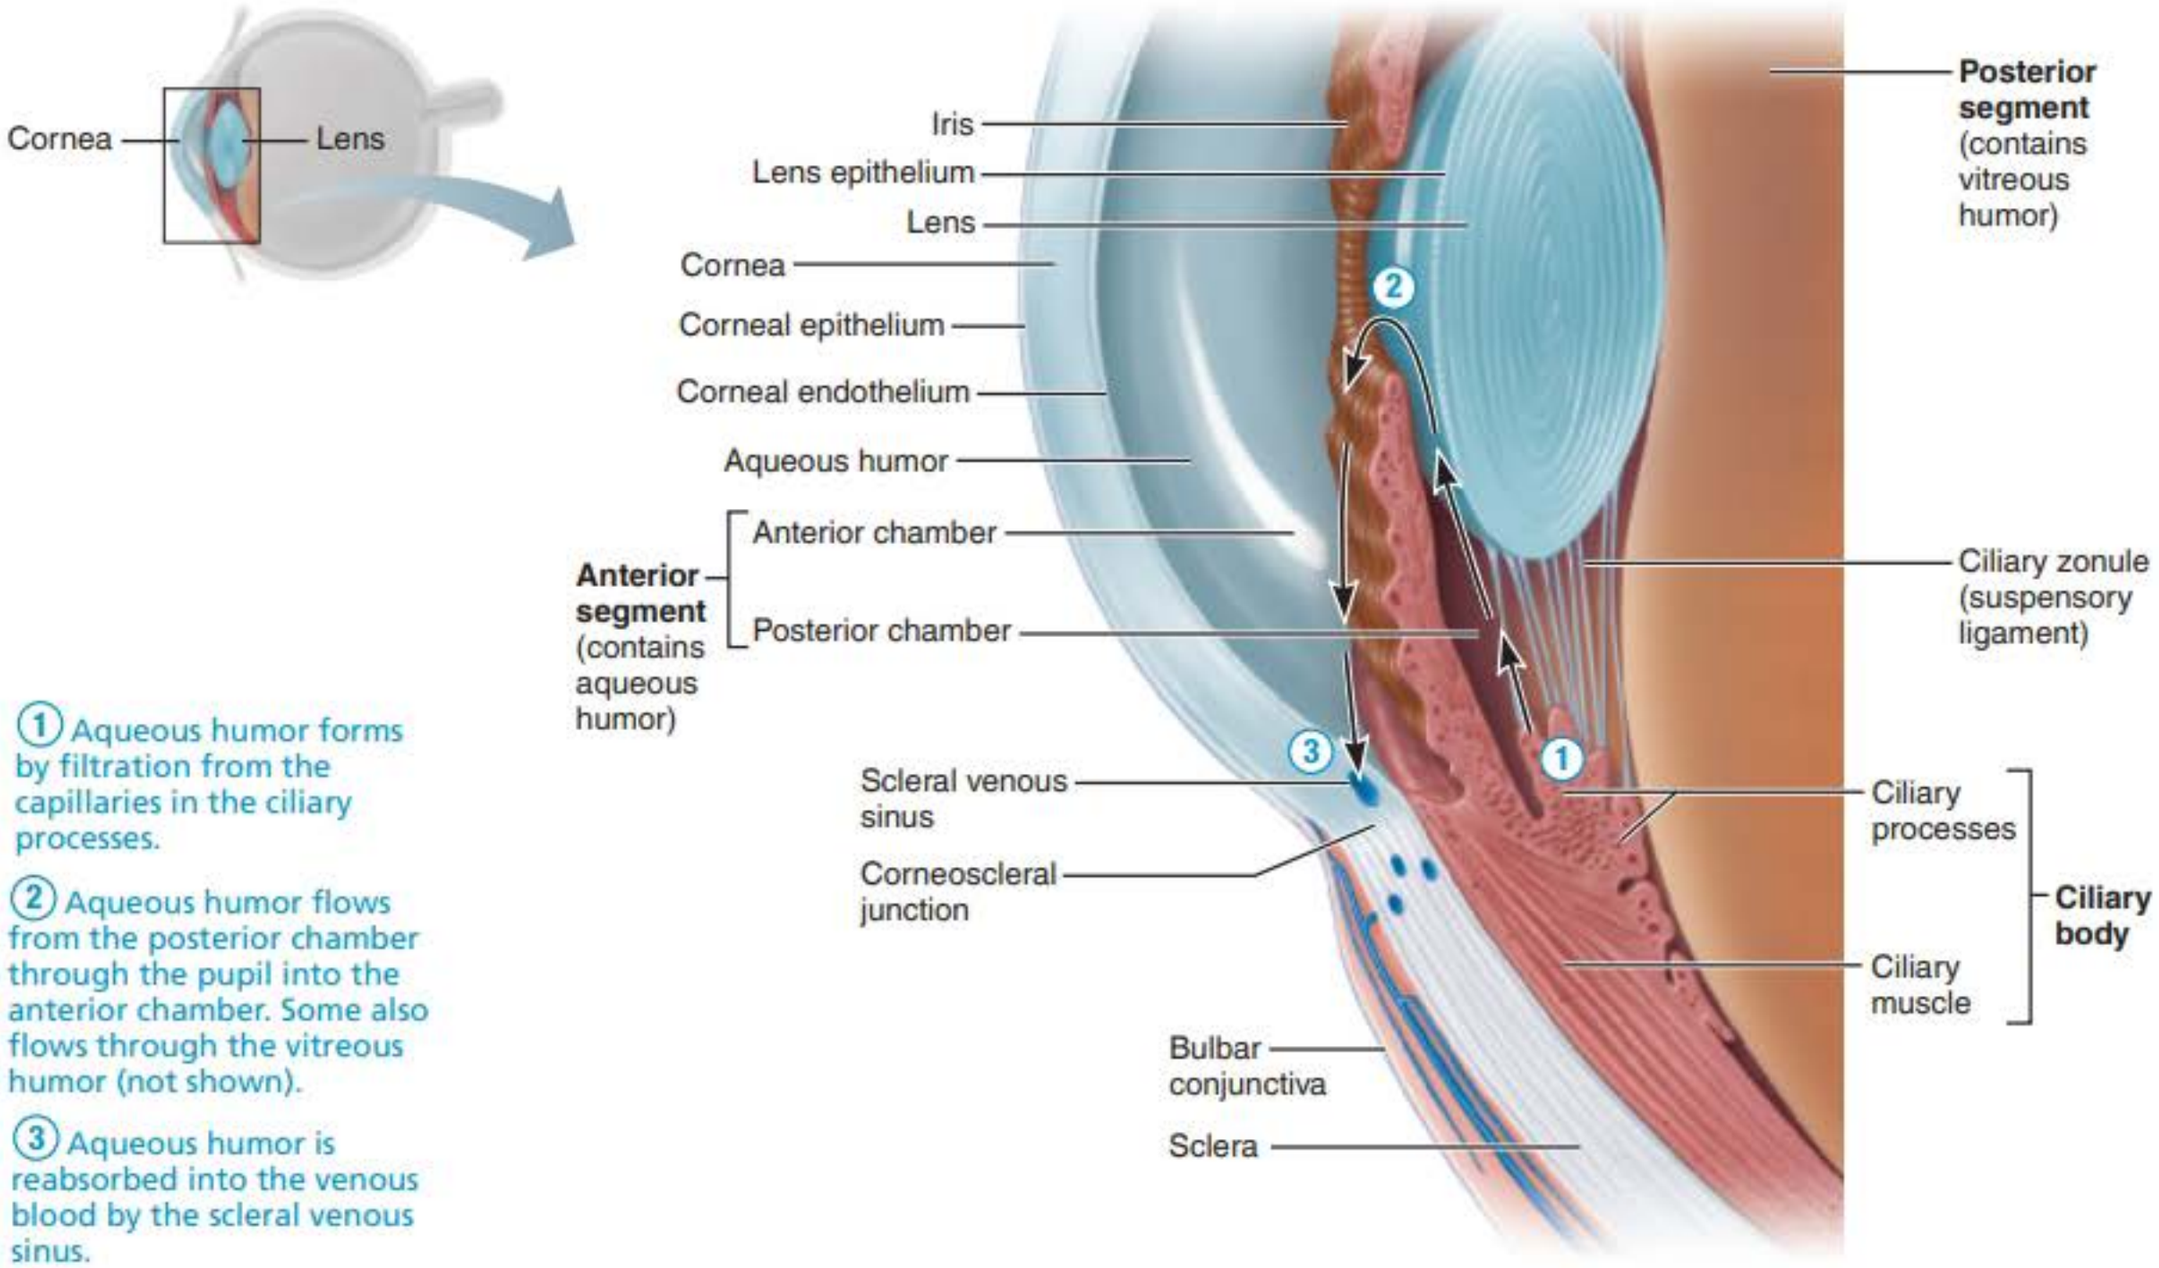

Figure 15.8 Circulation of aqueous humor. The arrows indicate the circulation pathway.

15

Internal Chambers and Fluids

As we noted earlier, the lens and its halolike ciliary zonule divide the eye into two segments, the anterior segment in front of the lens and the larger posterior segment behind it (**Figure 15.8** and Figure 15.4a). The **posterior segment** is filled with a clear gel called **vitreous humor** (*vitre* = glassy) that binds tremendous amounts of water. Vitreous humor:

- Transmits light
- Supports the posterior surface of the lens and holds the neural layer of the retina firmly against the pigmented layer
- Contributes to intraocular pressure, helping to counteract the pulling force of the extrinsic eye muscles

Vitreous humor forms in the embryo and lasts for a lifetime.

The iris divides the **anterior segment** into the **anterior chamber** (between the cornea and the iris) and the **posterior chamber** (between the iris and the lens) (Figure 15.8). The *entire* anterior segment is filled with **aqueous humor**, a clear fluid similar in composition to blood plasma. Unlike the vitreous humor, aqueous humor forms and drains continually. In Figure 15.8, you can follow its movement from the posterior chamber to the **scleral venous sinus**, an unusual venous channel that encircles the eye in the angle at the corneoscleral junction.

Normally, aqueous humor forms and drains at the same rate, maintaining a constant intraocular pressure of about 16 mm Hg, which helps to support the eyeball internally. Aqueous humor supplies nutrients and oxygen to the lens and cornea and to some cells of the retina, and it carries away metabolic wastes.

HOMEOSTATIC IMBALANCE 15.6 — CLINICAL

If the drainage of aqueous humor is blocked, fluid backs up as in a clogged sink. Pressure within the eye may increase to dangerous levels and compress the retina and optic nerve—a condition called **glaucoma** (glaw-ko′mah). The eventual result is blindness unless the condition is detected and treated early. Unfortunately, many forms of glaucoma steal sight so slowly and painlessly that people do not realize they have a problem until the damage is done. Late signs include seeing halos around lights and blurred vision.

The glaucoma examination is simple. The intraocular pressure is determined by directing a puff of air at the cornea and measuring the amount of corneal deformation it causes. This exam should be done yearly after age 40. The most common treatment is eye drops that increase the rate of aqueous humor drainage or decrease its production. Laser therapy or surgery can also help.

Lens

The **lens** is convex on both sides. It is a transparent, flexible structure that can change shape to precisely focus light on the retina. It is enclosed in a thin, elastic capsule and held in place just posterior to the iris by the ciliary zonule (Figure 15.8). Like the cornea, the lens is avascular; blood vessels interfere with transparency.

The lens has two regions: the **lens epithelium** and the lens fibers. The lens epithelium, confined to the anterior lens surface, consists of cuboidal cells that eventually differentiate into the **lens fibers** that form the bulk of the lens. The lens fibers, which are packed tightly together like the layers in an onion, contain no nuclei and few organelles. They do, however, contain transparent, precisely folded proteins called **crystallins** that form the body of the lens. Since new lens fibers are continually added, the lens enlarges throughout life, becoming denser, more convex, and less elastic, all of which gradually impair its ability to focus light properly.

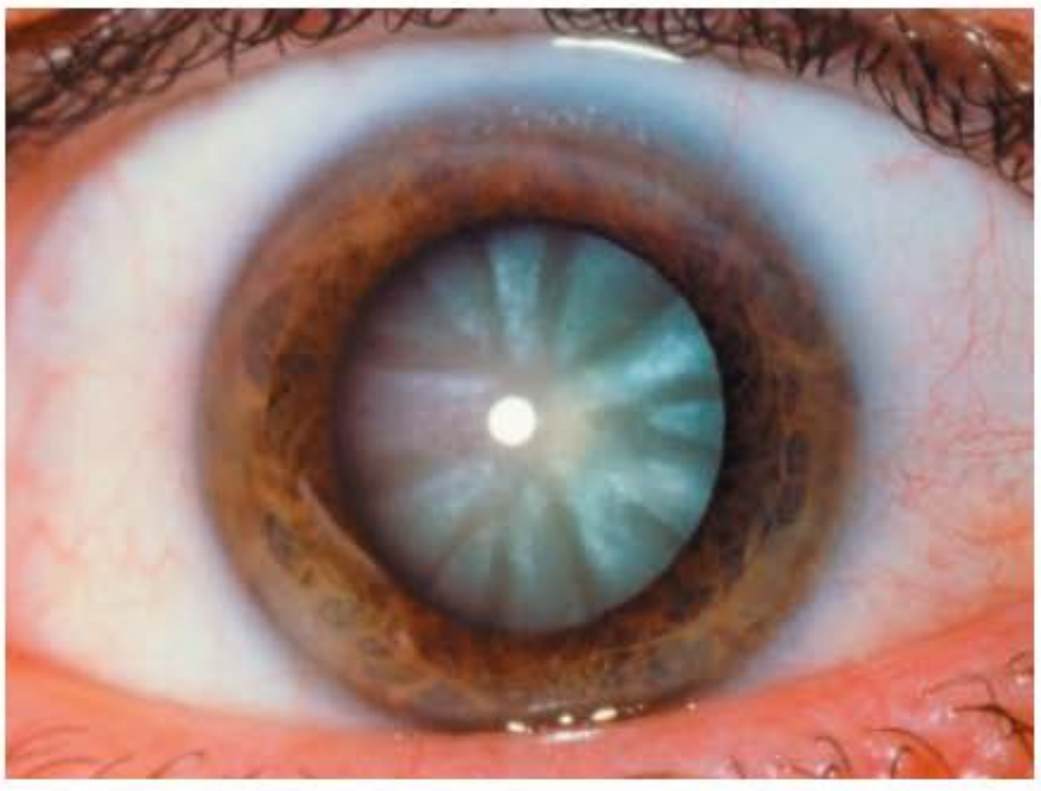

Figure 15.9 Photograph of a cataract. The lens, not the cornea, is milky and opaque.

HOMEOSTATIC IMBALANCE 15.7 — CLINICAL

A **cataract** ("waterfall") is a clouding of the lens that causes the world to appear distorted, as if seen through frosted glass (**Figure 15.9**). Some cataracts are congenital, but most result from age-related hardening and thickening of the lens or are a secondary consequence of diabetes mellitus. Heavy smoking, frequent exposure to intense sunlight, and steroid use increase the risk for cataracts.

Oxidative stress and metabolic changes in the deeper lens fibers promote clumping of the crystallin proteins. Fortunately, the offending lens can be surgically removed and an artificial lens implanted to save the patient's sight.

Check Your Understanding

15.2 The cornea and lens focus light on the retina

Learning Outcomes

- **Trace the pathway of light through the eye to the retina, and explain how light is focused for distant and close vision.**
- **Outline the causes and consequences of astigmatism, myopia, hyperopia, and presbyopia.**

Overview: Light and Optics

To comprehend the function of the eye as a photoreceptor organ, we need to understand the properties of light.

Wavelength and Color

Electromagnetic radiation includes all energy waves, from long radio waves (with wavelengths measured in meters) to very short waves [gamma (γ) waves and X rays with wavelengths of 1 nm and less]. (1 nm = 10^{-9} m, or one-billionth of a meter.) Our

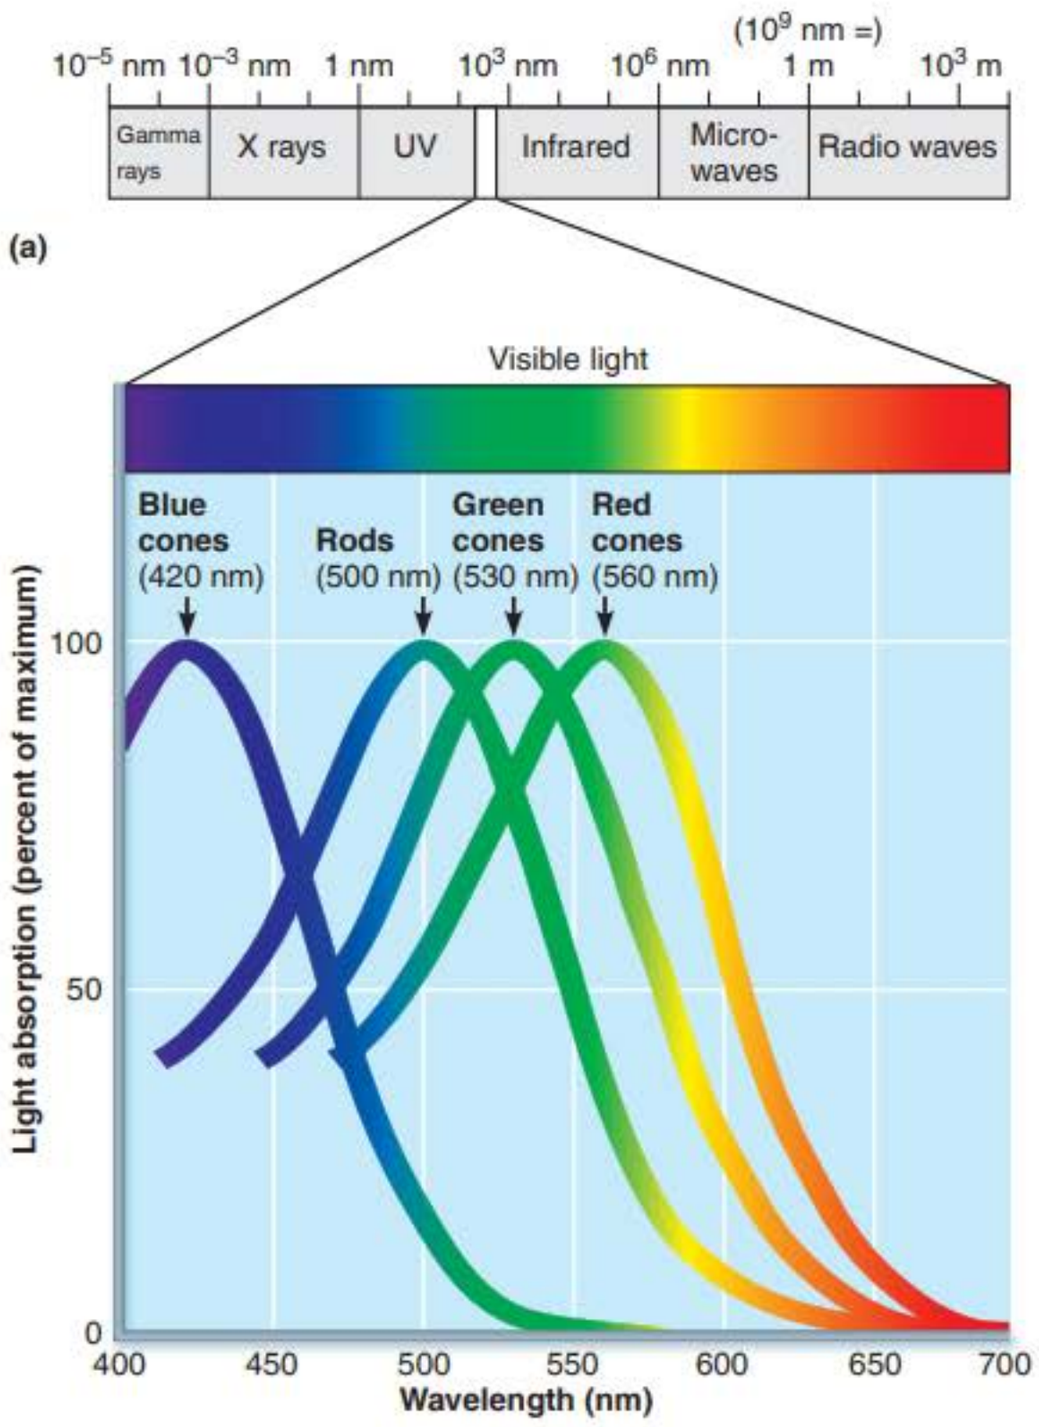

Figure 15.10 The electromagnetic spectrum and photoreceptor sensitivities. (a) The electromagnetic spectrum, of which visible light constitutes only a small portion. (nm = nanometers.) **(b)** Sensitivities of rods and the three cone types to the different wavelengths of the visible spectrum.

eyes respond to the part of the spectrum called **visible light**, which has a wavelength range of approximately 400–700 nm (**Figure 15.10a**).

Visible light travels in the form of waves, and its wavelengths can be measured very accurately. Light can also be envisioned as packets of energy, called **photons**, traveling in a wavelike fashion at very high speeds (300,000 km/s or about 186,000 mi/s). We can think of light as a vibration of pure energy ("a bright wiggle").

Visible light contains a mixture of wavelengths. When light passes through a prism, each of its component waves bends to a different degree. This disperses the beam of light into a **visible spectrum**, or band of colors (Figure 15.10b). (A rainbow that appears during a summer shower represents the collective prismatic effects of all the tiny water droplets suspended in air.) Red wavelengths are the longest and have the lowest energy, while violet wavelengths are the shortest and most energetic.

Like sound, light can reflect, or bounce, off a surface. This *reflection* of light by objects in our environment accounts for most of the light reaching our eyes. Objects have color because they absorb some wavelengths and reflect others. A red apple reflects mostly red light, while grass reflects more of the green. Things that look white reflect all wavelengths of light, whereas black objects absorb them all.

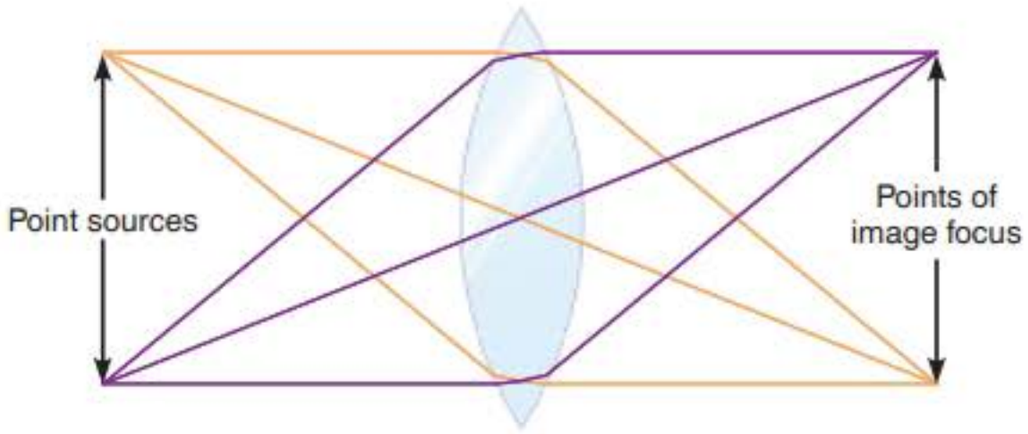
Refraction and Lenses

Light travels in straight lines (rays) and is blocked by any nontransparent object. When light travels in a given medium, its speed is constant. But when it passes from one transparent medium into another with a different density, its speed changes. Light speeds up as it passes into a less dense medium and slows as it passes into a denser medium. Because of these changes in speed, bending or **refraction** of a light ray occurs when it meets the surface of a different medium at an oblique angle rather than at a right angle. The greater this angle, the greater the amount of bending. **Figure 15.11** shows refraction: A straw in a glass of water appears to break at the air-water interface.

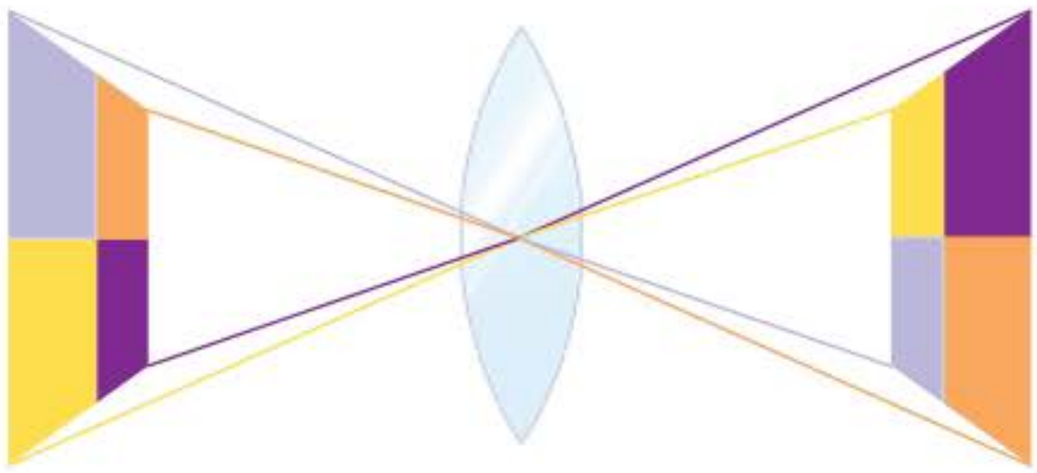
A lens is a transparent object curved on one or both surfaces. Since light hits the curve at an angle, it is refracted. If the lens surface is convex, that is, thickest in the center like a camera lens, the light rays bend so that they converge or intersect to focus at a single point (**Figure 15.12a**). If the light is from a distant source, the rays are nearly parallel and the point at which they focus is called the **focal point**. In general, the more convex the lens, the more the light bends and the shorter the focal distance (distance between the lens and focal point). The image formed by a convex lens, called a **real image**, is inverted—upside down and reversed from left to right (Figure 15.12b).

Concave lenses, which are thicker at the edges than at the center, diverge the light (bend it outward) so that the light rays move away from each other. Consequently, concave lenses prevent light from focusing and extend the focal distance.

Figure 15.11 Refraction. A straw standing in a glass of water appears to be broken at the water-air interface. This occurs because light bends when it travels from a less dense medium (such as air) to a more dense medium (such as water).



(a) Focusing of two points of light.



(b) The image is inverted—upside down and reversed.

Figure 15.12 Light is focused by a convex lens. The lens bends, or refracts, light rays so they converge to a point.

Focusing Light on the Retina

As light passes from air into the eye, it moves sequentially through the cornea, aqueous humor, lens, and vitreous humor, and then passes *through the entire neural layer of the retina* to excite the photoreceptors that are next to the pigmented layer (see Figures 15.4 and 15.6). During its passage, light is bent three times: (1) entering the cornea, (2) entering the lens, and (3) leaving the lens.

The cornea accounts for the majority of the refractory power of the eye. However, the refractory power of the cornea is constant. On the other hand, the lens is highly elastic, and its curvature and light-bending power can actively change to allow fine focusing.

Focusing for Distant Vision

Our eyes are best adapted ("preset to focus") for distant vision. To look at distant objects, we need only aim our eyeballs so that they are both fixated on the same spot. The **far point of vision** is that distance beyond which no change in lens shape (accommodation) is needed for focusing. For the normal or **emmetropic** (em″ĕ-tro′pik) eye, the far point is 6 m (20 feet).

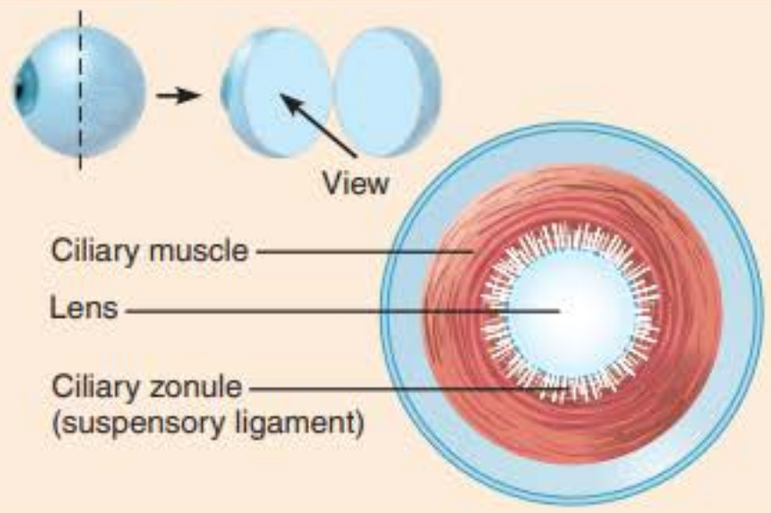
Any object being viewed can be said to consist of many small points, with light radiating outward in all directions from each point. However, because distant objects appear smaller, light from an object at or beyond the far point of vision approaches the eyes as nearly parallel rays. The cornea and the at-rest lens focus the light from these distant objects precisely on the retina (**Figure 15.13b**).

During distant vision, the sphincterlike ciliary muscles are completely relaxed, and tension in the ciliary zonule stretches the lens flat. Consequently, the lens is as thin as it gets and is at its lowest refractory power when the ciliary muscle is at rest. The ciliary muscles relax when sympathetic input to them increases and parasympathetic input decreases.

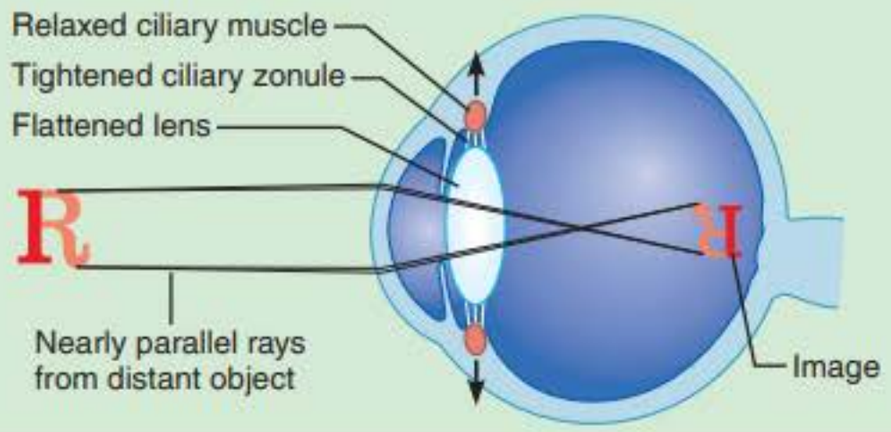
Focusing for Close Vision

Light from close objects (less than 6 m away) diverges as it approaches the eyes and comes to a focal point farther from the

(a) The ciliary muscle and the ciliary zonule focus an image by changing the shape of the lens.
- They are arranged sphincterlike around the lens.
- Ciliary muscle contraction loosens the ciliary zonule fibers and relaxation tightens them.



(b) The lens flattens for distant vision.
Sympathetic input relaxes the ciliary muscle. This tightens the ciliary zonule and flattens the lens.



(c) The lens bulges for close vision.
Parasympathetic input contracts the ciliary muscle. This loosens the ciliary zonule and allows the lens to bulge.

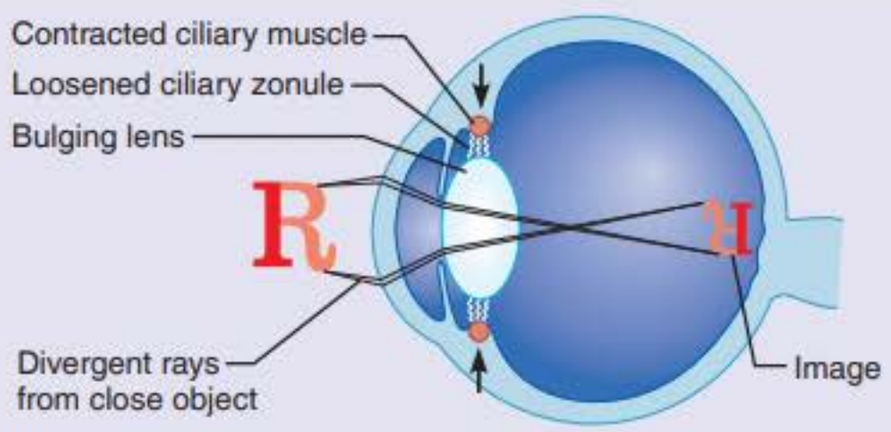


Figure 15.13 Focusing for distant and close vision.

15

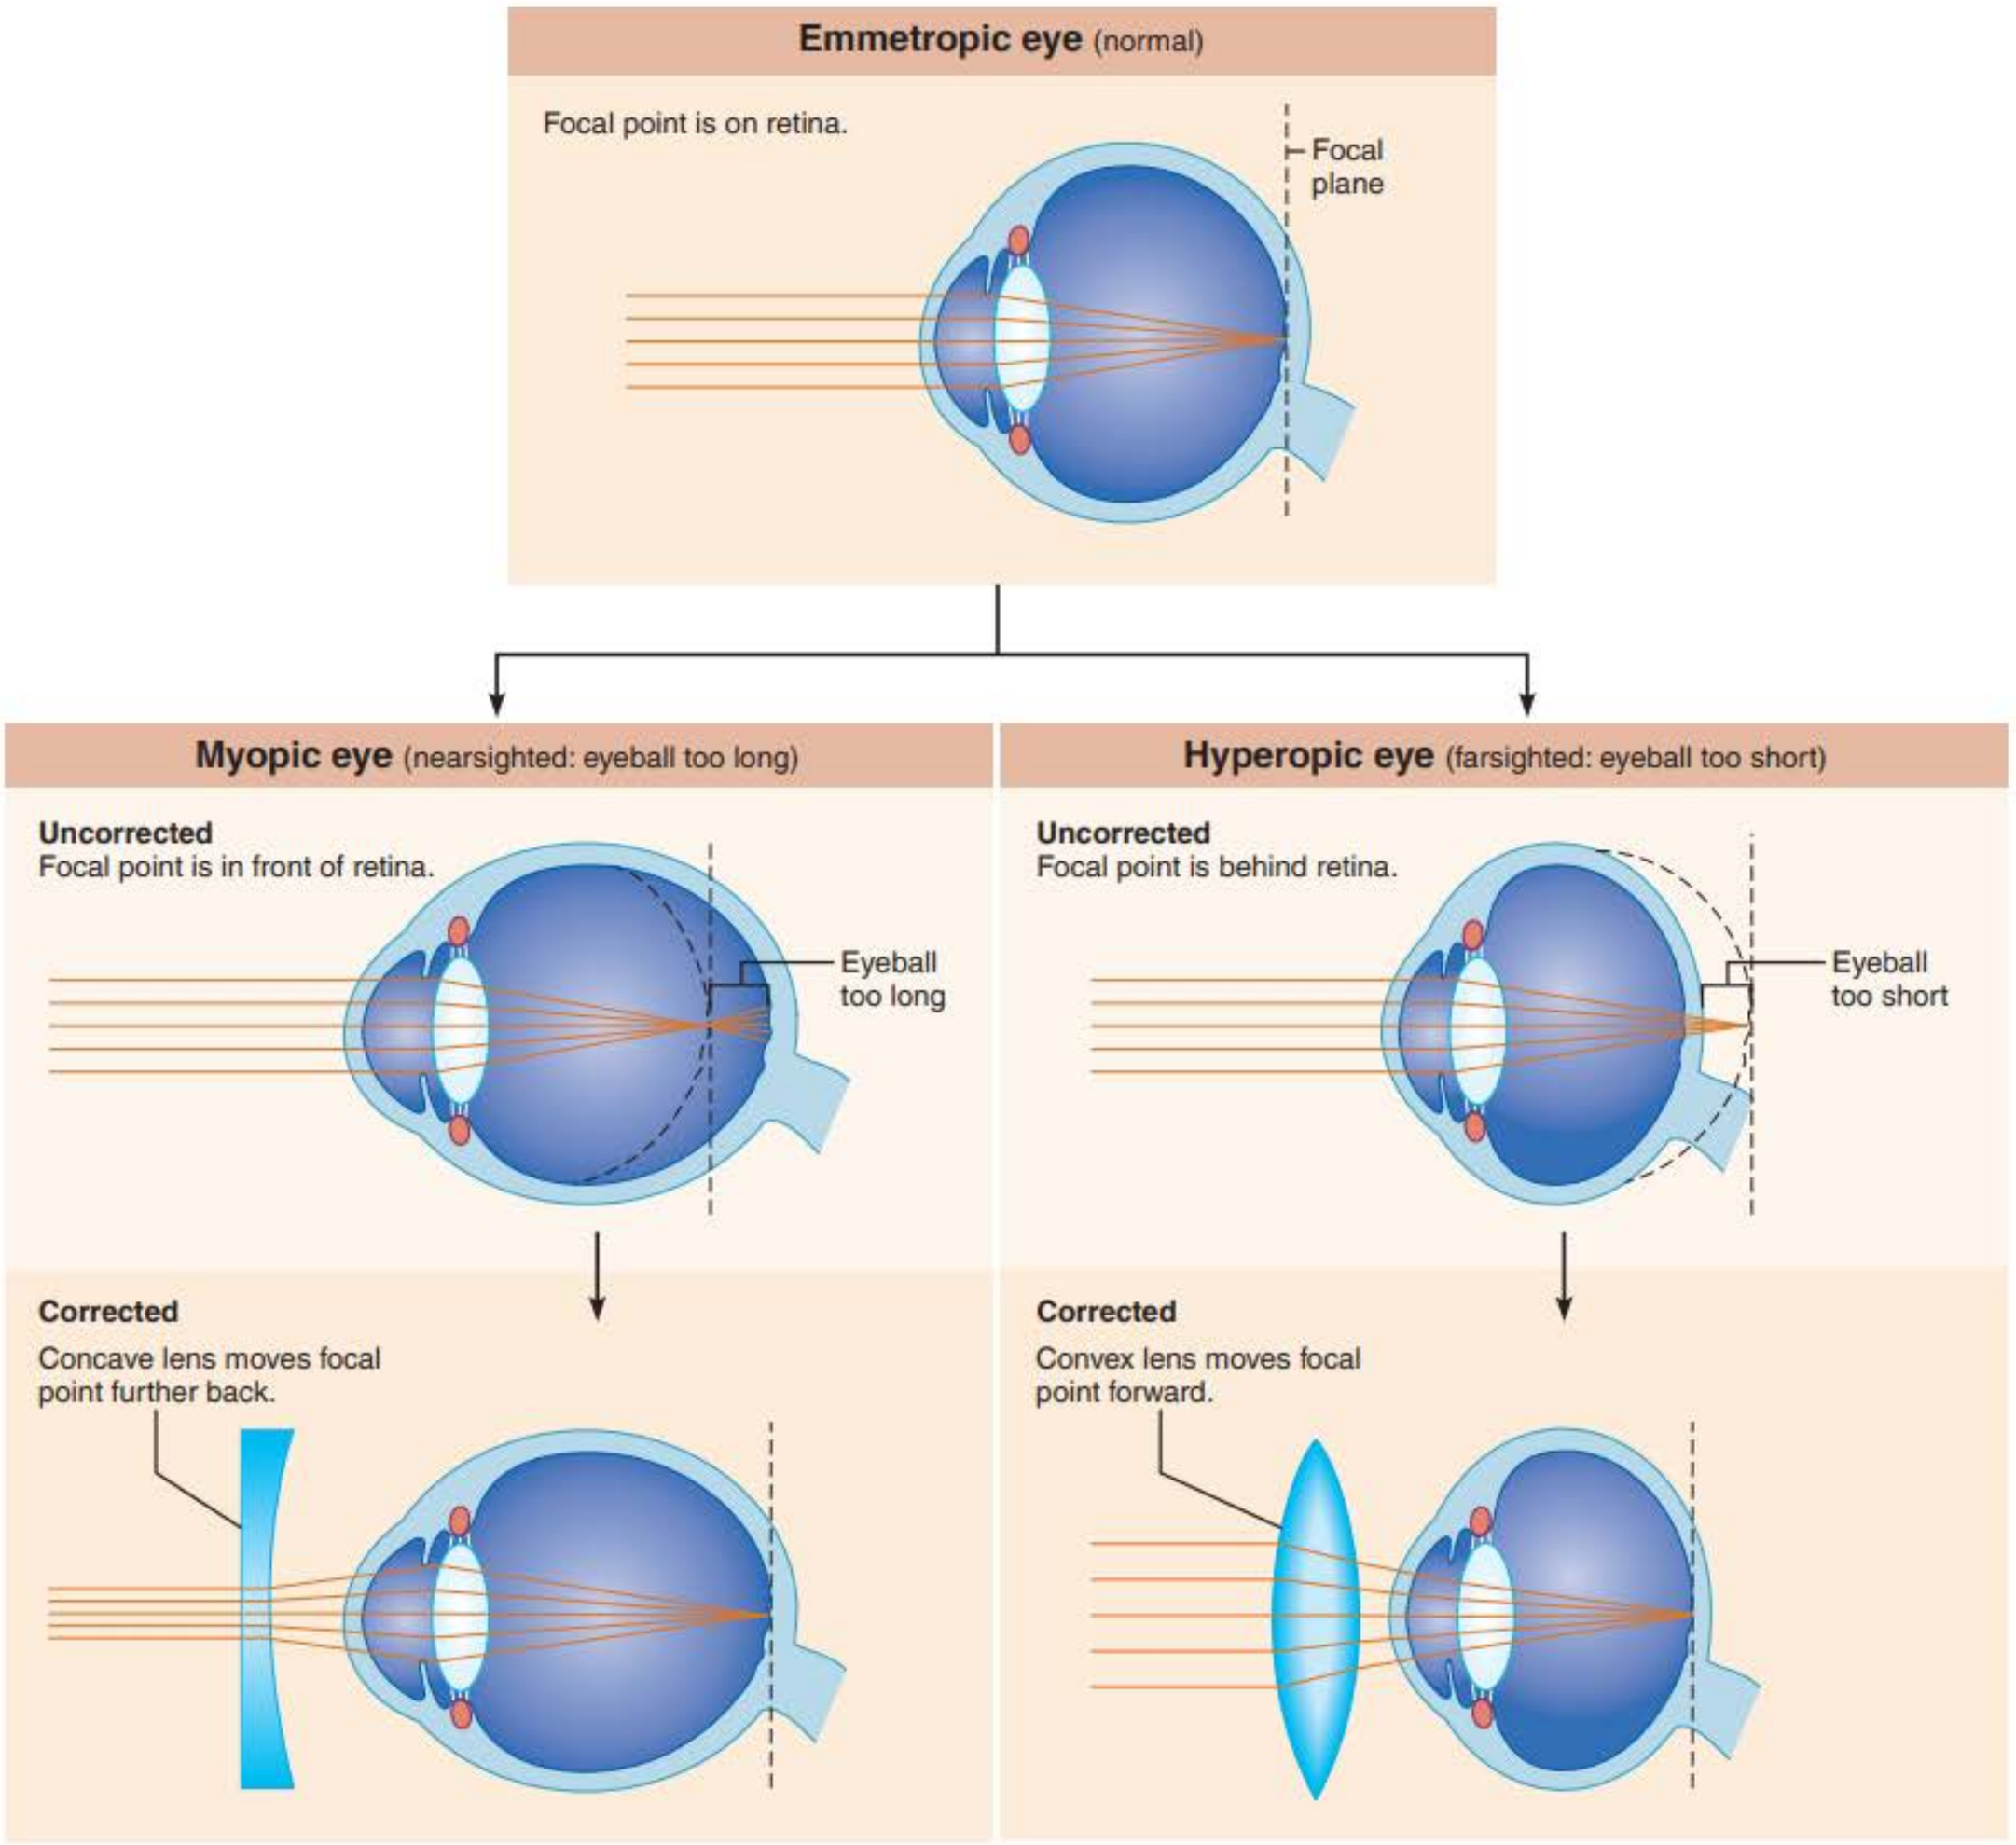

Figure 15.14 Problems of refraction. The refractive power of the cornea, which normally supplies about two-thirds of the light-bending power of the eye, is ignored here.

lens. For this reason, close vision demands that the eye make active adjustments. To restore focus, three processes must occur simultaneously: accommodation of the lenses, constriction of the pupils, and convergence of the eyeballs. The signal that induces this trio of reflex responses is blurring of the retinal image.

- **Accommodation of the lenses. Accommodation** is the process that increases the refractory power of the lens. The ciliary muscles contract, pulling the ciliary body anteriorly toward the pupil and inward, releasing tension in the ciliary zonule. No longer stretched, the elastic lens recoils and bulges, providing the shorter focal length needed to focus the image of a close object on the retina (Figure 15.13c). Parasympathetic fibers of the oculomotor nerves control the contraction of the ciliary muscles.

  The closest point on which we can focus clearly is called the **near point of vision**, and it represents the maximum bulge the lens can achieve. In young adults with emmetropic vision, the near point is 10 cm (4 inches) from the eye. However, it is closer in children and gradually recedes with age, explaining why children can hold their books very close to their faces while many elderly people must hold the

newspaper at arm's length. The gradual loss of accommodation with age reflects the lens's decreasing elasticity. In many people over age 50, the lens is nonaccommodating, a condition known as **presbyopia** (pres″be-o′pe-ah), literally "old person's vision."

- **Constriction of the pupils.** The sphincter pupillae muscles of the iris enhance the effect of accommodation by reducing the size of the pupil toward 2 mm (see Figure 15.5). This **accommodation pupillary reflex**, mediated by parasympathetic fibers of the oculomotor nerves, prevents the most divergent light rays from entering the eye. Such rays would pass through the extreme edge of the lens and would not focus properly, causing blurred vision.
- **Convergence of the eyeballs.** The visual goal is always to keep the object being viewed focused on the retinal foveae. When we look at distant objects, both eyes are directed either straight ahead or to one side to the same degree, but when we fixate on a close object, our eyes converge. **Convergence**, controlled by somatic motor fibers of the oculomotor nerves, is medial rotation of the eyeballs by the medial rectus muscles so that each is directed toward the object being viewed. The closer that object, the greater the degree of convergence required. For example, when you focus on the tip of your nose, you "go cross-eyed."

Reading or viewing a smartphone screen requires almost continuous accommodation, pupillary constriction, and convergence. This is why these activities can tire the eye muscles and result in eyestrain. When your eyes tire, it helps to look up and stare into the distance occasionally to relax your intrinsic eye muscles.

HOMEOSTATIC IMBALANCE 15.8 — CLINICAL

The vast majority of refractive problems are related to eyeball shape—either too long or too short—and not to a lens that is too strong or too weak.

Myopia (mi-o′pe-ah; "short vision"), or *nearsightedness,* occurs when distant objects focus in front of the retina, rather than on it (**Figure 15.14**, left). Myopic people see close objects without problems because they can focus them on the retina, but distant objects are blurred. Myopia typically results from an eyeball that is too long.

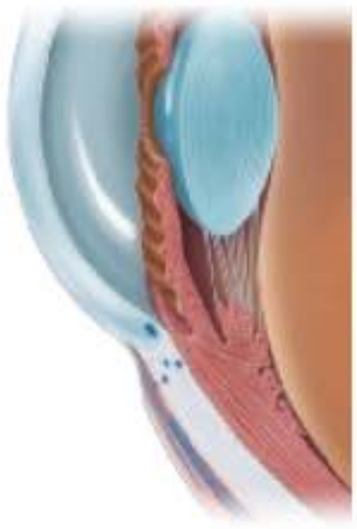
Correction has traditionally involved using concave lenses that diverge the light before it enters the eye. Laser procedures to flatten the cornea slightly offer other treatment options.

Hyperopia (hi″per-o′pe-ah; "far vision"), or *farsightedness*, occurs when the parallel light rays from distant objects focus *behind* the retina (Figure 15.14, right). Hyperopic individuals can see distant objects because their ciliary muscles contract almost continuously to increase the light-bending power of the lens, which moves the focal point forward onto the retina. However, diverging light rays from *nearby* objects focus so far behind the retina that the lens cannot bring the focal point onto the retina even at its full refractory power. As a result, close objects appear blurry, and convex corrective lenses are needed to converge the light more strongly for close vision. Hyperopia usually results from an eyeball that is too short.

Unequal curvatures in different parts of the cornea or lens also lead to blurry images. This refractory problem is **astigmatism** (*astigma* = not a point). Special cylindrically ground lenses or laser procedures are used to correct this problem.

Check Your Understanding

4. Arrange the following in the order that light passes through them to reach the photoreceptors (rods and cones): lens, bipolar cells, vitreous humor, cornea, aqueous humor, ganglion cells. (Hint: See Figure 15.6 if you need a reminder of where ganglion cells and bipolar cells are.)
5. Why does your near point of vision move farther away as you age?
6. DRAW You have been reading this book for a while now and your eyes are beginning to tire. Which intrinsic eye muscles relax as you stare thoughtfully into the distance? Label them on the image below.



7. DRAW Create a simple linear flowchart illustrating the sequence of steps that lead to a decrease in the lens's focal length to allow close vision. Begin with parasympathetic nerve activation .
8. MAKE CONNECTIONS Figures 15.5 and 15.13 show the effects sympathetic nervous system (SNS) activation has on intrinsic eye muscles. These effects make sense in situations (as discussed in Chapter 14) that cause massive SNS activation. Explain how these SNS actions on intrinsic eye muscles might help during such situations.

For answers, see Answers Appendix.

15.3 Phototransduction begins when light activates visual pigments in retinal photoreceptors

Learning Outcomes

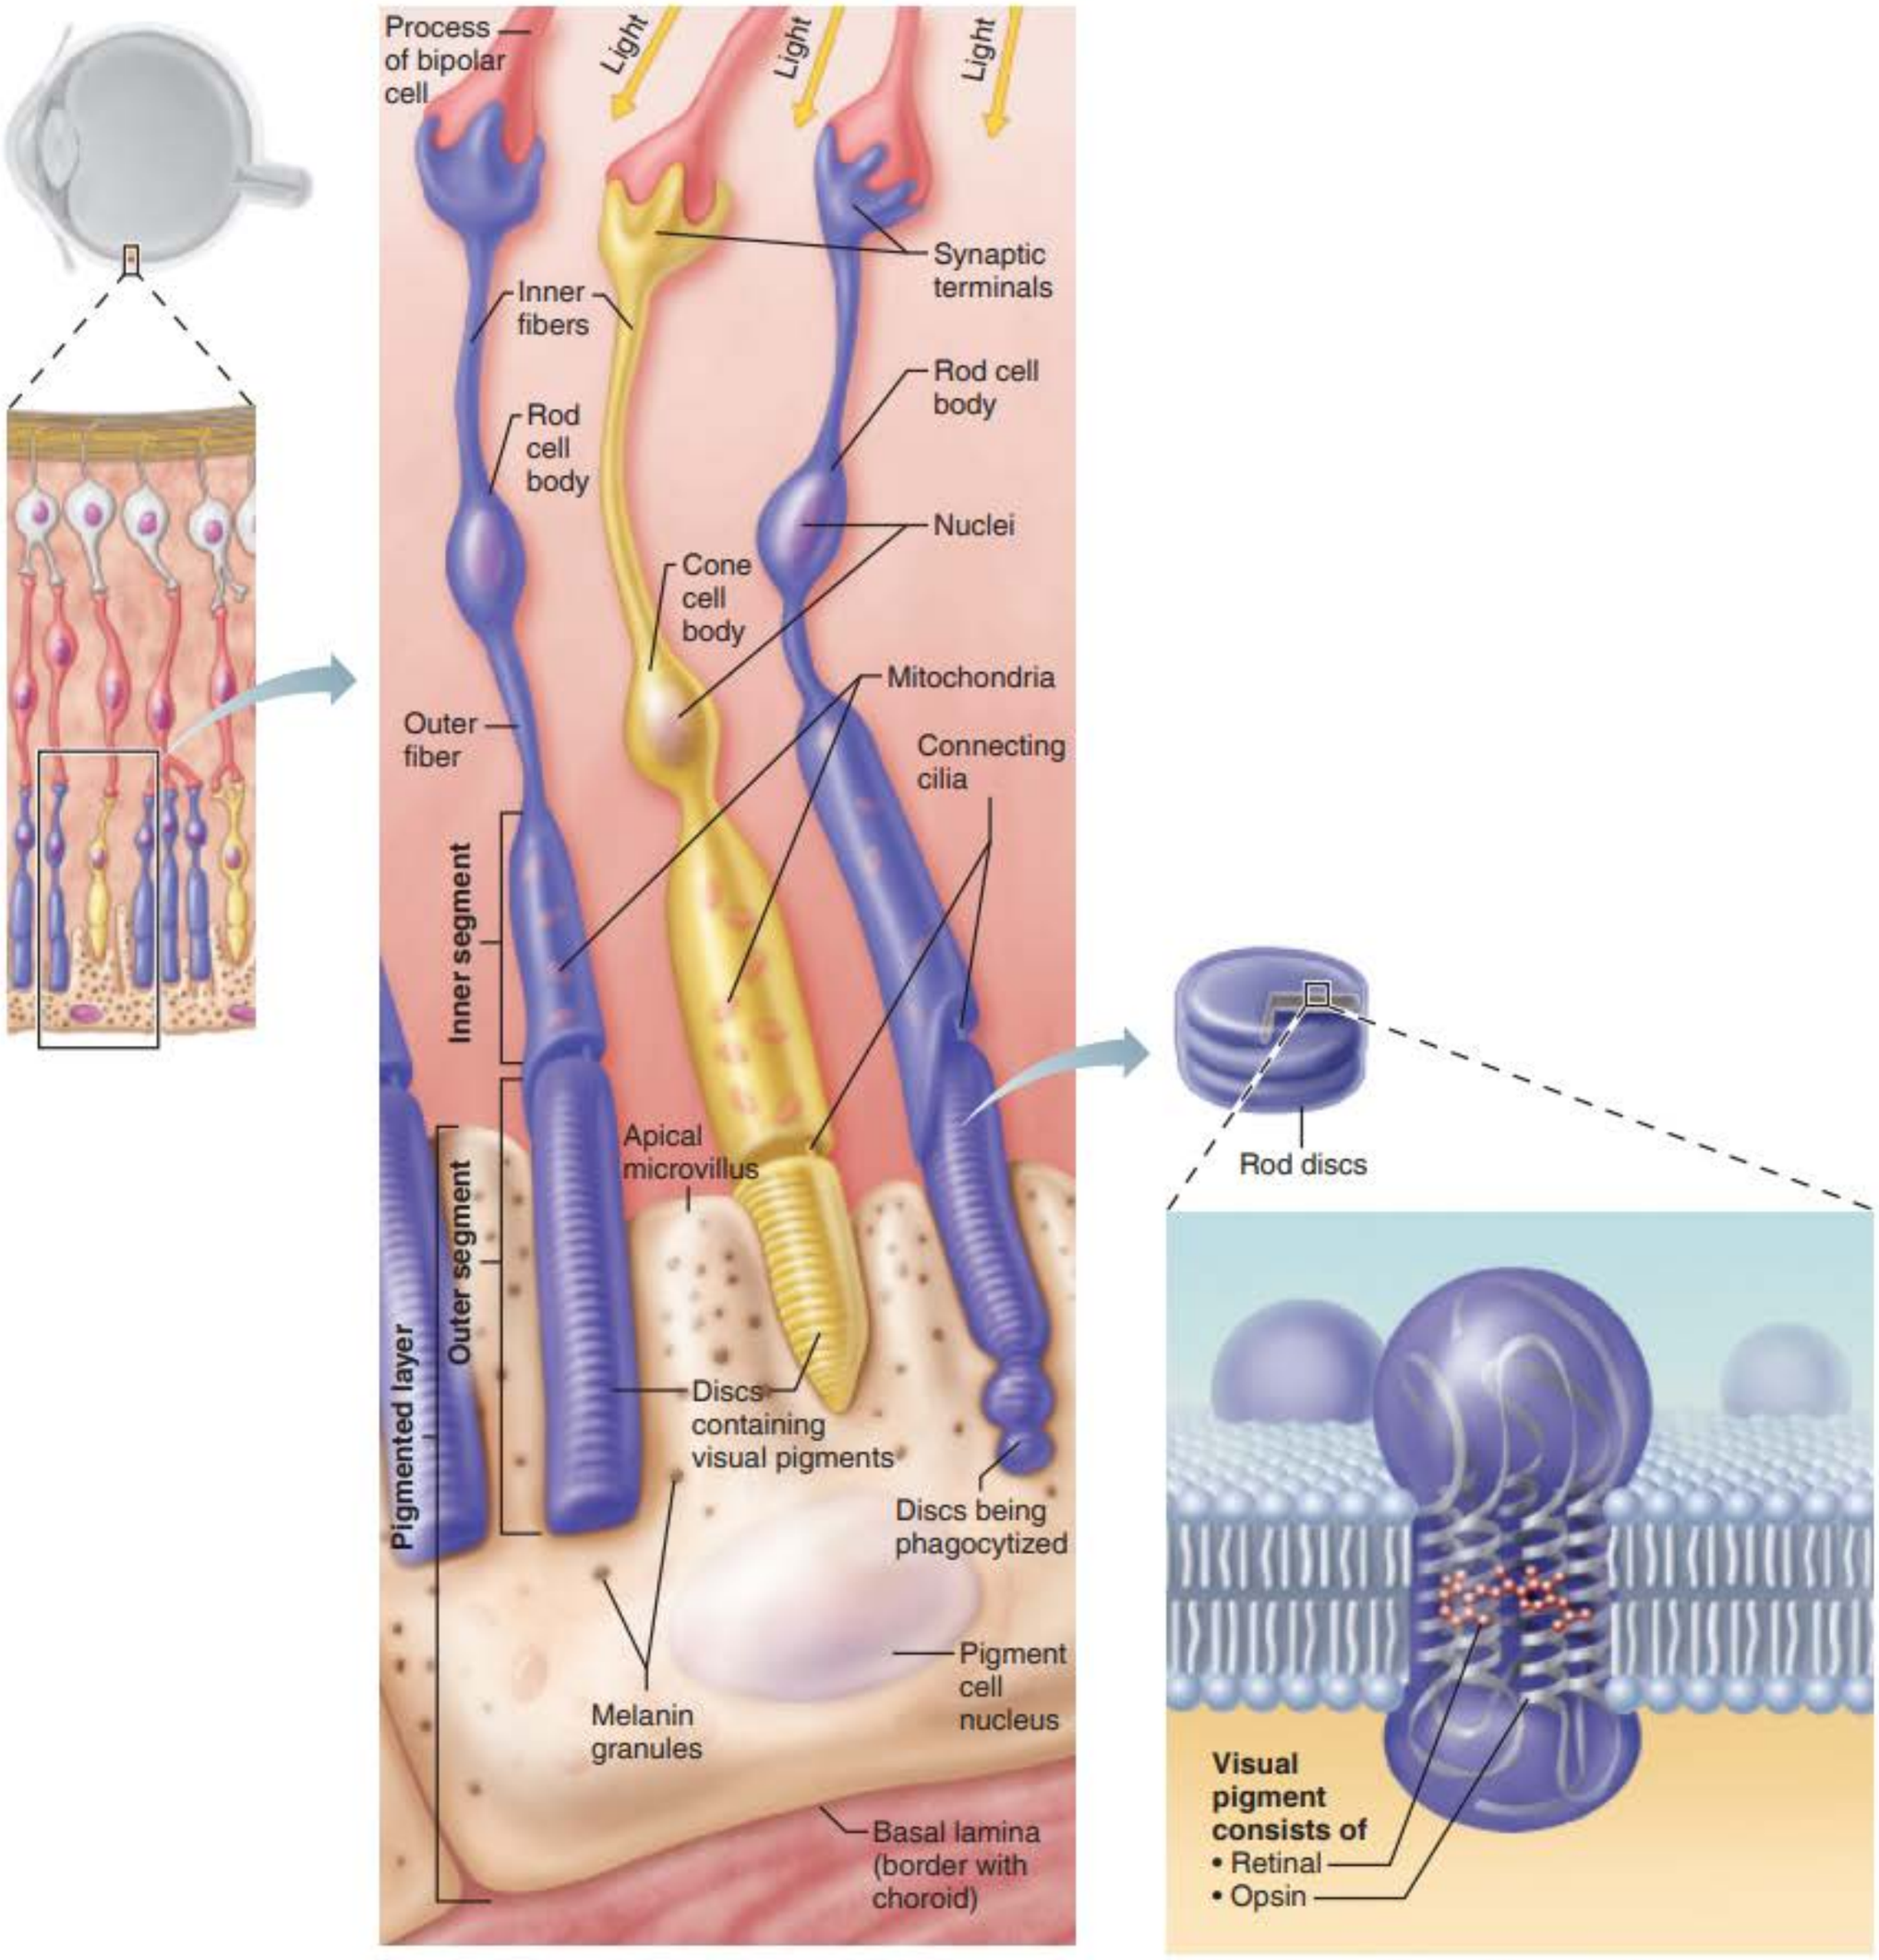
- **Describe the events that convert light into a neural signal.**
- **Compare and contrast the roles of rods and cones in vision.**
- **Compare and contrast light and dark adaptation.**

Once light is focused on the retina, the photoreceptors come into play. First, we will describe the functional anatomy of the rod and cone photoreceptor cells, then the chemistry and response of their visual pigments to light, and finally, photoreceptor activation, phototransduction, and information processing in the retina.

Functional Anatomy of the Photoreceptors

Photoreceptors are modified neurons, but structurally they resemble tall epithelial cells turned upside down with their "tips" immersed in the pigmented layer of the retina (**Figure 15.15a**). These "tips" are the receptive regions of rods and cones and are called the **outer segments**. Moving from the pigmented layer into the neural layer, a connecting cilium joins the outer segment of a rod or cone to the **inner segment**. The inner segment then connects to the *cell body*, which is continuous with an *inner fiber* bearing *synaptic terminals*.

In rods, the outer segment is slender and rod shaped and the inner segment connects to the cell body by the *outer fiber*. In



(a) The outer segments of rods and cones are embedded in the pigmented layer of the retina.

(b) Rhodopsin, the visual pigment in rods, is embedded in the membrane that forms discs in the outer segment.

Figure 15.15 Photoreceptors of the retina.

contrast, the cones have a short conical outer segment and the inner segment directly joins the cell body.

The outer segments contain an elaborate array of **visual pigments (photopigments)** that change shape as they absorb light. These pigments are embedded in areas of the plasma membrane that form discs (Figure 15.15b). Folding the plasma membrane into discs increases the surface area available for trapping light. In rods, the discs are discontinuous—stacked inside a cylinder of plasma membrane like pennies in a coin wrapper. In cones, the disc membranes are continuous with the plasma membrane, so the interiors of the cone discs are continuous with the extracellular space.

Photoreceptor cells are highly vulnerable to damage and immediately begin to degenerate if the retina becomes detached. They are also destroyed by intense light. How is it, then, that we do not all gradually go blind? The answer lies in the photoreceptors' unique system for renewing their light-trapping outer segment. Every 24 hours, new components are synthesized in the cell body and added to the base of the outer segment. As new discs are made, the discs at the tip of the outer segment fragment off and pigment cells phagocytize them.

Comparing Rod and Cone Vision

Rods and cones have different thresholds for activation. Rods, for example, are very sensitive (they respond to very dim light—a single photon), making them best suited for night vision and peripheral vision. Cones, on the other hand, need bright light for activation (have low sensitivity), but react more rapidly. Cones have one of three different pigments that furnish a vividly colored view of the world, but rods contain a single kind of visual pigment so their inputs are perceived only in gray tones.

Rods and cones also differ in their "wiring" to other retinal neurons. Rods participate in converging pathways, and as many as 100 rods may ultimately feed into each ganglion cell. As a result, rod effects are summated and considered collectively, resulting in vision that is fuzzy and indistinct. (The visual cortex has no way of knowing exactly *which* rods of the large number influencing a particular ganglion cell are actually activated.)

In contrast, each cone in the fovea (or at most a few) has a straight-through pathway via its "own personal bipolar cell" to a ganglion cell (see Figure 15.6b). Essentially, each foveal cone has its own direct line to the higher visual centers—permitting detailed, high-acuity (high-resolution) views of very small areas of the visual field.

Because rods are absent from the foveae and cones do not respond to low-intensity light, we see dimly lit objects best when we do not look at them directly, and we recognize them best when they move.

Table 15.1 summarizes the differences between rods and cones.

Table 15.1 Comparison of Rods and Cones

RODS	CONES
Noncolor vision (one visual pigment)	Color vision (three visual pigments)
High sensitivity; function in dim light	Low sensitivity; function in bright light
Low acuity (many rods converge onto one ganglion cell)	High acuity (one cone per ganglion cell in fovea)
More numerous (20 rods for every cone)	Less numerous
Mostly in peripheral retina	Mostly in central retina

Visual Pigments

How do photoreceptors translate incoming light into electrical signals? The key is a light-absorbing molecule called **retinal** that combines with proteins called **opsins** to form four types of visual pigments. Depending on the type of opsin to which it is bound, retinal absorbs different wavelengths of the visible spectrum.

The cone opsins differ both from the opsin of the rods and from one another. The naming of cones reflects the colors (that is, wavelengths) of light that each cone variety absorbs best. Blue cones respond maximally to wavelengths around 420 nm, green cones to wavelengths of 530 nm, and red cones to wavelengths at or close to 560 nm (see Figure 15.10b).

How do we see other colors besides blue, green, and red? Cones' absorption spectra overlap, and our perception of intermediate hues, such as yellow, orange, and purple, results from differential activation of more than one type of cone at the same time. For example, yellow light stimulates both red and green cone receptors, but if the red cones are stimulated more than the green cones, we see orange instead of yellow. When all cones are stimulated equally, we see white.

HOMEOSTATIC IMBALANCE 15.9 CLINICAL

Color blindness is due to a congenital lack of one or more cone pigments. It is far more common in males than in females because it is inherited as an X-linked condition (see Chapter 29). As many as 8–10% of males have some form of color blindness.

The most common type is red-green color blindness, resulting from a deficit or absence of either red or green cone pigments. Red and green are seen as the same color—either red or green, depending on the cone pigment present. Many color-blind people are unaware of their condition because they have learned to rely on other cues—such as different intensities of the same color—to distinguish something green from something red, such as traffic signals.

Retinal is chemically related to vitamin A and is made from it. The cells of the pigmented layer of the retina absorb vitamin A from the blood and serve as the local vitamin A depot for rods and cones.

Retinal can assume a variety of three-dimensional forms, each form called an isomer. When bound to opsin, retinal has a bent shape called **11-*cis*-retinal**, as shown at the top of Figure 15.16. However, when the pigment absorbs a photon of light, retinal

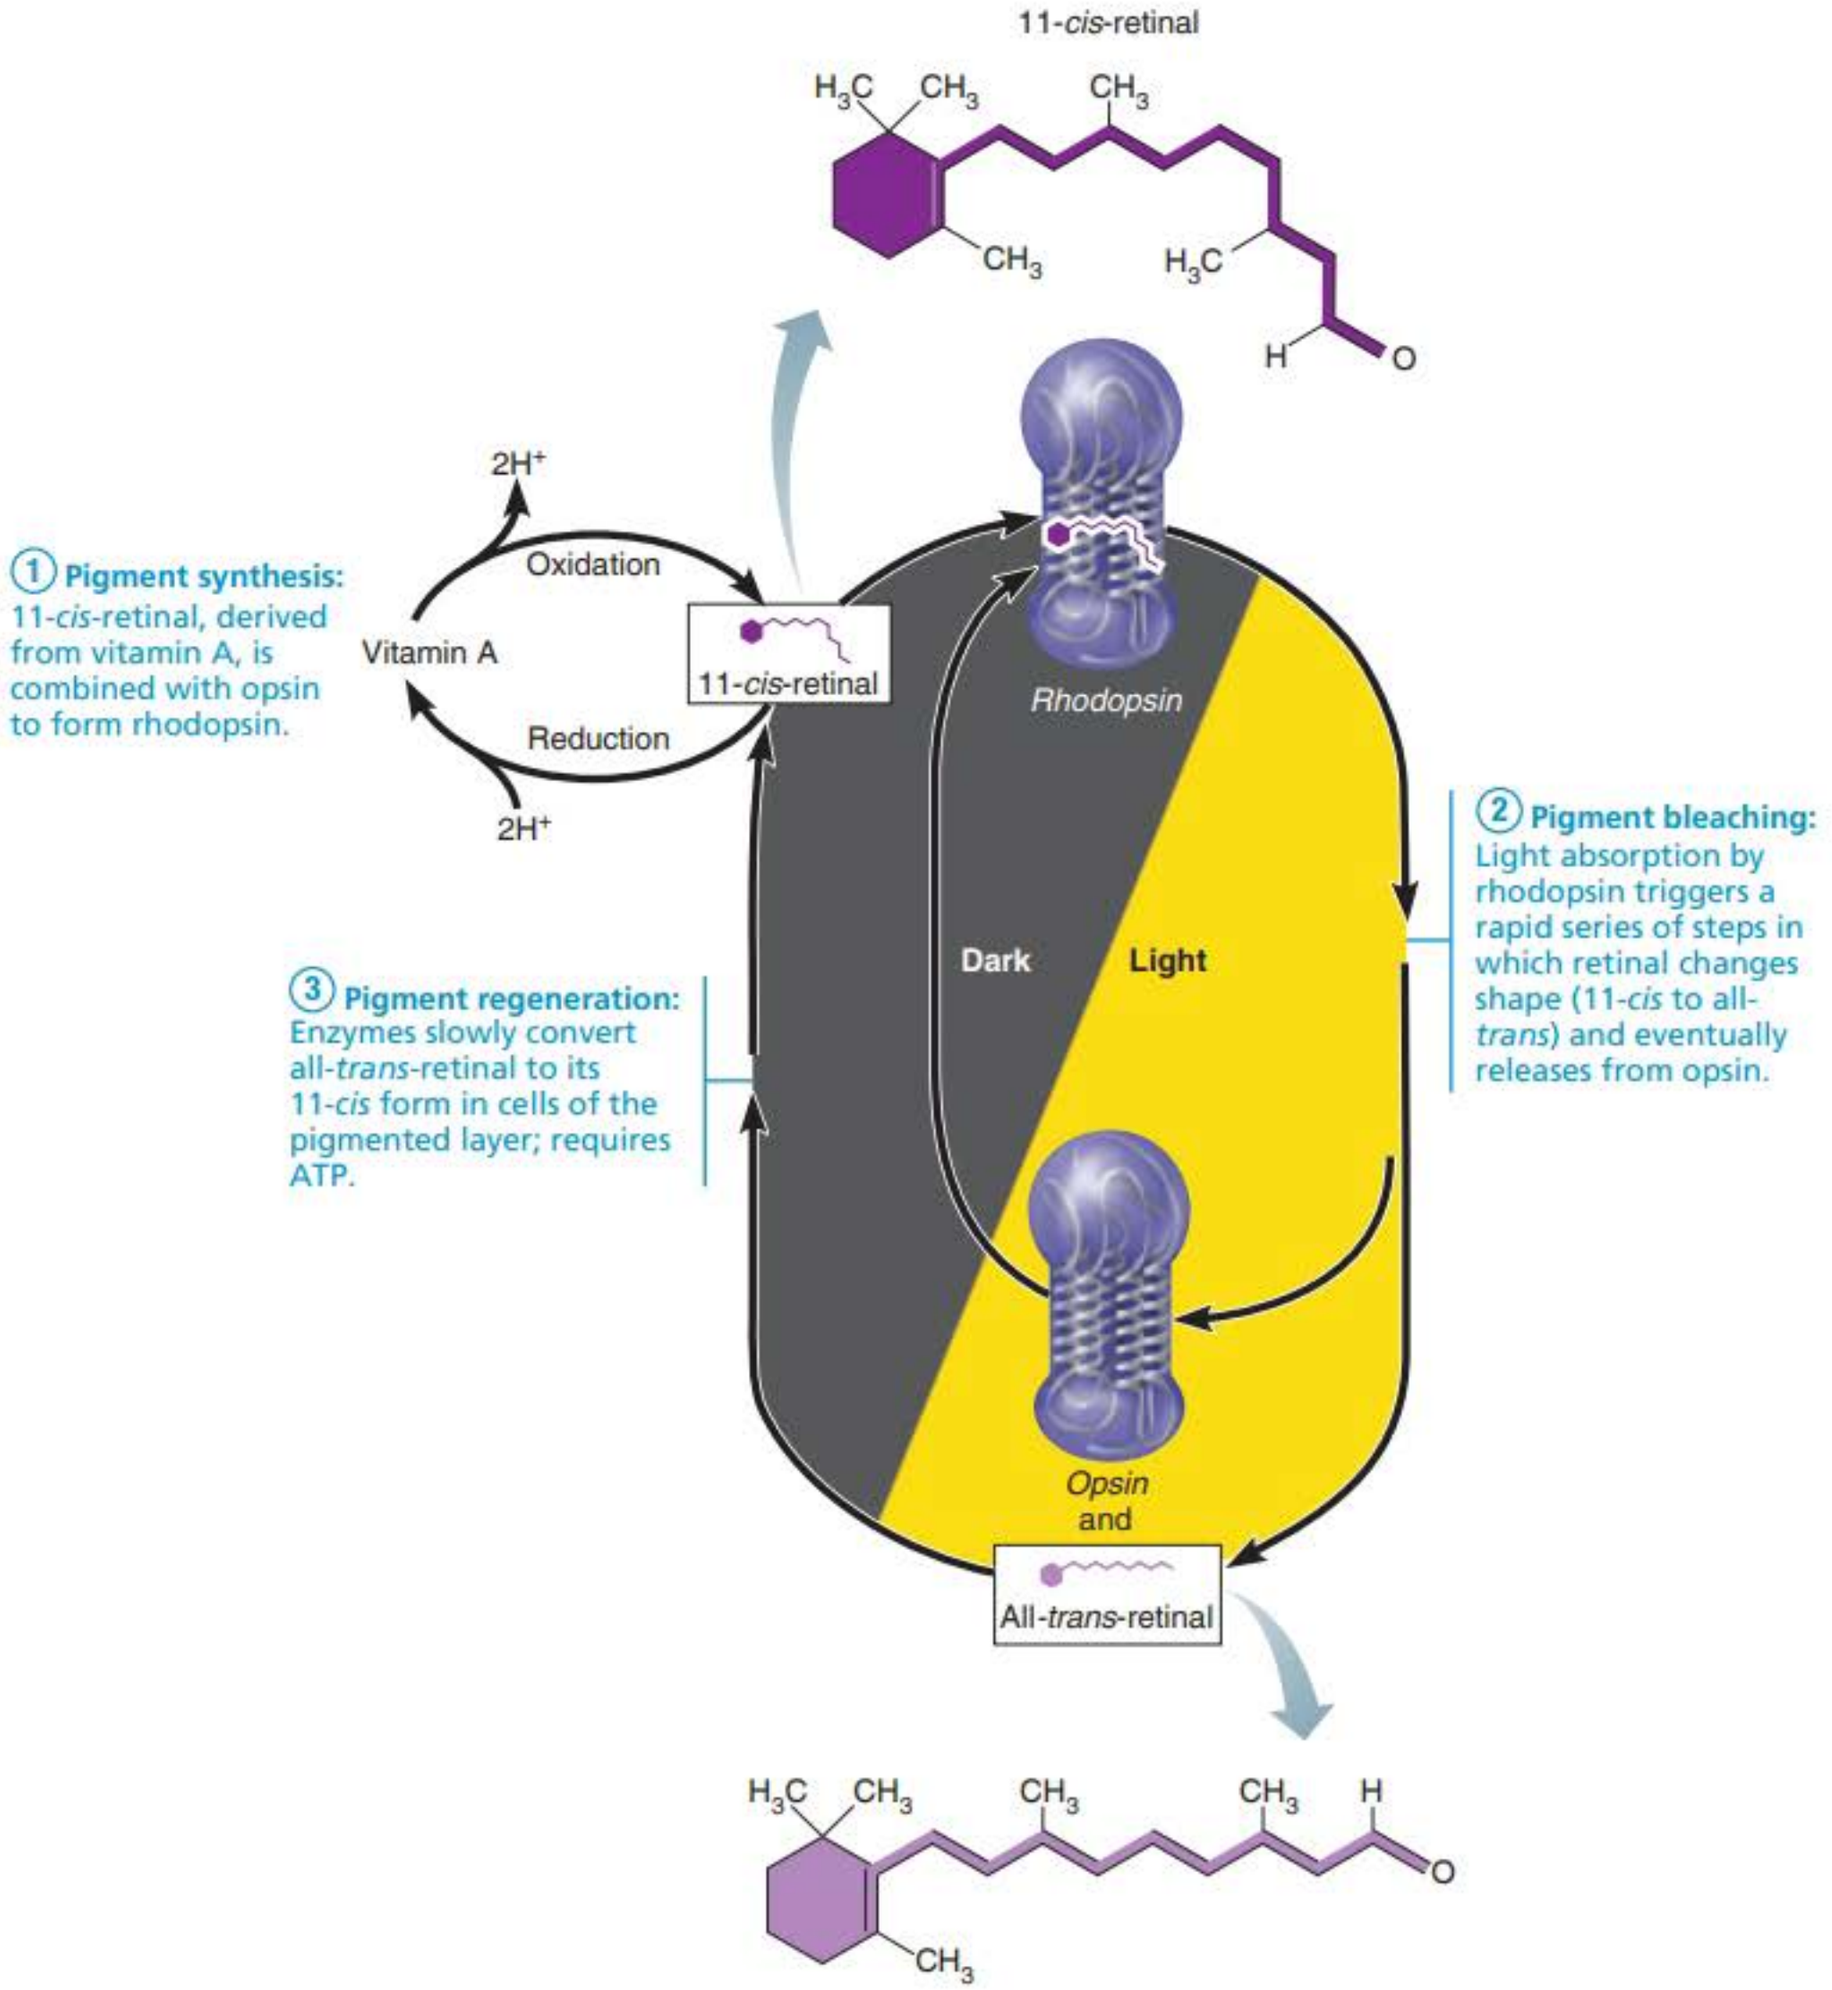


Figure 15.16 The formation and breakdown of rhodopsin.
11-*cis*-retinal can either be regenerated from all-*trans*-retinal or made from vitamin A.

twists and snaps into a new configuration, **all-*trans*-retinal** (Figure 15.16, bottom). This change, in turn, causes opsin to change shape and assume its activated form.

The capture of light by visual pigments is the *only* light-dependent stage, and this simple photochemical event initiates a whole chain of chemical and electrical reactions in rods and cones that ultimately causes action potentials to be transmitted along the optic nerve. Let's look more closely at these events in rods and cones.

Phototransduction

Phototransduction is the process by which light energy is converted into a graded receptor potential. It begins when a visual pigment captures a photon of light.

Capturing Light

The visual pigment of rods is a deep purple pigment called **rhodopsin** (ro-dop′sin; *rhodo* = rose, *opsis* = vision). (Do you

suppose the person who coined the expression "looking at the world through rose-colored glasses" knew the meaning of "rhodopsin"?) Rhodopsin molecules are arranged in a single layer in the membranes of each of the thousands of discs in the rods' outer segments. The formation and breakdown of rhodopsin follows the process shown in **Figure 15.16**.

1. **Pigment synthesis:** Rhodopsin forms and accumulates in the dark. Vitamin A is oxidized (and isomerized) to the 11-*cis*-retinal form and then combined with opsin to form rhodopsin.
2. **Pigment bleaching:** When rhodopsin absorbs light, retinal changes shape to its all-*trans* isomer, allowing the surrounding protein to quickly relax like an uncoiling spring into its light-activated form. Eventually, the retinal-opsin combination breaks down, allowing retinal and opsin to separate. The breakdown of rhodopsin to retinal and opsin is known as the **bleaching of the pigment**.
3. **Pigment regeneration:** Once the light-struck all-*trans*-retinal detaches from opsin, enzymes within the pigmented epithelium reconvert it to its 11-*cis* isomer. Then, retinal heads "homeward" again to the photoreceptor cells' outer segments. Rhodopsin is regenerated when 11-*cis*-retinal is rejoined to opsin.

The breakdown and regeneration of visual pigments in cones is essentially the same as for rhodopsin. However, cones are about a hundred times less sensitive than rods, which means that it takes higher-intensity (brighter) light to activate cones.

Light Transduction Reactions

What happens when light changes opsin's shape? An enzymatic cascade occurs that ultimately results in closing cation channels that are normally kept open in the dark. **Figure 15.17** illustrates this process in detail, but in short, light-activated rhodopsin activates a G protein called **transducin**. Transducin, in turn, activates *PDE* (*phosphodiesterase*), the enzyme that breaks down **cyclic GMP (cGMP)**. In the dark, cGMP binds to cation channels in the outer segments of photoreceptor cells, holding them open. This allows Na^+ and Ca^{2+} to enter, depolarizing the cell to its *dark potential* of about –40 mV. In the light, PDE breaks down cGMP, the cation channels close, Na^+ and Ca^{2+} stop entering the cell, and the cell hyperpolarizes to about –70 mV.

This arrangement can seem bewildering, to say the least. Here we have receptors built to detect light that depolarize in the dark and hyperpolarize when exposed to light! However, all

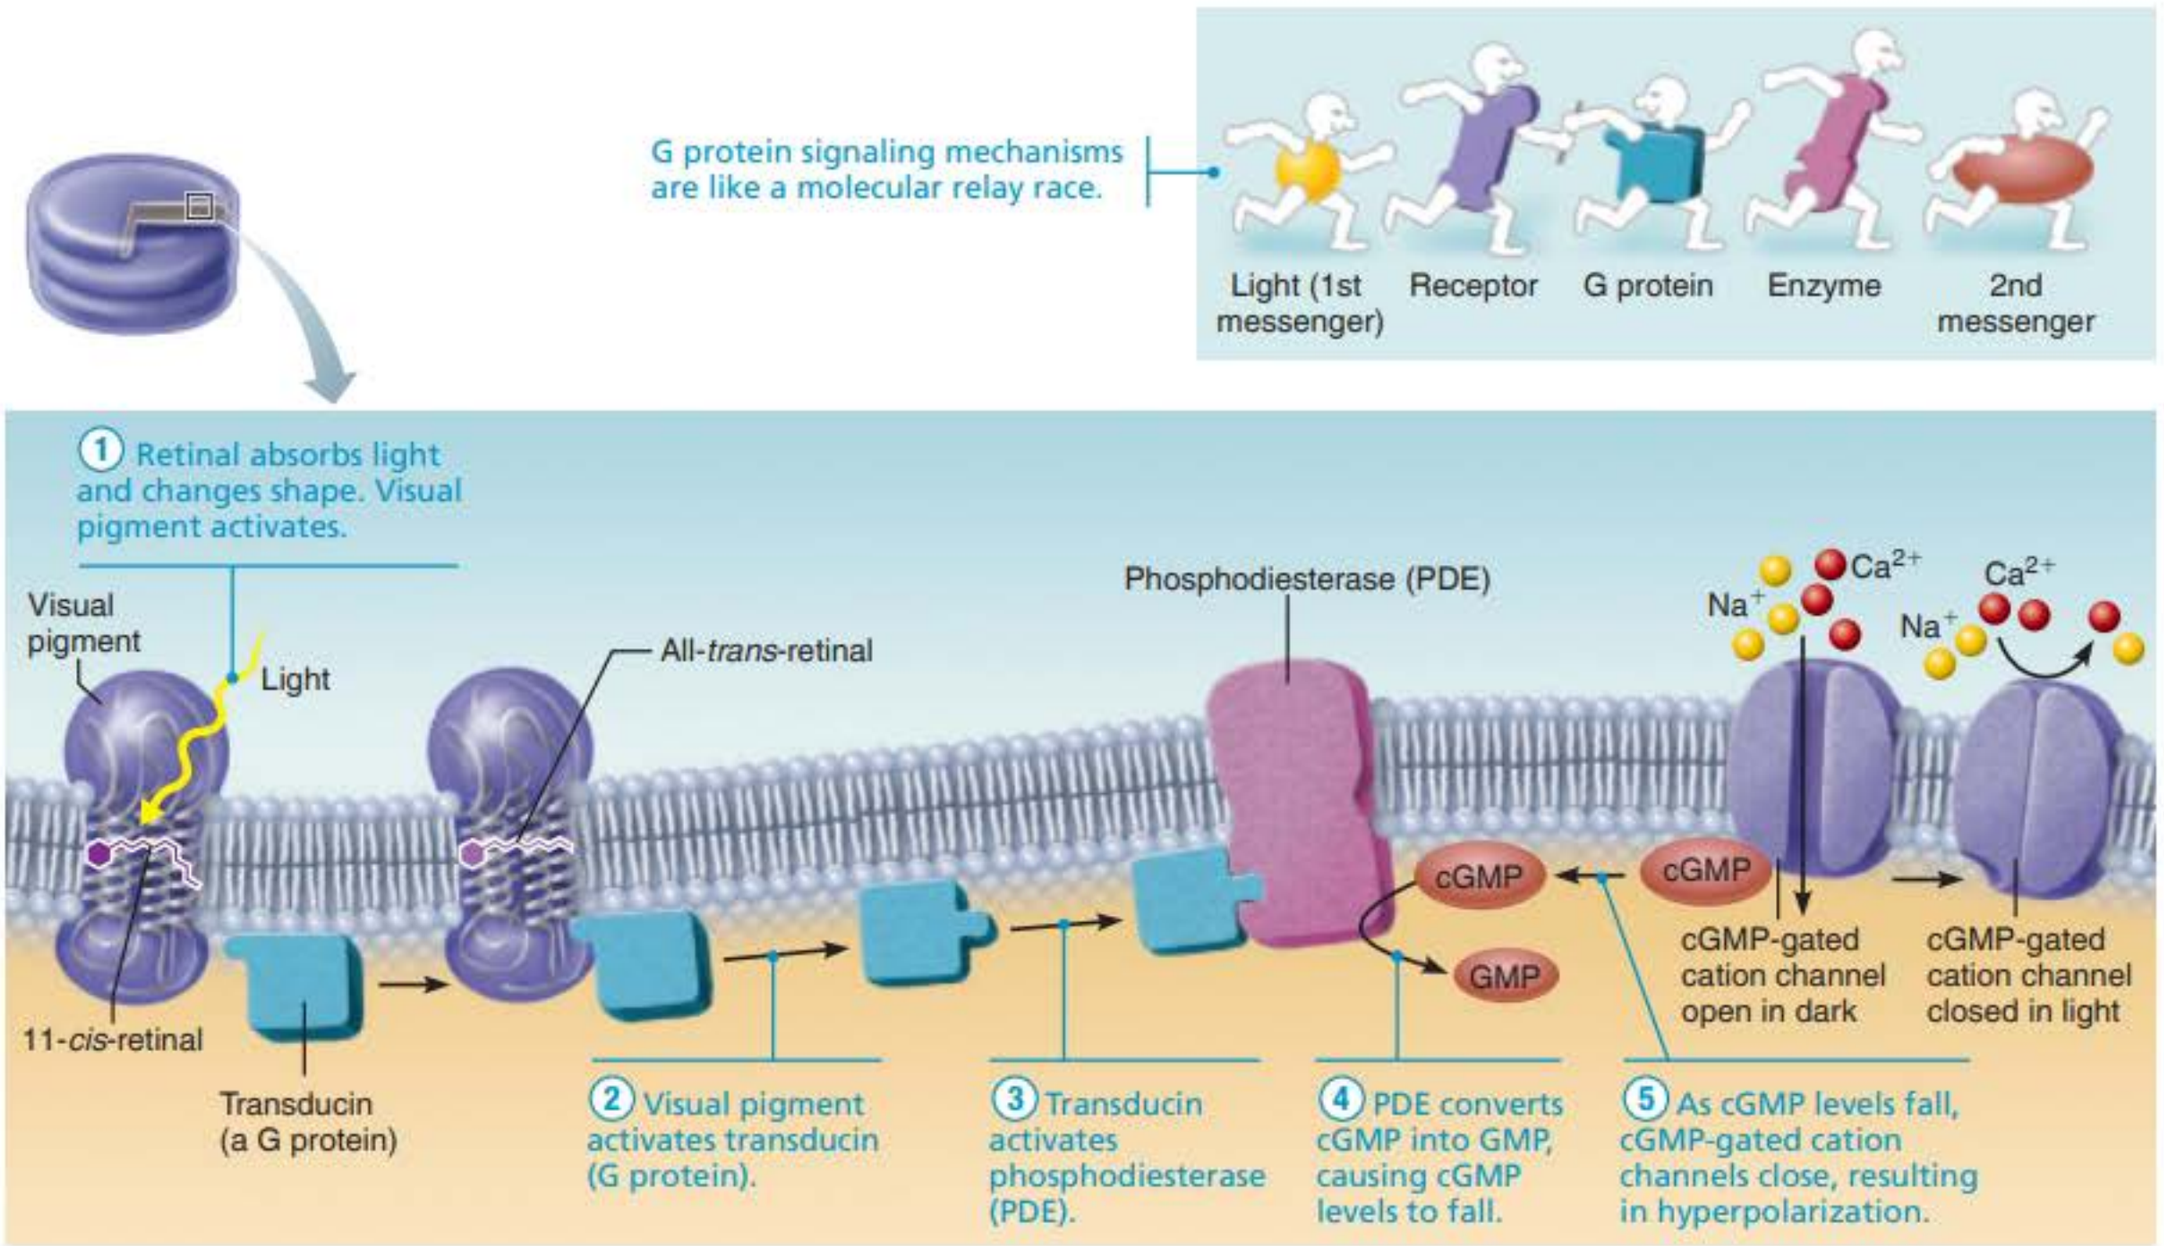

Figure 15.17 Events of phototransduction. A portion of photoreceptor disc membrane is shown. The G protein conversion of GTP to GDP has been omitted for clarity. For simplicity, the channels gated by cyclic GMP (cGMP) are shown on the same membrane as the visual pigment instead of in the plasma membrane. (For the basics of G protein signaling mechanisms, see *Focus on G Proteins*, Focus Figure 3.3 on p. 82.)

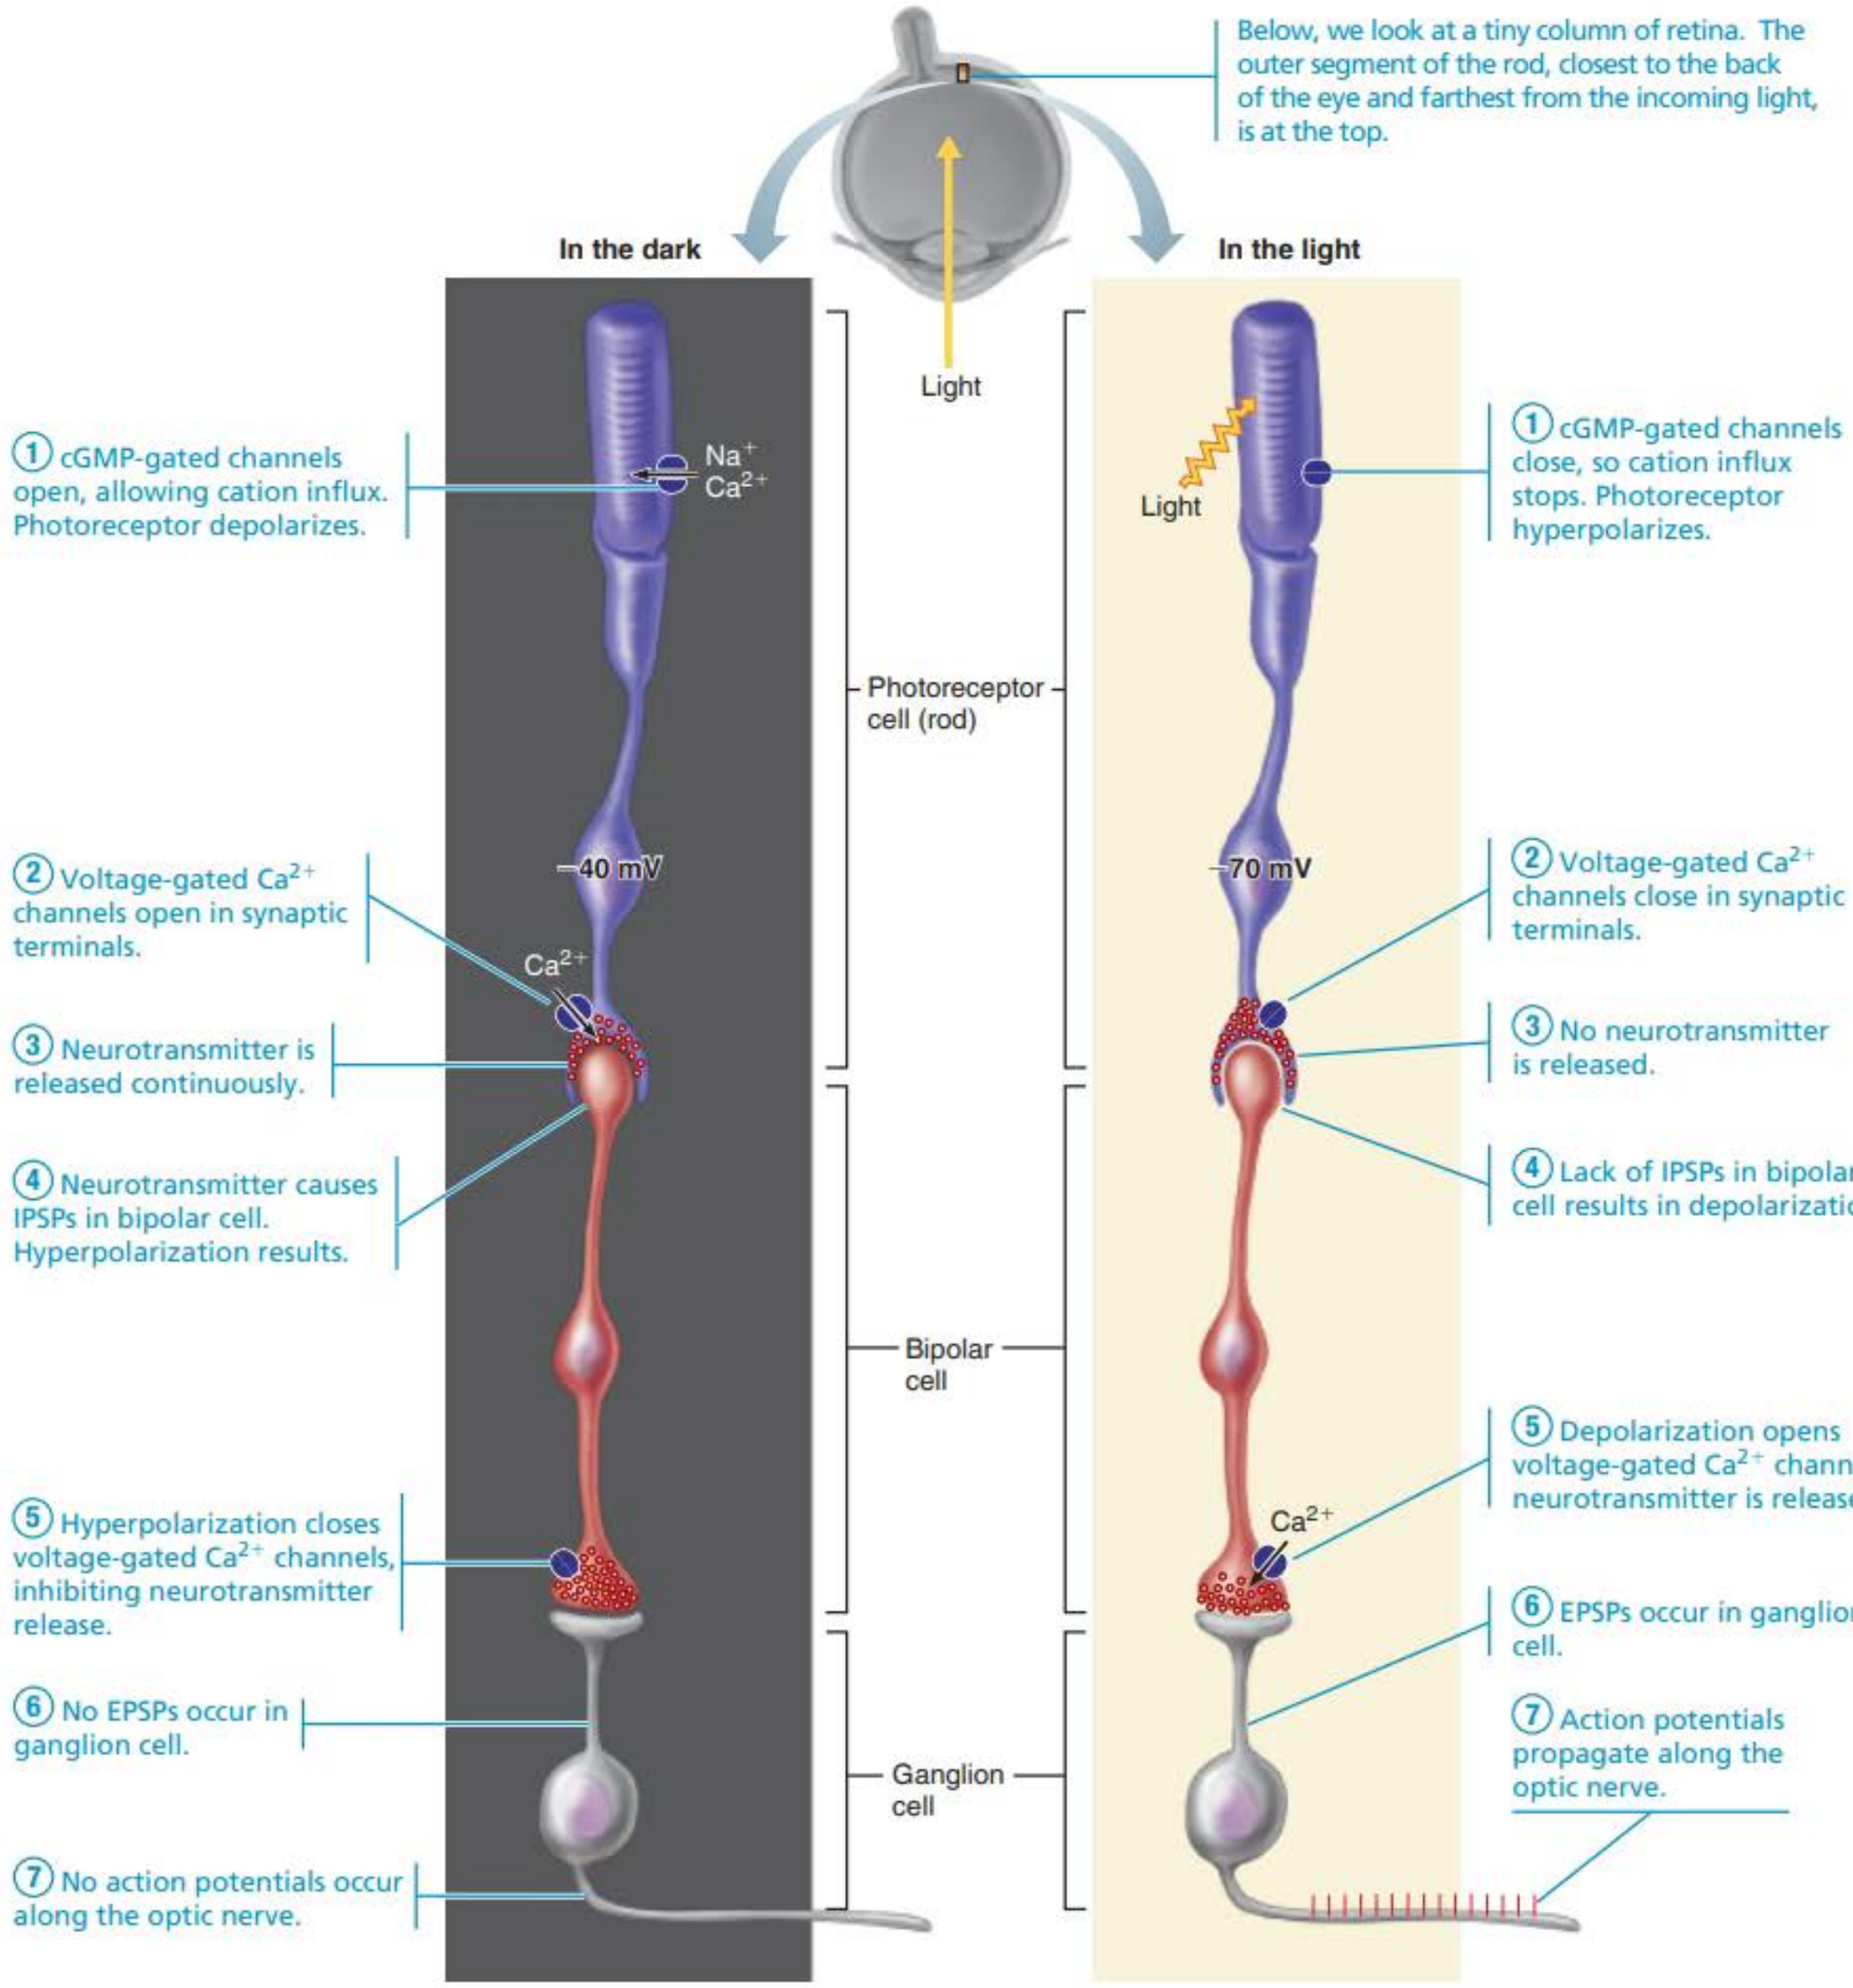

Figure 15.18 Signal transmission in the retina. (EPSP = excitatory postsynaptic potential; IPSP = inhibitory postsynaptic potential)

that is required is a signal and hyperpolarization is just as good a signal as depolarization.

Information Processing in the Retina

How is the hyperpolarization of the photoreceptors transmitted through the retina and on to the brain? **Figure 15.18** illustrates this process. Notice that the photoreceptors do not generate action potentials (APs), and neither do the bipolar cells that are next in line. They only generate graded potentials. Photoreceptors generate receptor potentials, and bipolar cells generate excitatory or inhibitory postsynaptic potentials (EPSPs or IPSPs).

This is not surprising if you remember that the primary function of APs is to carry information rapidly over long distances. Retinal cells are small cells that are very close together. Graded potentials can serve quite adequately as signals that directly regulate neurotransmitter release at the synapse by opening or closing voltage-gated Ca^{2+} channels.

As shown in the right panel of Figure 15.18, for example, light hyperpolarizes photoreceptors, which then stop releasing their inhibitory neurotransmitter (glutamate). No longer inhibited, bipolar cells depolarize and release neurotransmitter onto ganglion cells. Once the signal reaches the ganglion cells, it is converted into an AP. This AP is transmitted to the brain along the ganglion cell axons that make up the optic nerve.

Light and Dark Adaptation

Rhodopsin is amazingly sensitive. Even starlight bleaches some of its molecules. As long as the light is low intensity, relatively little rhodopsin bleaches and the retina continues to respond to light stimuli. However, in high-intensity light, there is wholesale bleaching of the pigment, and rhodopsin bleaches as fast as it is re-formed. At this point, the rods are nonfunctional, but cones still respond. As a result, retinal sensitivity automatically adjusts to the amount of light present.

Light Adaptation

Light adaptation occurs when we move from darkness into bright light, as when leaving a movie matinee. We are momentarily dazzled—all we see is white light—because the sensitivity of the retina is still "set" for dim light. Both rods and cones are strongly stimulated, and large amounts of the visual pigments break down almost instantaneously, producing a flood of signals that accounts for the glare.

Under such conditions, compensations occur. The rod system turns off—all of the transducins migrate to the inner segment, uncoupling rhodopsin from the rest of the transduction cascade. Without transducin in the outer segment, light hitting rhodopsin cannot produce a signal. At the same time, the less sensitive cone system and other retinal neurons rapidly adapt, and retinal sensitivity decreases dramatically. Within about 60 seconds, the cones, initially overexcited by the bright light, are sufficiently desensitized to take over. Visual acuity and color vision continue to improve over the next 5–10 minutes. Thus, during light adaptation, we lose retinal sensitivity (rod function) but gain visual acuity.

Dark Adaptation

Dark adaptation, essentially the reverse of light adaptation, occurs when we go from a well-lit area into a dark one. Initially, we see nothing but velvety blackness because (1) our cones stop functioning in low-intensity light, and (2) the bright light bleached our rod pigments, and the rods are still turned off.

But once we are in the dark, rhodopsin accumulates, transducin returns to the outer segment, and retinal sensitivity increases. Dark adaptation is much slower than light adaptation and can go on for hours. However, there is usually enough rhodopsin within 20–30 minutes to allow adequate dim-light vision.

During both light and dark adaptation, reflexive changes occur in pupil size. Bright light shining in one or both eyes constricts both pupils (elicits the *pupillary* and *consensual light reflexes*). These pupillary reflexes are mediated by the pretectal nucleus of the midbrain and by parasympathetic fibers. In dim light, the pupils dilate, allowing more light to enter the eye.

HOMEOSTATIC IMBALANCE 15.10 CLINICAL

Night blindness, or *nyctalopia* (nic″tă-lo′pe-uh), is a condition in which rod function is seriously hampered, impairing one's ability to drive safely at night. In countries where malnutrition is common, the most common cause of night blindness is prolonged vitamin A deficiency, which leads to rod degeneration. Vitamin A supplements restore function if they are administered early.

In countries where nutrition isn't a problem, *retinitis pigmentosa*—a group of degenerative retinal diseases that destroy rods—are the most common causes of night blindness. Retinitis pigmentosa results from pigment epithelial cells that are unable to recycle the tips of the rods as they get sloughed off.

15

Check Your Understanding

9. For each of the following, indicate whether it applies to rods or cones: vision in bright light; only one type of visual pigment; most abundant in the periphery of the retina; many feed into one ganglion cell; color vision; higher sensitivity; higher acuity.
10. What does bleaching of the pigment mean and when does it happen?

For answers, see Answers Appendix.

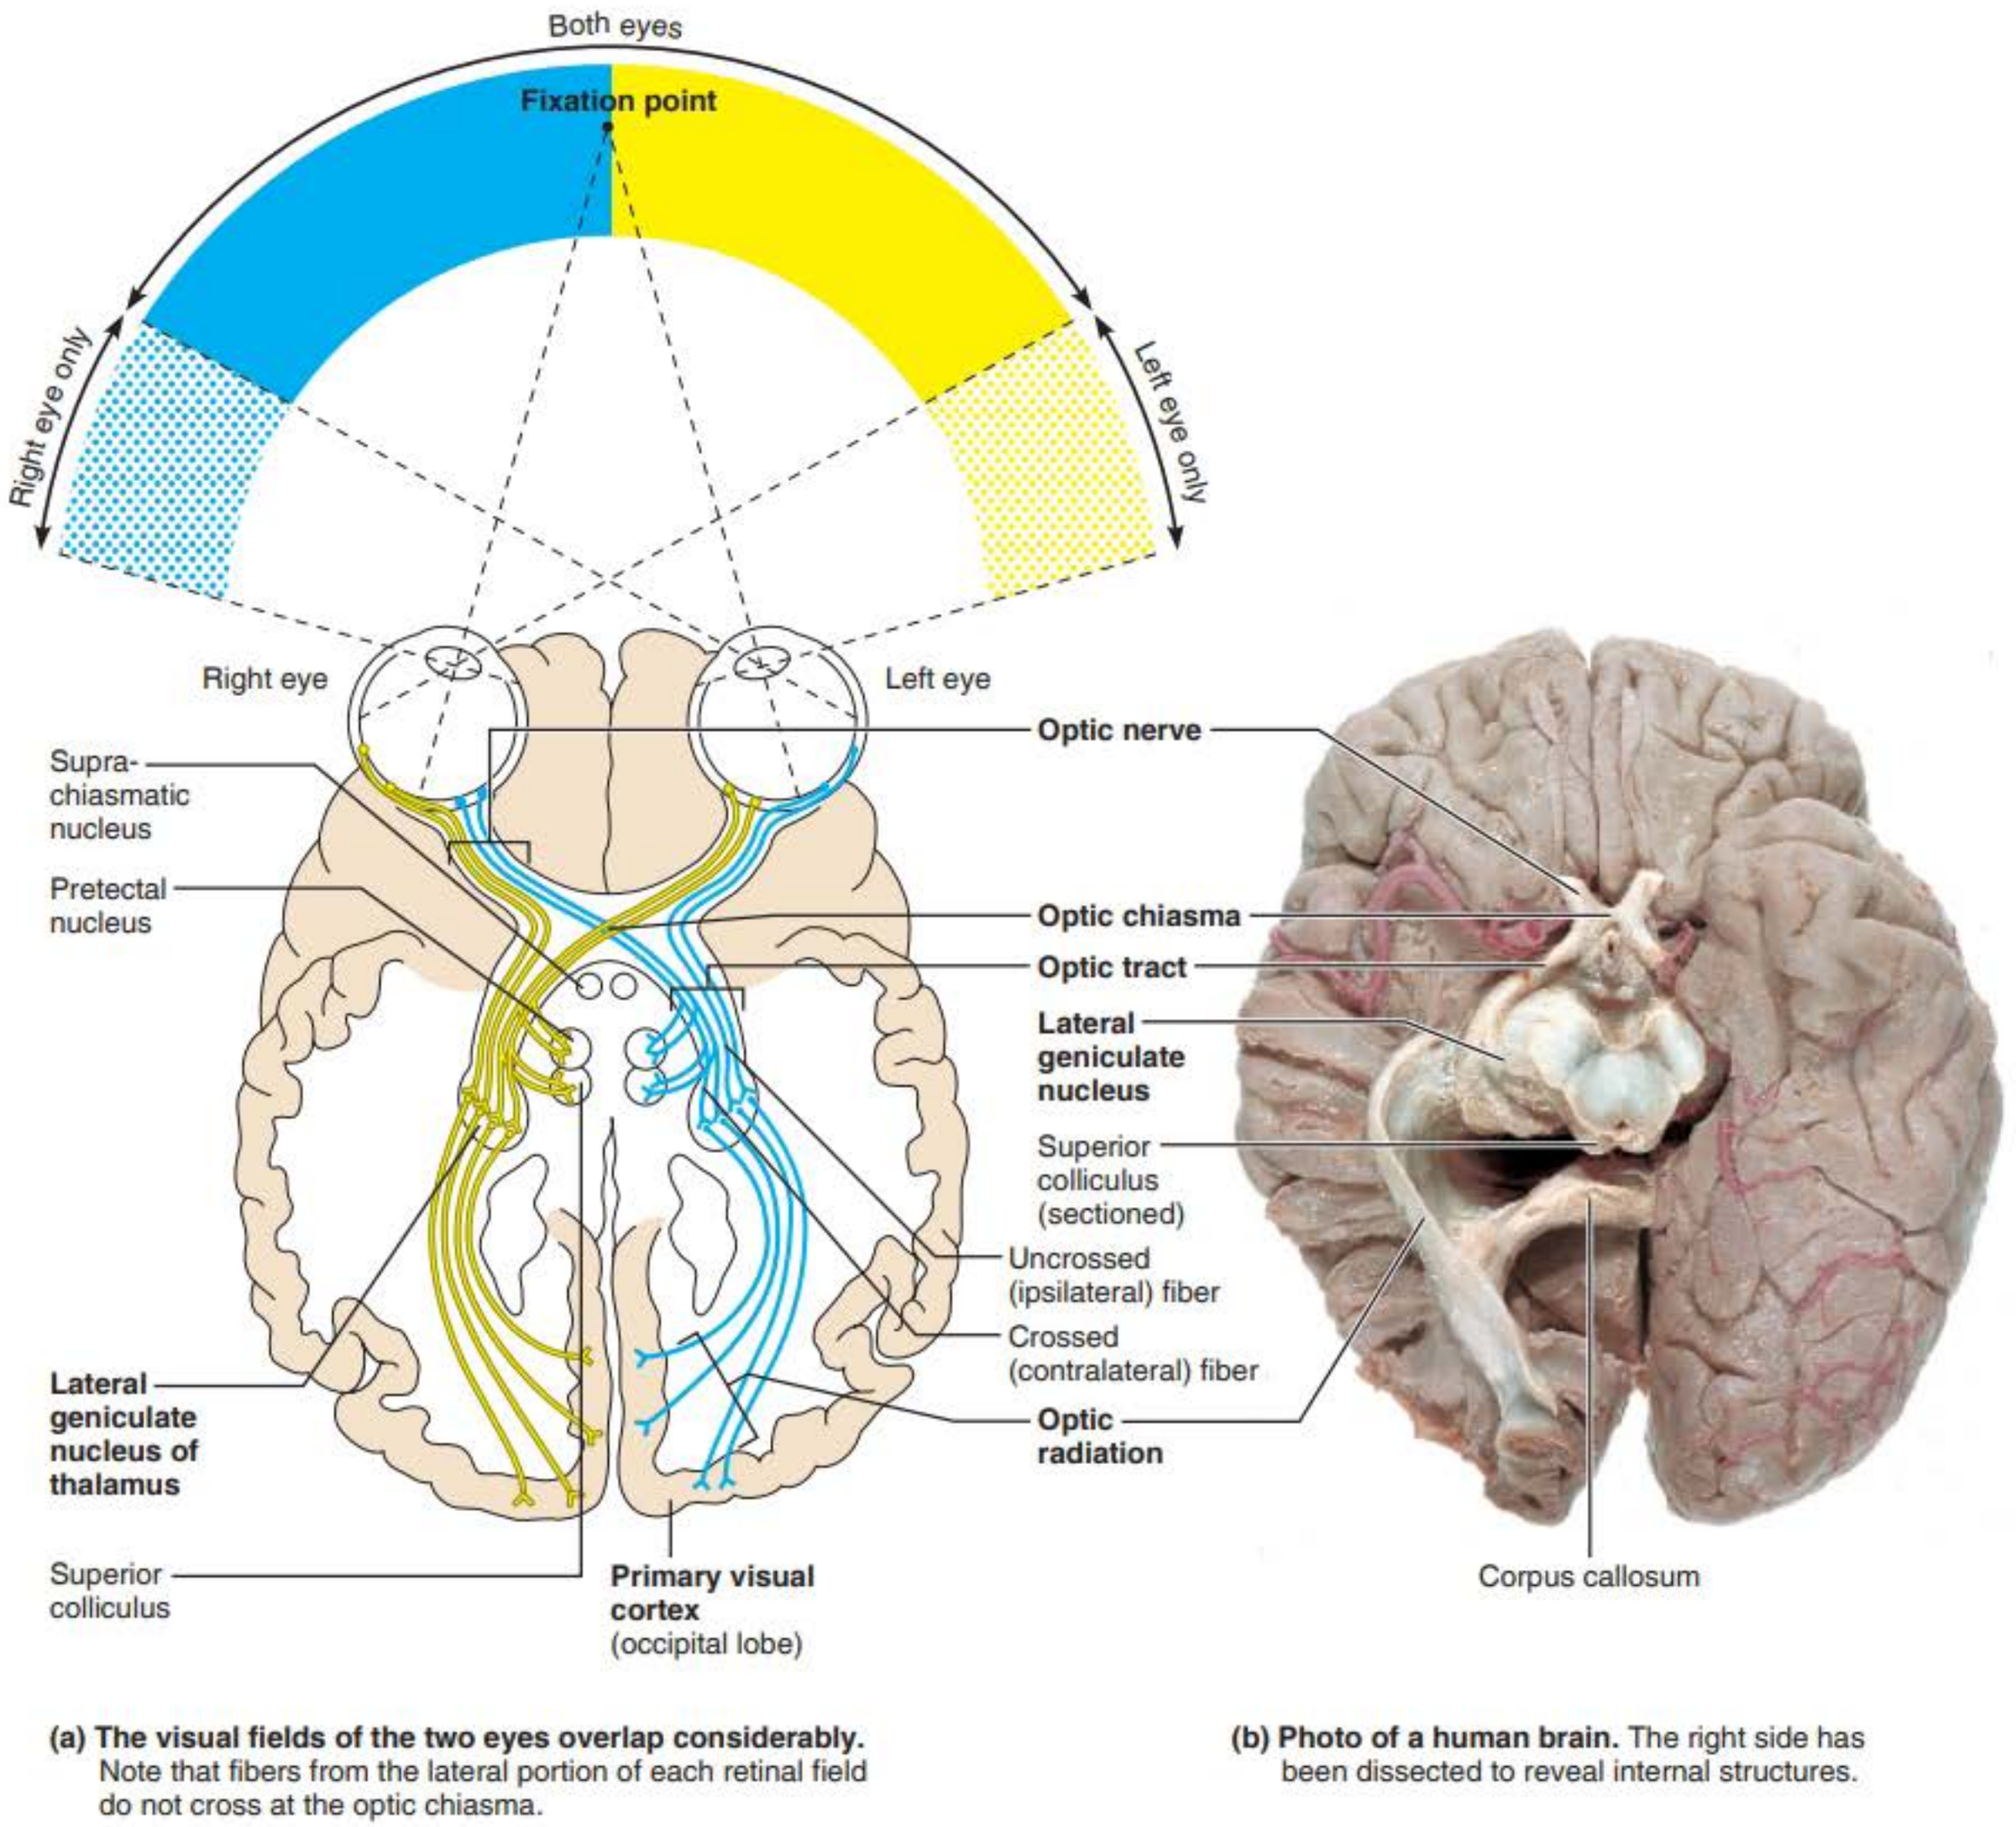
15.4 Visual information from the retina passes through relay nuclei to the visual cortex

Learning Outcome

- **Trace the visual pathway to the visual cortex, and briefly describe the steps in visual processing.**

The Visual Pathway to the Brain

As we described earlier, the axons of the retinal ganglion cells exit the eye in the **optic nerves**. At the X-shaped **optic chiasma**



(a) The visual fields of the two eyes overlap considerably. Note that fibers from the lateral portion of each retinal field do not cross at the optic chiasma.

(b) Photo of a human brain. The right side has been dissected to reveal internal structures.

Figure 15.19 Visual pathway to the brain and visual fields, inferior view.

Practice Human Cadaver lab questions:
MasteringA&P® > Study Area > Lab Tools > PAL

(*chiasm* = cross), fibers from the medial aspect of each eye cross over to the opposite side and then continue on via the **optic tracts** (**Figure 15.19**). As a result, each optic tract:

- Contains fibers from the lateral (temporal) aspect of the eye on the same side and fibers from the medial (nasal) aspect of the opposite eye
- Carries all the information from the same half of the visual field

Notice that, because the lens system of each eye reverses all images, the medial half of each retina receives light rays from the *temporal* (lateralmost) part of the visual field (from the far left or far right rather than from straight ahead), and the lateral half of each retina receives an image of the nasal (central) part of the visual field. Consequently, the left optic tract carries a complete representation of the right half of the visual field, and the opposite is true for the right optic tract.

The paired optic tracts sweep posteriorly around the hypothalamus and send most of their axons to synapse with neurons in the **lateral geniculate nuclei** (contained within the lateral geniculate bodies) of the thalamus. The lateral geniculate nuclei maintain the fiber separation established at the chiasma, but they balance and combine the retinal input for delivery to the visual cortex. Axons of these thalamic neurons project through the internal capsule to form the **optic radiation** of fibers in the cerebral white matter (Figure 15.19). These fibers project to the

primary visual cortex in the occipital lobes, where conscious perception of visual images (seeing) occurs.

Some nerve fibers in the optic tracts send branches to the midbrain. One set of these fibers ends in the **superior colliculi**, visual reflex centers controlling the extrinsic muscles of the eyes. Another set comes from a small subset of ganglion cells in the retina that contain the visual pigment *melanopsin*, dubbed the circadian pigment. These ganglion cells respond directly to light stimuli and their fibers project to the **pretectal nuclei**, which mediate pupillary light reflexes, and to the **suprachiasmatic nucleus** of the hypothalamus, which functions as the "timer" to set our daily biorhythms.

Depth Perception

Each eye's visual field is about 170 degrees. The two visual fields overlap considerably, but each eye sees a slightly different view (Figure 15.19a). The visual cortex fuses the slightly different images delivered by the two eyes, providing us with **depth perception** (or **three-dimensional vision**), an accurate means of locating objects in space.

In contrast, many animals (pigeons, rabbits, and others) have *panoramic vision*. Their eyes are placed more laterally on the head, so that the visual fields overlap very little. Each visual cortex receives input principally from a single eye and a totally different visual field.

Depth perception depends on the two eyes working together. If only one eye is used, depth perception is lost, and the person must learn to judge an object's position based on learned cues (for example, nearer objects appear larger, and parallel lines converge with distance).

HOMEOSTATIC IMBALANCE 15.11 — CLINICAL

Loss of an eye or destruction of one optic nerve eliminates 3-D vision, the major component of depth perception, and peripheral vision on the damaged side.

If neural destruction occurs beyond the optic chiasma—in an optic tract, the thalamus, or visual cortex—then part or all of the opposite half of the visual field is lost. For example, a stroke affecting the left visual cortex leads to blindness in the right half of the visual field.

Visual Processing

How does information received by rods and cones become vision? Visual processing begins in the retina.

Retinal cells simplify and condense the information from rods and cones, splitting it into a number of different "channels," each with its own type of ganglion cell. These "channels" include information about color and brightness, but also about more complex aspects of what we see—the angle, direction and speed of movement of *edges* (sudden changes in brightness or color). Edges are detected by a kind of contrast enhancement called *lateral inhibition*, which is the job of the amacrine and horizontal cells mentioned on pp. 560–561.

The ganglion cells pass the processed information to the lateral geniculate nuclei of the thalamus. There, information from each eye is combined in preparation for depth perception and input from cones is emphasized.

The *primary visual cortex* contains an accurate topographical map of the retina, with the left visual cortex receiving input from the right visual field and vice versa. Visual processing here occurs at a relatively basic level, with the processing neurons responding to dark and bright edges (contrast information) and object orientation. Surrounding areas process form, color, and movement.

Functional neuroimaging of humans has revealed that complex visual processing extends well forward into the temporal, parietal, and frontal lobes via two parallel streams, one that identifies objects in the visual field and another that assesses the location of objects in space. Output from these regions then passes to the frontal cortex for further processing.

PART 2 THE CHEMICAL SENSES: SMELL AND TASTE

Smell and taste are gritty, primitive senses that alert us to whether that "stuff" nearby (or in our mouth) is to be savored or avoided. The receptors for smell (olfaction) and taste (gustation) are **chemoreceptors** (they respond to chemicals in an aqueous solution). They complement each other and respond to different classes of chemicals. Smell receptors are excited by airborne chemicals that dissolve in fluids coating nasal membranes, and taste receptors are excited by food chemicals dissolved in saliva.

15.5 Airborne chemicals are detected by olfactory receptors in the nose

Learning Outcome

- **Describe the location, structure, and afferent pathways of smell receptors, and explain how these receptors are activated.**

Although our olfactory sense (*olfact* = to smell) is far less acute than that of many other animals, the human nose is still no slouch in picking up small differences in odors. Some people capitalize on this ability by becoming wine tasters.

Location and Structure of Olfactory Receptors

The organ of smell is a yellow-tinged patch (about 5 cm^2) of pseudostratified epithelium, called the **olfactory epithelium**,

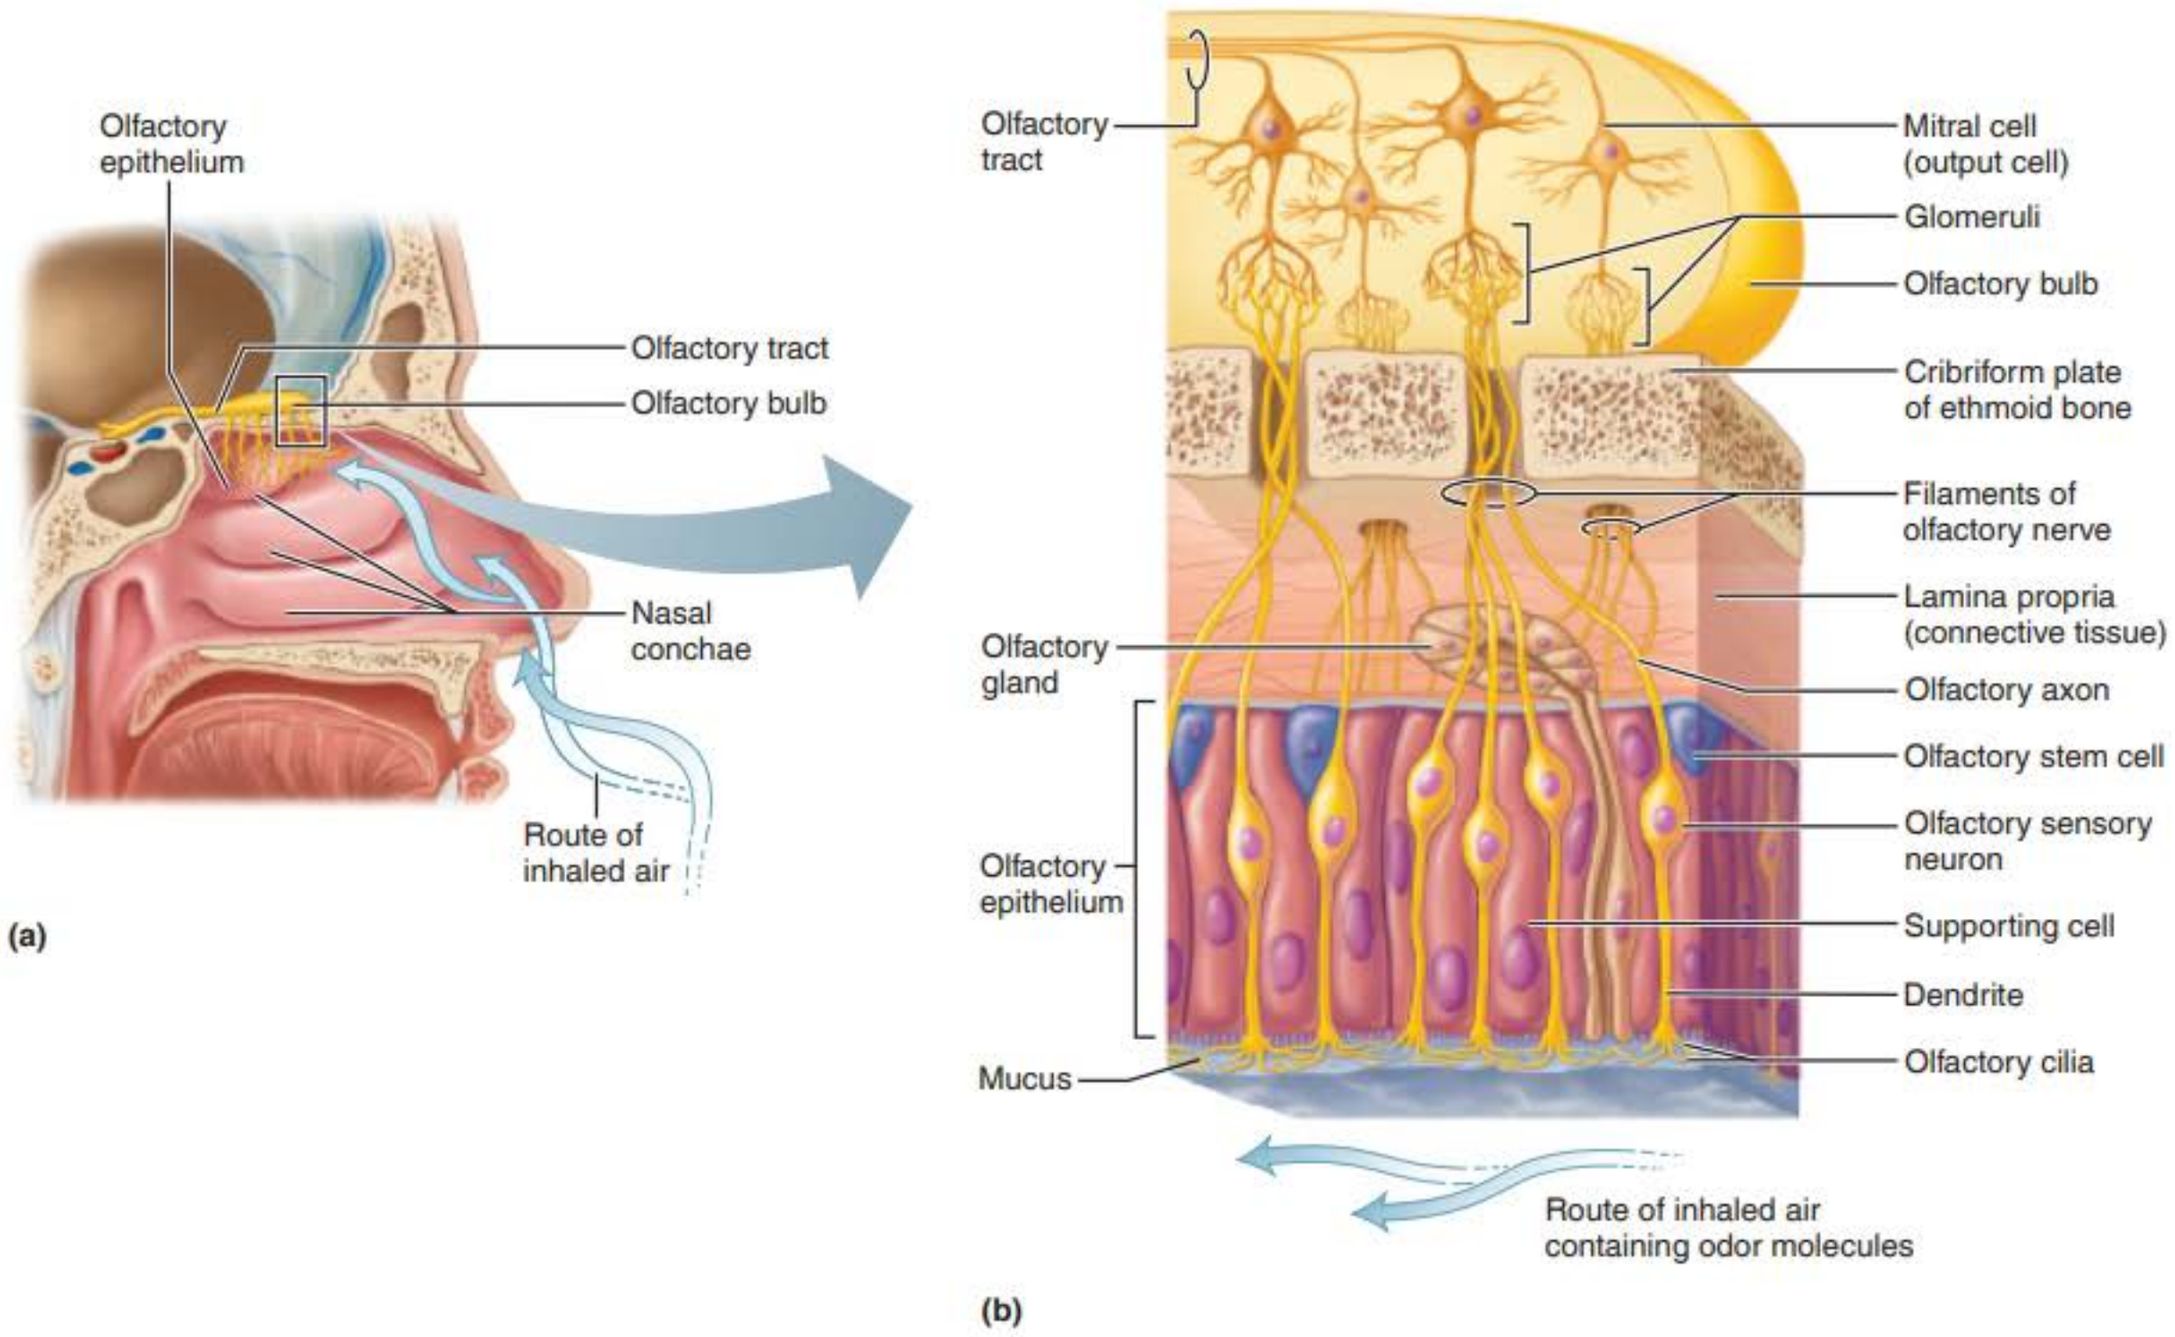

Figure 15.20 Olfactory receptors. (a) Site of olfactory epithelium in the superior nasal cavity. **(b)** An enlarged view of the olfactory epithelium showing the course of the fibers [filaments of the olfactory nerve (I)] through the ethmoid bone. These synapse in the glomeruli of the overlying olfactory bulb. The mitral cells are the output cells of the olfactory bulb.

located in the roof of the nasal cavity (**Figure 15.20a**). Air entering the nasal cavity must make a hairpin turn to stimulate olfactory receptors before entering the respiratory passageway below, so the human olfactory epithelium is in a poor position for doing its job. (This is why sniffing, which draws more air superiorly across the olfactory epithelium, intensifies the sense of smell.)

The olfactory epithelium covers the superior nasal concha on each side of the nasal septum, and contains millions of bowling pin–shaped receptor cells—the **olfactory sensory neurons**. These are surrounded and cushioned by columnar **supporting cells**, which make up the bulk of the penny-thin epithelial membrane (Figure 15.20b). The supporting cells contain a yellow-brown pigment similar to lipofuscin, which gives the olfactory epithelium its yellow hue. At the base of the epithelium lie the short **olfactory stem cells**.

The olfactory sensory neurons are unusual bipolar neurons. Each has a thin apical dendrite that terminates in a knob from which several long cilia radiate. These **olfactory cilia**, which substantially increase the receptive surface area, typically lie flat on the nasal epithelium and are covered by a coat of thin mucus produced by the supporting cells and by olfactory glands in the underlying connective tissue. This mucus is a solvent that "captures" and dissolves airborne odorants. Unlike other cilia in the body, which beat rapidly in a coordinated manner, olfactory cilia are largely nonmotile.

The slender, nonmyelinated axons of the olfactory sensory neurons are gathered into small fascicles that collectively form the **filaments of the olfactory nerve** (cranial nerve I). They project superiorly through the openings in the cribriform plate of the ethmoid bone, where they synapse in the overlying olfactory bulbs.

Olfactory sensory neurons are also unusual because they are one of the few types of *neurons* that undergo noticeable turnover throughout adult life. Their superficial location puts them at risk for damage, and their typical life span is 30–60 days. Olfactory stem cells in the olfactory epithelium differentiate to replace them.

Specificity of Olfactory Receptors

Smell is difficult to research because any given odor (say, tobacco smoke) may be made up of hundreds of different chemicals (called *odorants*). Taste has been neatly packaged into five taste qualities as you will see, but science has yet to discover any similar means for classifying smell. How many different odors can we distinguish? Estimates range from 10,000 to 1 trillion.

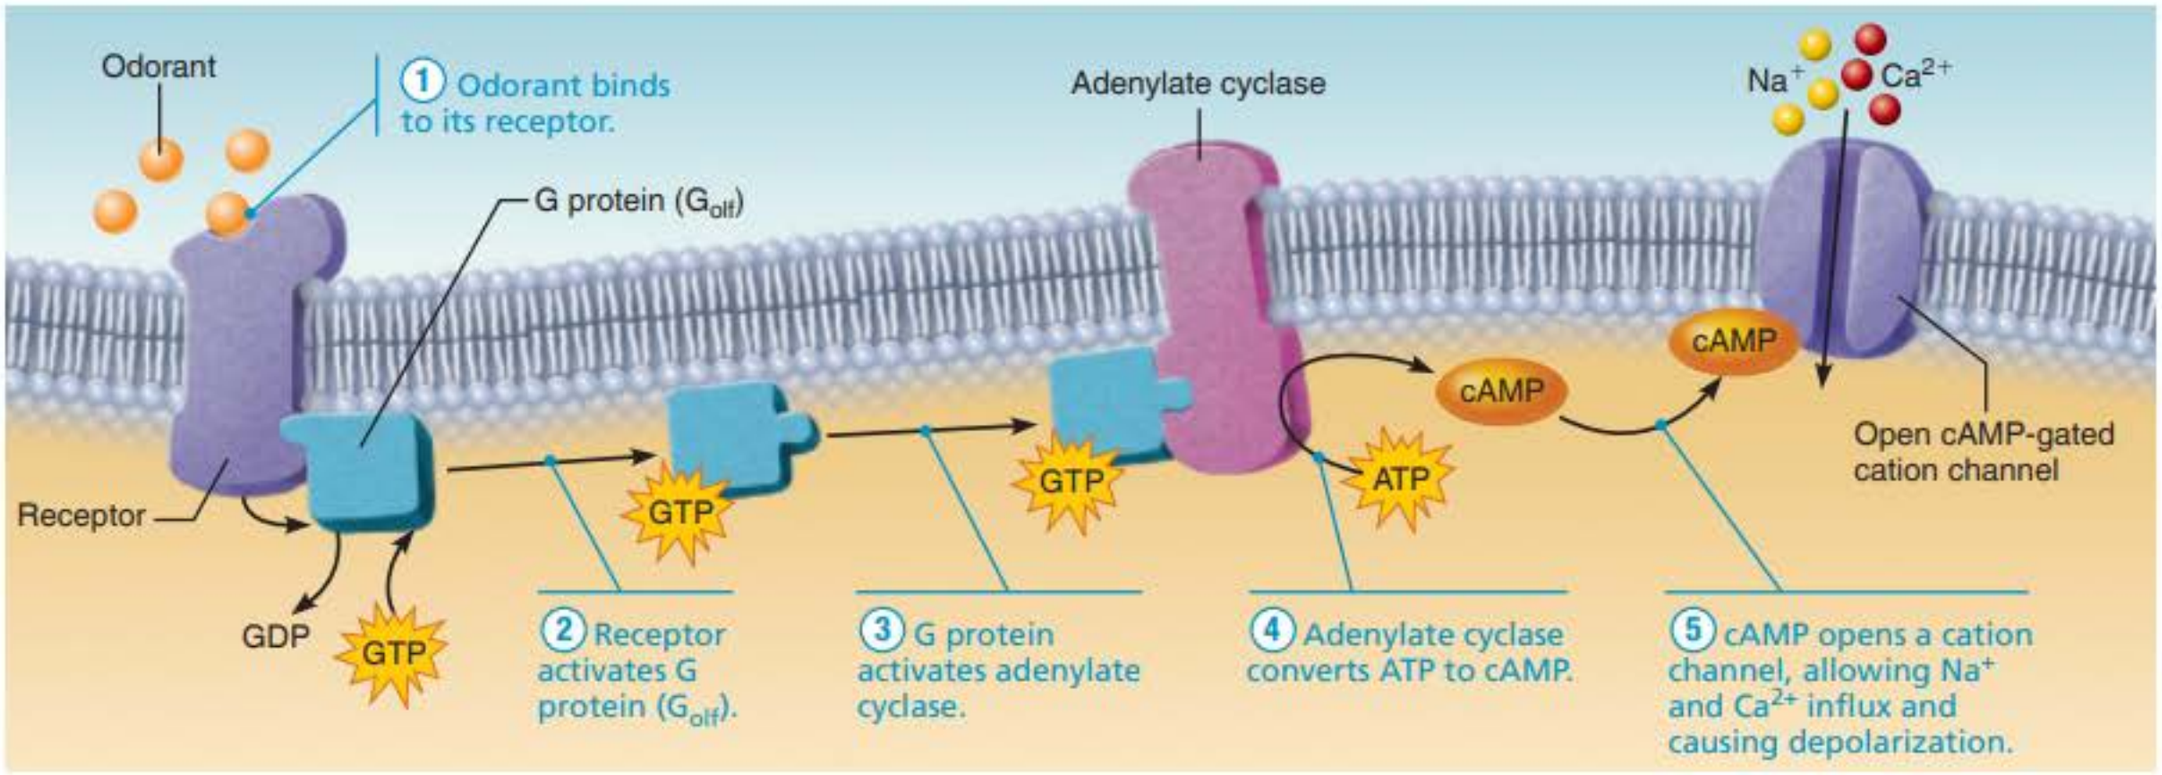

Figure 15.21 Olfactory transduction process. A portion of olfactory cilium membrane is shown.

However, our olfactory sensory neurons are stimulated by combinations of a more limited number of olfactory qualities.

There are about 350 different odorant receptors in humans. Each receptor responds to one or more odorants and each odorant binds to several different receptor types. However, each receptor cell has only one type of receptor protein.

Olfactory neurons are exquisitely sensitive—in some cases, just a few molecules activate them. Some of what we call smell is really pain. The nasal cavities contain pain and temperature receptors that respond to irritants such as the sharpness of ammonia, the hotness of chili peppers, and the "chill" of menthol. Impulses from these receptors reach the central nervous system via afferent fibers of the trigeminal nerves.

Physiology of Smell

For us to smell a particular odorant, it must be *volatile*—that is, it must be in the gaseous state as it enters the nasal cavity. Additionally, it must dissolve in the fluid coating the olfactory epithelium.

Activation of Olfactory Sensory Neurons

Dissolved odorants stimulate olfactory sensory neurons by binding to receptor proteins in the olfactory cilium membranes, opening cation channels and generating a receptor potential. Ultimately (assuming threshold stimulation) an action potential is conducted to the first relay station in the olfactory bulb.

Smell Transduction

Transduction of odorants uses a receptor linked to a G protein. The events that follow odorant binding will be easy to remember if you compare them to what you already know: general mechanisms of receptors and G proteins (◀ **Figure 11.17, p. 425**) and phototransduction (see Figure 15.17).

As **Figure 15.21** shows, olfactory transduction begins when an odorant binds to a receptor. This event activates G proteins (G_{olf}), which activate enzymes (adenylate cyclases) that synthesize cyclic AMP (cAMP) as a second messenger. Cyclic AMP then acts directly on plasma membrane cation channels, causing them to open, allowing Na^+ and Ca^{2+} to enter.

Na^+ influx leads to depolarization and impulse transmission. Ca^{2+} influx causes the transduction process to adapt, decreasing its response to a sustained stimulus. This *olfactory adaptation* helps explain how a person working in a paper mill or sewage treatment plant can still enjoy lunch!

The Olfactory Pathway

As we have already noted, axons of the olfactory sensory neurons form the olfactory nerves that synapse in the overlying **olfactory bulbs**, the distal ends of the olfactory tracts (◀ **Table 13.2, p. 500**). There, the filaments of the olfactory nerves synapse with **mitral cells** (mi′tral), which are second-order sensory neurons, in complex structures called **glomeruli** (glo-mer′u-li; "little balls") (Figure 15.20).

Axons from neurons bearing the same kind of receptor converge on a given type of glomerulus. That is, each glomerulus represents a single aspect of an odor (like one note in a chord) but each odor activates a unique set of glomeruli (the chord itself). Different odors activate different subsets of glomeruli (making different chords which may have some of the same notes). The mitral cells refine the signal, amplify it, and then relay it. The olfactory bulbs also house *amacrine granule cells* that inhibit mitral cells, so that only highly excitatory olfactory impulses are transmitted.

When the mitral cells are activated, impulses flow from the olfactory bulbs via the **olfactory tracts** (composed mainly of mitral cell axons) to the piriform lobe of the olfactory cortex (◀ **p. 443**). From there, two major pathways take information to various parts of the brain:

- One pathway brings information to part of the frontal lobe just above the orbit, where smells are consciously interpreted

15

and identified. Only some of this information passes through the thalamus.

- The other pathway flows to the hypothalamus, amygdaloid body, and other regions of the limbic system. There, emotional responses to odors are elicited. Smells associated with danger—smoke, cooking gas, or skunk scent—trigger the sympathetic fight-or-flight response. Appetizing odors stimulate salivation and the digestive tract, and unpleasant odors can trigger protective reflexes such as sneezing or choking.

HOMEOSTATIC IMBALANCE 15.12 CLINICAL

Most olfactory disorders, or *anosmias* (an-oz′me-ahz; "without smells"), result from head injuries that tear the olfactory nerves, the aftereffects of nasal cavity inflammation, and neurological disorders such as Parkinson's disease. Anosmia may also be an early sign of Alzheimer's disease. Some people have olfactory hallucinations during which they experience a particular (usually unpleasant) odor, such as rotting meat. These are usually caused by temporal lobe epilepsy involving the olfactory cortex and can occur as olfactory auras before the seizure begins or as olfactory hallucinations during the seizure.

12. How do the cilia of olfactory sensory neurons help these cells perform their function?

For answers, see Answers Appendix.

15

15.6 Dissolved chemicals are detected by receptor cells in taste buds

Learning Outcome

- **Describe the location, structure, and afferent pathways of taste receptors, and explain how these receptors are activated.**

The word *taste* comes from the Latin *taxare*, meaning "to touch, estimate, or judge." When we taste things, we are in fact intimately testing or judging our environment, and the sense of taste is considered by many to be the most pleasurable of the special senses.

Location and Structure of Taste Buds

Most of our 10,000 or so **taste buds**—the sensory organs for taste—are located on the tongue. A few taste buds are scattered on the soft palate, inner surface of the cheeks, pharynx, and epiglottis of the larynx, but most are found in **papillae** (pah-pil′e), peglike projections of the tongue mucosa that make the tongue surface slightly abrasive (**Figure 15.22a,b**). Three kinds of papillae have taste buds:

- Mushroom-shaped **fungiform papillae** (fun′jĭ-form) are scattered over the entire tongue surface, but have only one to five taste buds each.
- **Vallate papillae** (val′āt) are the largest and least numerous papillae, but have many taste buds. Eight to 12 vallate papillae form an inverted V at the back of the tongue.
- **Foliate papillae**, located laterally on the tongue, contain many taste buds during childhood, but fewer with age.

Each flask-shaped taste bud consists of 50 to 100 *epithelial cells* of two major types: *gustatory epithelial cells* and *basal epithelial cells* (Figure 15.22c).

Gustatory Epithelial Cells

The **gustatory epithelial cells** are the receptor cells for taste—the *taste cells*. Long microvilli called **gustatory hairs** project from the tips of all gustatory epithelial cells and extend through a **taste pore** to the surface of the epithelium, where they are bathed by saliva. The gustatory hairs are the sensitive portions (*receptor membranes*) of the gustatory epithelial cells. Coiling intimately around the gustatory epithelial cells are sensory dendrites that represent the initial part of the gustatory pathway to the brain. Each afferent fiber receives signals from several gustatory epithelial cells within the taste bud.

There are at least three kinds of gustatory epithelial cells. One kind forms traditional synapses with the sensory dendrites and releases the neurotransmitter serotonin. The other two kinds lack synaptic vesicles, but at least one of these kinds releases ATP that acts as a neurotransmitter.

Basal Epithelial Cells

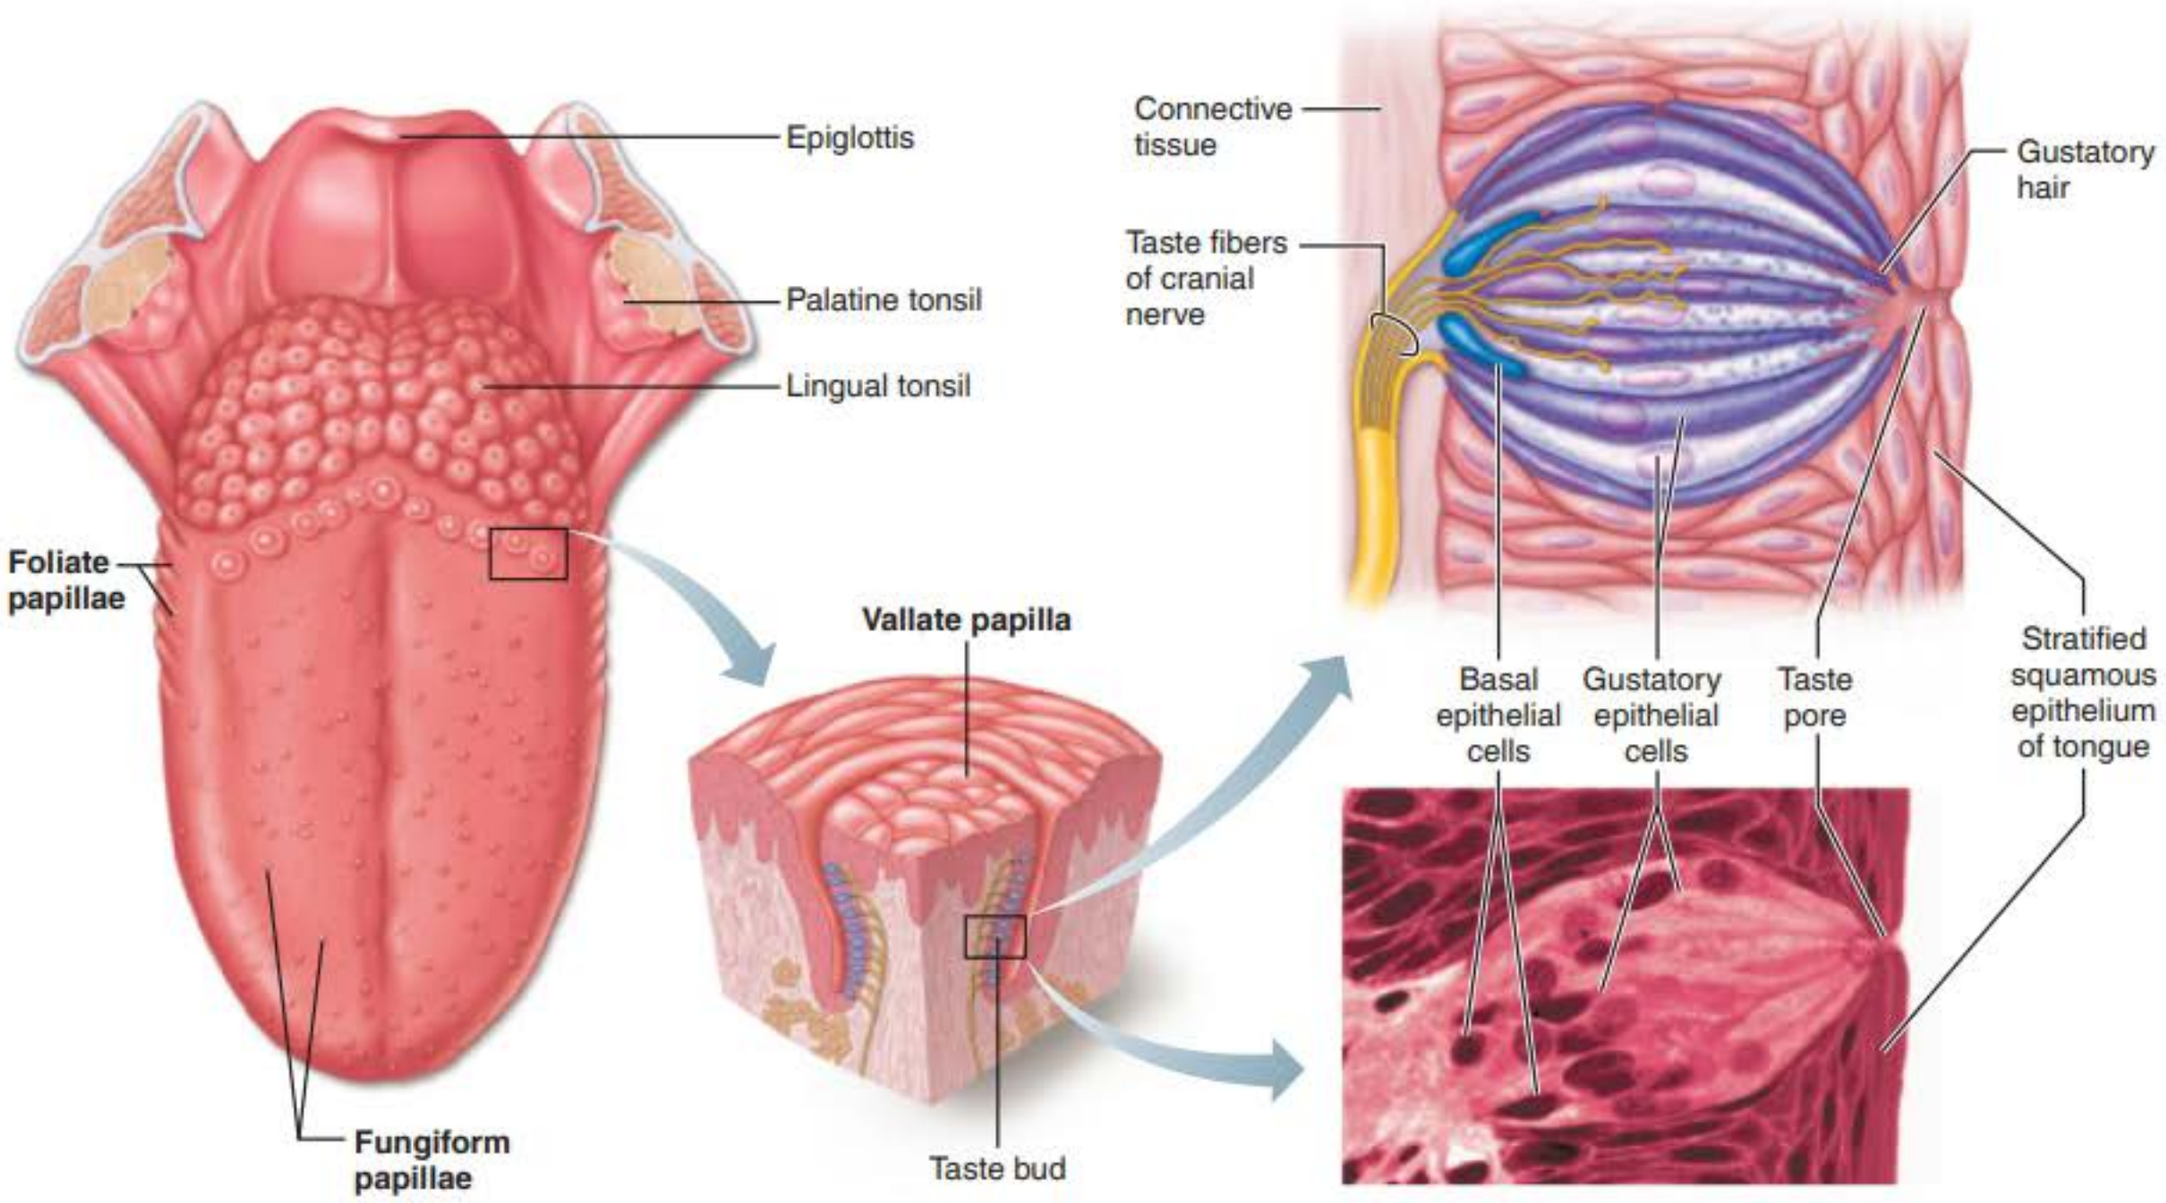
Because of their location, taste bud cells are subjected to friction and are routinely burned by hot foods. Luckily, they are replaced every seven to ten days. **Basal epithelial cells** act as stem cells, dividing and differentiating into new gustatory epithelial cells.

Basic Taste Sensations

Normally, our taste sensations are complicated mixtures of qualities. However, all taste sensations can be grouped into one of five basic modalities: sweet, sour, salty, bitter, and umami.

- *Sweet* taste is elicited by many organic substances including sugars, saccharin, alcohols, some amino acids, and some lead salts (such as those found in lead paint).
- *Sour* taste is produced by acids, specifically their hydrogen ions (H^+) in solution.
- *Salty* taste is produced by metal ions (inorganic salts); table salt (sodium chloride) tastes the "saltiest."
- *Bitter* taste is elicited by alkaloids (such as quinine, nicotine, caffeine, morphine, and strychnine) as well as a number of nonalkaloid substances, such as aspirin.
- *Umami* (oo-mam′e; "delicious"), a subtle taste discovered by the Japanese, is elicited by the amino acids glutamate and aspartate, which are responsible for the "beef taste" of steak, the characteristic tang of aging cheese, and the flavor of the food additive monosodium glutamate (MSG).

In addition, there is growing evidence for our ability to taste long-chain fatty acids from lipids. This possible sixth modality may help explain our liking for fatty foods.



(a) Taste buds are associated with fungiform, foliate, and vallate papillae.

(b) Enlarged section of a vallate papilla.

(c) Enlarged view of a taste bud (210×).

Figure 15.22 Location and structure of taste buds on the tongue.

15

Practice Histology questions:
MasteringA&P® > Study Area > Lab Tools > PAL

Keep in mind that many substances produce a mixture of these basic taste sensations, and taste buds generally respond to all five. However, it appears that a single taste cell has receptors for only one taste modality. Also, all areas of the tongue can detect all taste modalities.

Taste likes and dislikes have homeostatic value. Umami guides the intake of proteins, and a liking for sugar and salt helps satisfy the body's need for carbohydrates and minerals (as well as some amino acids). Many sour, naturally acidic foods (such as oranges, lemons, and tomatoes) are rich sources of vitamin C, an essential vitamin. On the other hand, intensely sour tastes warn us of spoilage. Likewise, many natural poisons and spoiled foods are bitter. Consequently, our dislike for intense sourness and bitterness is protective.

Physiology of Taste

For a chemical to be tasted it must dissolve in saliva, diffuse into a taste pore, and contact the gustatory hairs.

Activation of Taste Receptors

Gustatory epithelial cells contain neurotransmitters. When a food chemical, or *tastant*, binds to receptors in the gustatory epithelial cell membrane, it induces a graded depolarizing potential that causes neurotransmitter release. Binding of the neurotransmitter to the associated sensory dendrites triggers generator potentials that elicit action potentials in these fibers.

The different gustatory epithelial cells have different thresholds for activation. In line with their protective nature, the bitter receptors detect substances present in minute amounts. The other receptors are less sensitive. Taste receptors adapt rapidly, with partial adaptation in 3–5 seconds and complete adaptation in 1–5 minutes.

Taste Transduction

The mechanisms of taste transduction are only now beginning to become clear. Three different mechanisms underlie how we taste.

- Salty taste is due to Na^+ influx through Na^+ channels, which directly depolarizes gustatory epithelial cells.
- Sour is mediated by H^+, which acts intracellularly to open channels that allow other cations to enter.
- Bitter, sweet, and umami responses share a common mechanism, but each occurs in a different cell. Each taste's unique set of receptors is coupled to a common G protein called *gustducin*. Activation leads to the release of Ca^{2+} from intracellular stores, which causes cation channels in the plasma membrane to open, thereby depolarizing the cell and releasing the neurotransmitter ATP.

Influence of Other Sensations on Taste

What we think of as taste is actually 80% smell. When nasal congestion blocks access to your olfactory receptors, food tastes bland. Without smell, our morning coffee would lack its richness and simply taste bitter.

The mouth also contains thermoreceptors, mechanoreceptors, and nociceptors, and the temperature and texture of foods can enhance or detract from their taste. "Hot" foods such as chili peppers actually bring about their pleasurable effects by exciting pain receptors in the mouth.

HOMEOSTATIC IMBALANCE 15.13 CLINICAL

Taste disorders are less common than disorders of smell, in part because the taste receptors are served by three different nerves and thus are less likely to be disabled completely. Causes of taste disorders include upper respiratory tract infections, head injuries, chemicals or medications, or head and neck radiation for cancer treatment. Zinc supplements may help some cases of radiation-induced taste disorders.

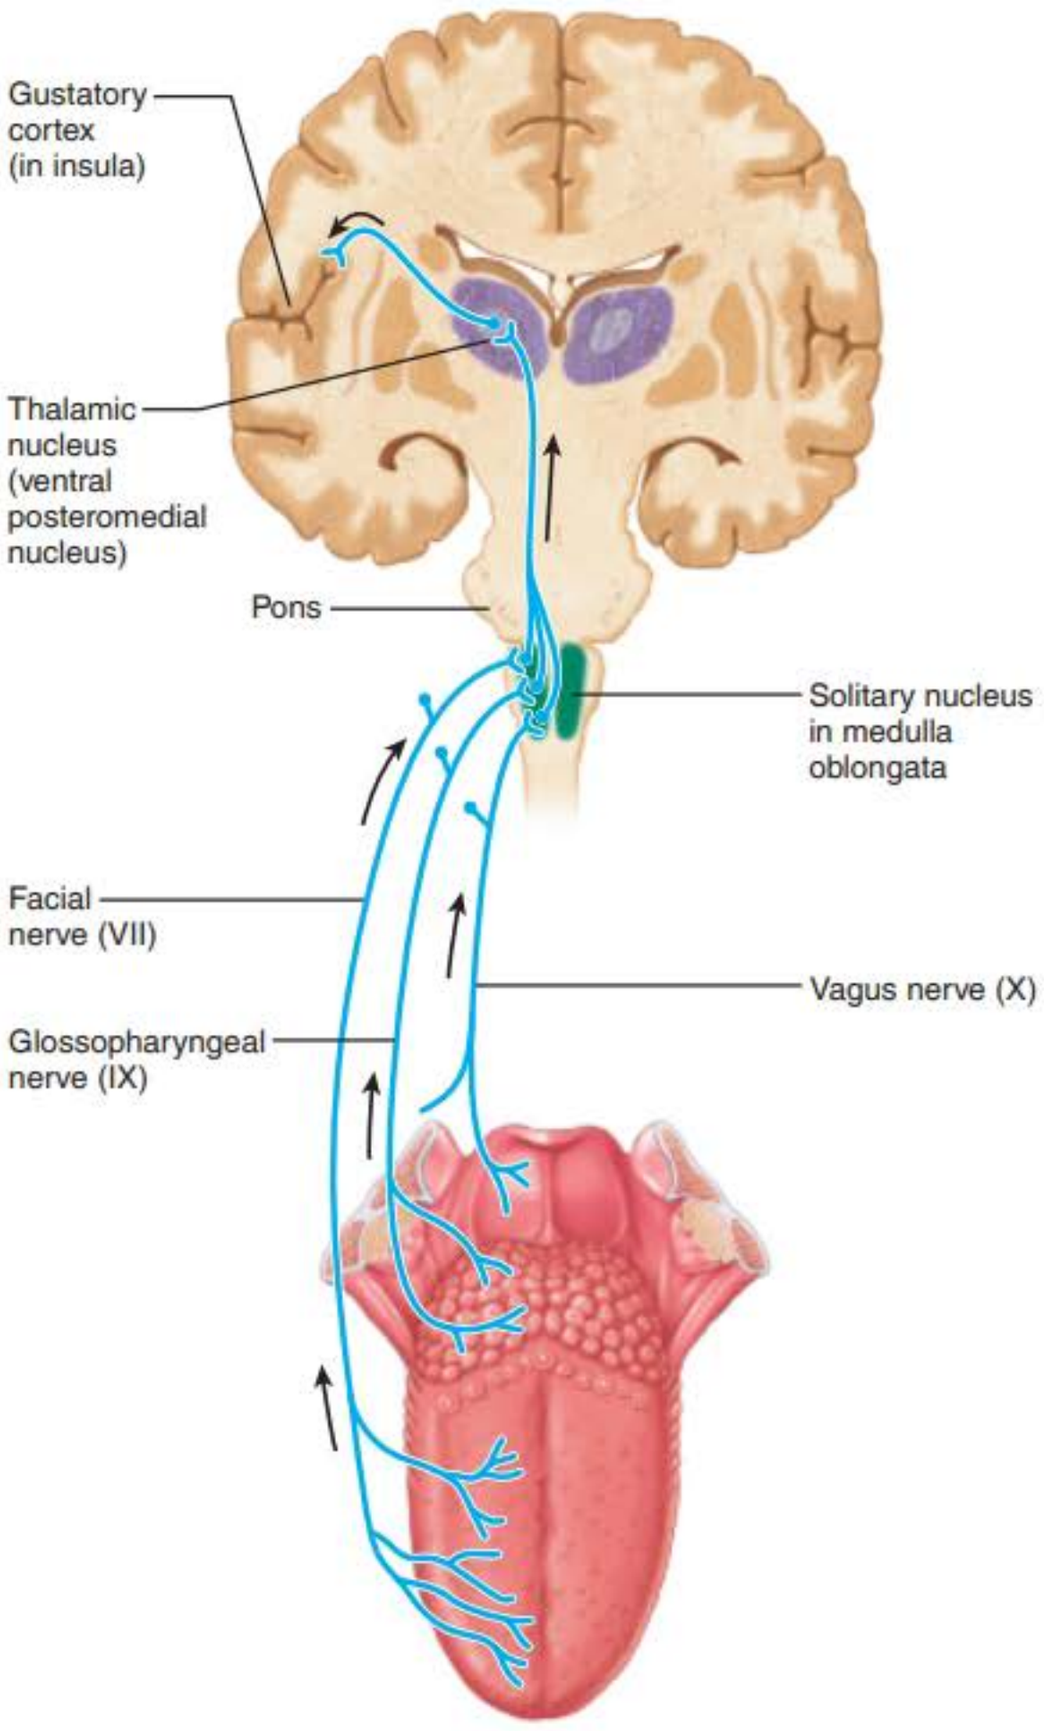


Figure 15.23 The gustatory pathway. Taste signals are relayed from the taste buds to the gustatory area of the cerebral cortex.

The Gustatory Pathway

Afferent fibers carrying taste information from the tongue are found primarily in two cranial nerve pairs. A branch of the **facial nerve** (VII), the *chorda tympani*, transmits impulses from taste receptors in the anterior two-thirds of the tongue (**Figure 15.23**). The lingual branch of the **glossopharyngeal nerve** (IX) services the posterior third and the pharynx just behind. Taste impulses from the few taste buds in the epiglottis and the lower pharynx are conducted primarily by the **vagus nerve** (X).

These afferent fibers synapse in the **solitary nucleus** of the medulla, and from there impulses stream to the thalamus and ultimately to the *gustatory cortex* in the insula. Fibers also project to the hypothalamus and limbic system structures, regions that determine our appreciation of what we are tasting.

An important role of taste is to trigger reflexes involved in digestion. As taste impulses pass through the solitary nucleus, they initiate reflexes (via synapses with parasympathetic nuclei) that increase secretion of saliva into the mouth and of gastric juice into the stomach. Saliva contains mucus that moistens food and digestive enzymes that begin digesting starch. When we ingest foul-tasting substances, the taste may initiate protective reactions such as gagging or vomiting.

13. Name the five taste modalities. Name the three types of papillae that have taste buds.

For answers, see Answers Appendix.

PART 3

THE EAR: HEARING AND BALANCE

At first glance, the machinery for hearing and balance appears very crude—fluids must be stirred to stimulate the mechanoreceptors of the internal ear. Nevertheless, our hearing apparatus allows us to hear an extraordinary range of sound, and our equilibrium (balance) receptors continually inform the nervous system of head movements and position. Although the organs serving these two senses are structurally interconnected within the ear, their receptors respond to different stimuli and are activated independently of one another.

15.7 The ear has three major areas

Learning Outcome

- **Describe the structure and general function of the outer, middle, and internal ears.**

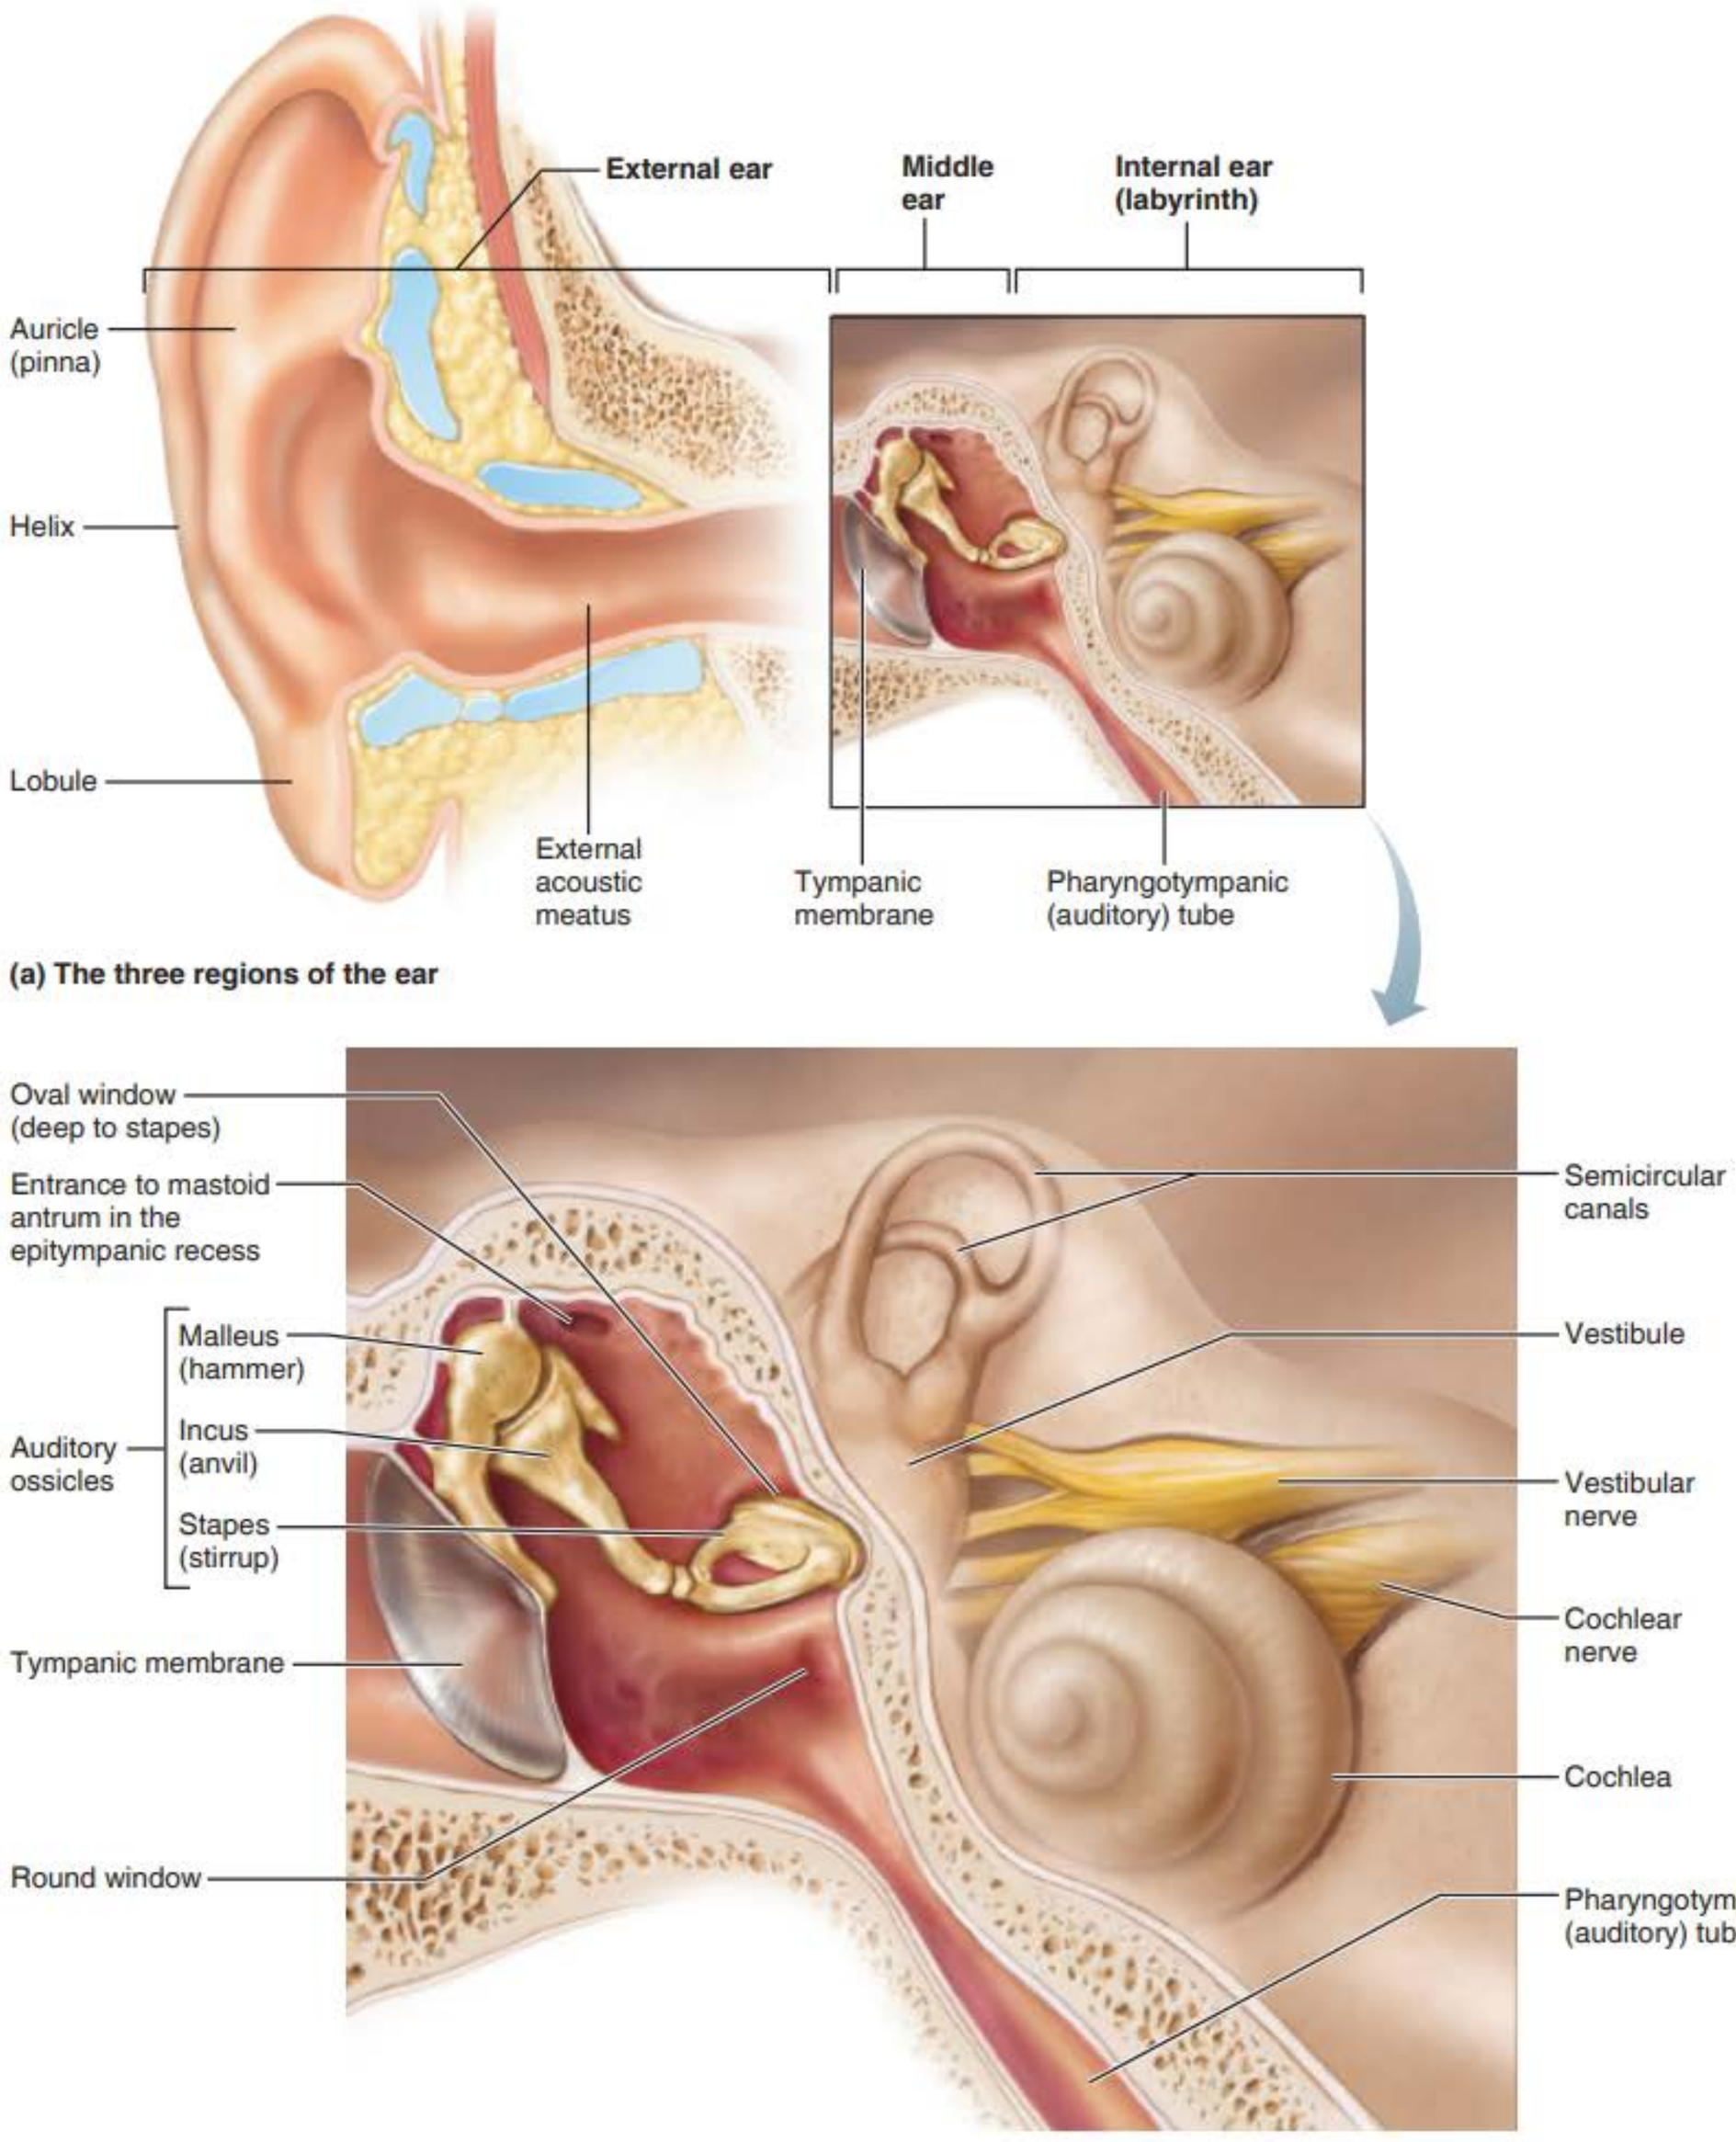

Figure 15.24 Structure of the ear. The inner ear structures in (b) appear as though they are veiled because they are cavities within the temporal bone.

The ear is divided into three major areas: external ear, middle ear, and internal ear (**Figure 15.24a**). The external and middle ear structures are involved with hearing only and are rather simply engineered. The internal ear functions in both equilibrium and hearing and is extremely complex.

External Ear

The **external (outer) ear** consists of the auricle and the external acoustic meatus. The **auricle**, or **pinna**, is what most people call the ear—the shell-shaped projection surrounding the opening of the external acoustic meatus. The auricle is composed of elastic cartilage covered with thin skin and an occasional hair. Its rim, the **helix**, is somewhat thicker, and its fleshy, dangling **lobule** ("earlobe") lacks supporting cartilage. The function of the auricle is to funnel sound waves into the external acoustic meatus.

The **external acoustic meatus** (auditory canal) is a short, curved tube (about 2.5 cm long by 0.6 cm wide) that extends from the auricle to the eardrum. Near the auricle, its framework is elastic cartilage; the remainder of the canal is carved into the temporal bone. The entire canal is lined with skin bearing hairs, sebaceous glands, and modified apocrine sweat glands called **ceruminous glands** (sĕ-roo′mĭ-nus). These glands secrete yellow-brown waxy **cerumen**, or earwax (*cere* = wax), which provides a sticky trap for foreign bodies and repels insects.

In many people, the ear is naturally cleansed as the cerumen dries and then falls out of the external acoustic meatus. Jaw movements as a person eats, talks, and so on, move the wax out. In other people, cerumen builds up and becomes compacted.

Sound waves entering the external acoustic meatus eventually hit the **tympanic membrane**, or *eardrum* (*tympanum* = drum), the boundary between the outer and middle ears. The eardrum is a thin, translucent, connective tissue membrane, covered by skin on its external face and by mucosa internally. Shaped like a flattened cone, its apex protrudes medially into the middle ear.

Sound waves make the eardrum vibrate. The eardrum, in turn, transfers the sound energy to the tiny bones of the middle ear and sets them vibrating.

Middle Ear

The **middle ear**, or **tympanic cavity**, is a small, air-filled, mucosa-lined cavity in the petrous part of the temporal bone (◀ p. 208). It is flanked laterally by the eardrum and medially by a bony wall with two openings, the superior **oval window** and the inferior **round window**. Superiorly the tympanic cavity arches upward as the **epitympanic recess**, the "roof" of the middle ear cavity. The **mastoid antrum**, a canal in the posterior wall of the tympanic cavity, allows it to communicate with *mastoid air cells* housed in the mastoid process.

The anterior wall of the middle ear is next to the internal carotid artery (the main artery supplying the brain) and contains the opening of the **pharyngotympanic (auditory) tube** (formerly called the eustachian tube). The pharyngotympanic tube runs obliquely downward to link the middle ear cavity with the nasopharynx (the superiormost part of the throat), and the mucosa of the middle ear is continuous with that lining the pharynx (throat).

Normally, the pharyngotympanic tube is flattened and closed, but swallowing or yawning opens it briefly to equalize pressure in the middle ear cavity with external air pressure. This is important because the eardrum vibrates freely only if the pressure on both of its surfaces is the same; otherwise sounds are distorted. The ear-popping sensation of the pressures equalizing is familiar to anyone who has flown in an airplane.

HOMEOSTATIC IMBALANCE 15.14 CLINICAL

Otitis media (me′de-ah), or middle ear inflammation, is a fairly common result of a sore throat, especially in children, whose pharyngotympanic tubes are shorter and run more horizontally. Otitis media is the most frequent cause of hearing loss in children. In acute infectious forms, the eardrum bulges and becomes inflamed and red. Otitis media is sometimes treated with antibiotics.

The tympanic cavity is spanned by the three smallest bones in the body: the **auditory ossicles** (Figure 15.24 and **Figure 15.25**). These bones, named for their shape, are the **malleus** (mal′e-us; "hammer"); the **incus** (ing′kus; "anvil"); and the **stapes** (sta′pēz; "stirrup"). The "handle" of the malleus is secured to the eardrum, and the base of the stapes fits into the oval window.

Tiny ligaments suspend the ossicles, and mini synovial joints link them into a chain that spans the middle ear cavity. The incus articulates with the malleus laterally and the stapes medially. The ossicles transmit the vibratory motion of the eardrum to the oval window, which in turn sets the fluids of the internal ear into motion, eventually exciting the hearing receptors.

Two tiny skeletal muscles are associated with the ossicles (Figure 15.25). The **tensor tympani** (ten′sor tim′pah-ni) arises

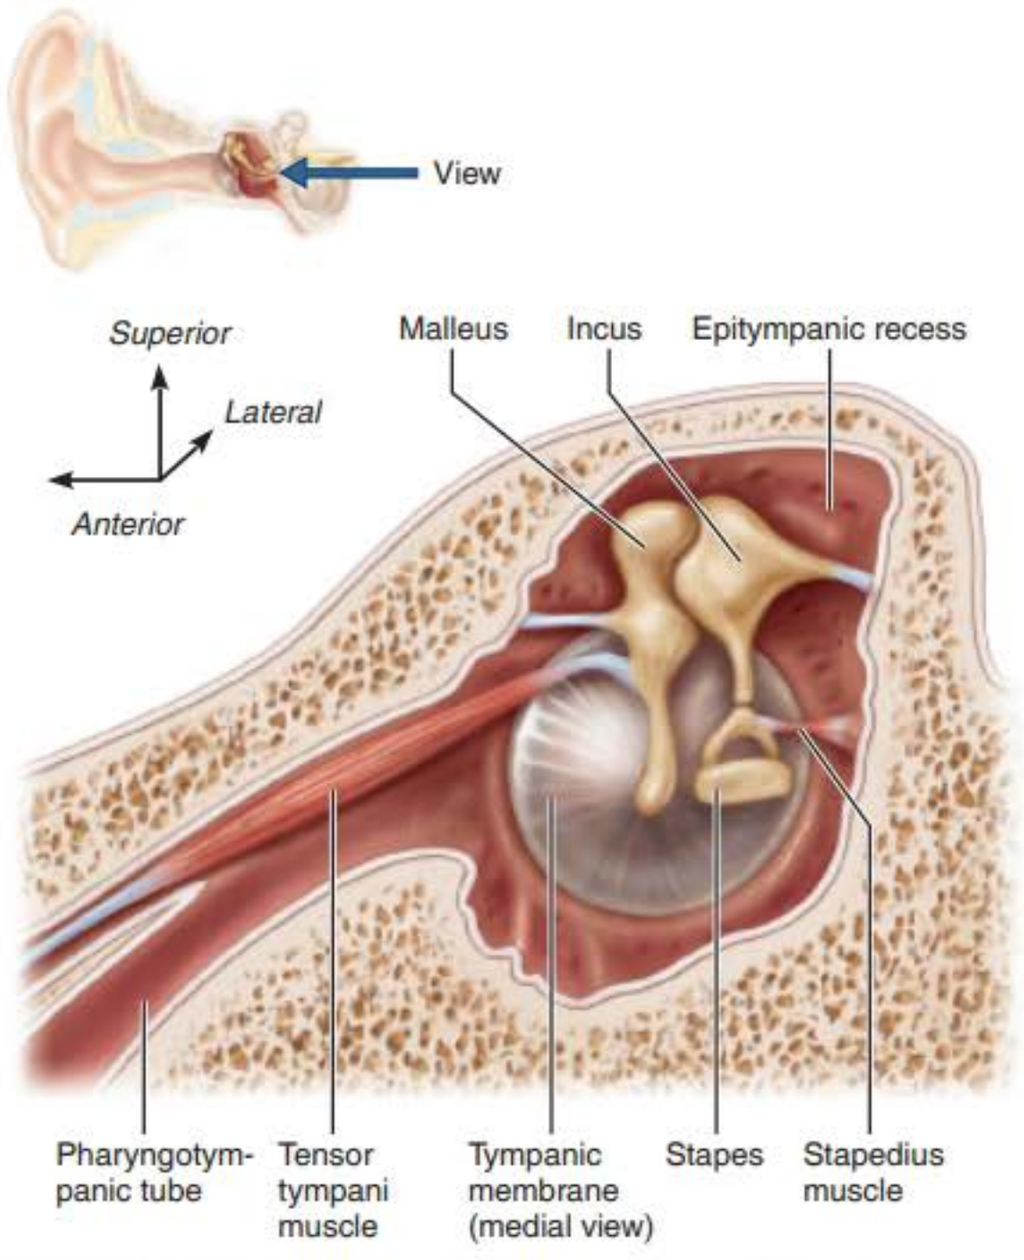

Figure 15.25 The three auditory ossicles and associated skeletal muscles. Right middle ear, medial view.

from the wall of the pharyngotympanic tube and inserts on the malleus. The **stapedius** (stah-pe′de-us) runs from the posterior wall of the middle ear to the stapes. When loud sounds assault the ears, these muscles contract reflexively to limit the ossicles' vibration and minimize damage to the hearing receptors.

Internal Ear

The **internal ear** is also called the **labyrinth** ("maze") because of its complicated shape (**Figure 15.26**). It lies deep in the temporal bone behind the eye socket and provides a secure site for all of the delicate receptor machinery.

The internal ear has two major divisions: the bony labyrinth and the membranous labyrinth.

- The **bony labyrinth** is a system of tortuous channels worming through the bone. Illustrations such as Figure 15.24 are, by necessity, somewhat misleading because we are trying to depict a *cavity* (the hollow space inside the bony labyrinth). The representation in Figure 15.24 can be compared to a plaster of paris cast of the cavity or hollow space inside the bony labyrinth.
- The **membranous labyrinth** is a continuous series of membranous sacs and ducts contained within the bony labyrinth and (more or less) following its contours (Figure 15.26).

The bony labyrinth is filled with **perilymph**, a fluid similar to cerebrospinal fluid and continuous with it. The membranous labyrinth is suspended in the surrounding perilymph, and its interior contains **endolymph**, which is chemically similar to K^+-rich intracellular fluid. These two fluids conduct the sound vibrations involved in hearing and respond to the mechanical forces occurring during changes in body position and acceleration.

The bony labyrinth has three regions: the *vestibule*, the *semicircular canals*, and the *cochlea*.

Vestibule

The **vestibule** is the central egg-shaped cavity of the bony labyrinth. It lies posterior to the cochlea, anterior to the semicircular canals, and flanks the middle ear medially. In its lateral wall is the oval window.

Suspended in the vestibular perilymph and united by a small duct are two membranous labyrinth sacs, the **saccule** and **utricle** (u′trĭ-kl) (Figure 15.26). The smaller saccule is continuous with the membranous labyrinth extending anteriorly into the cochlea (the *cochlear duct*), and the utricle is continuous with the semicircular ducts extending into the semicircular canals posteriorly. The saccule and utricle house equilibrium receptor regions called *maculae* that respond to the pull of gravity and report on changes of head position.

Semicircular Canals

The **semicircular canals** lie posterior and lateral to the vestibule. The cavities of the bony semicircular canals project from the posterior aspect of the vestibule, each oriented in one of the three planes of space. Accordingly, there is an *anterior*, a *posterior*, and a *lateral* semicircular canal in each internal ear. The anterior and posterior canals are oriented at right angles to each other in the vertical plane, whereas the lateral canal lies horizontally (Figure 15.26).

Snaking through each semicircular canal is a corresponding membranous **semicircular duct**, which communicates with the utricle anteriorly. Each of these ducts has an enlarged swelling at one end called an **ampulla**, which houses an equilibrium

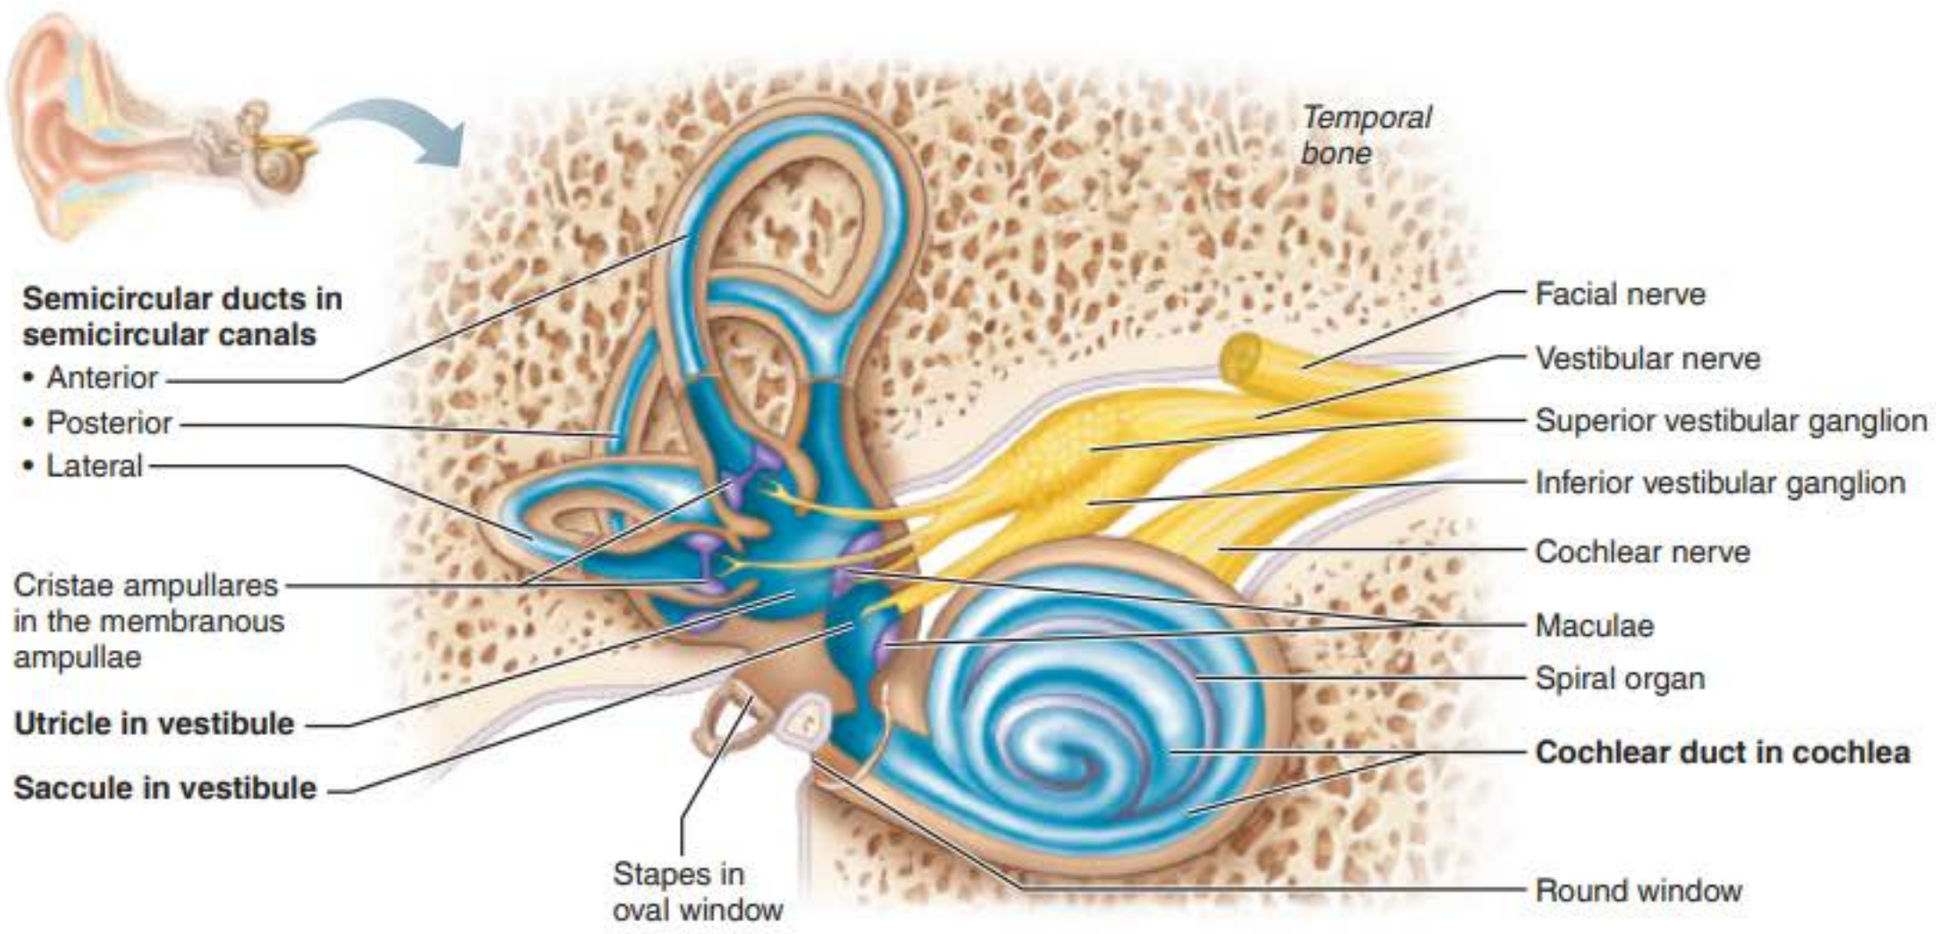

Figure 15.26 Membranous labyrinth of the internal ear. The membranous labyrinth (blue) lies within the chambers of the bony labyrinth (tan). The locations of the sensory organs for hearing (spiral organ) and equilibrium (maculae and cristae ampullares) are shown in purple.

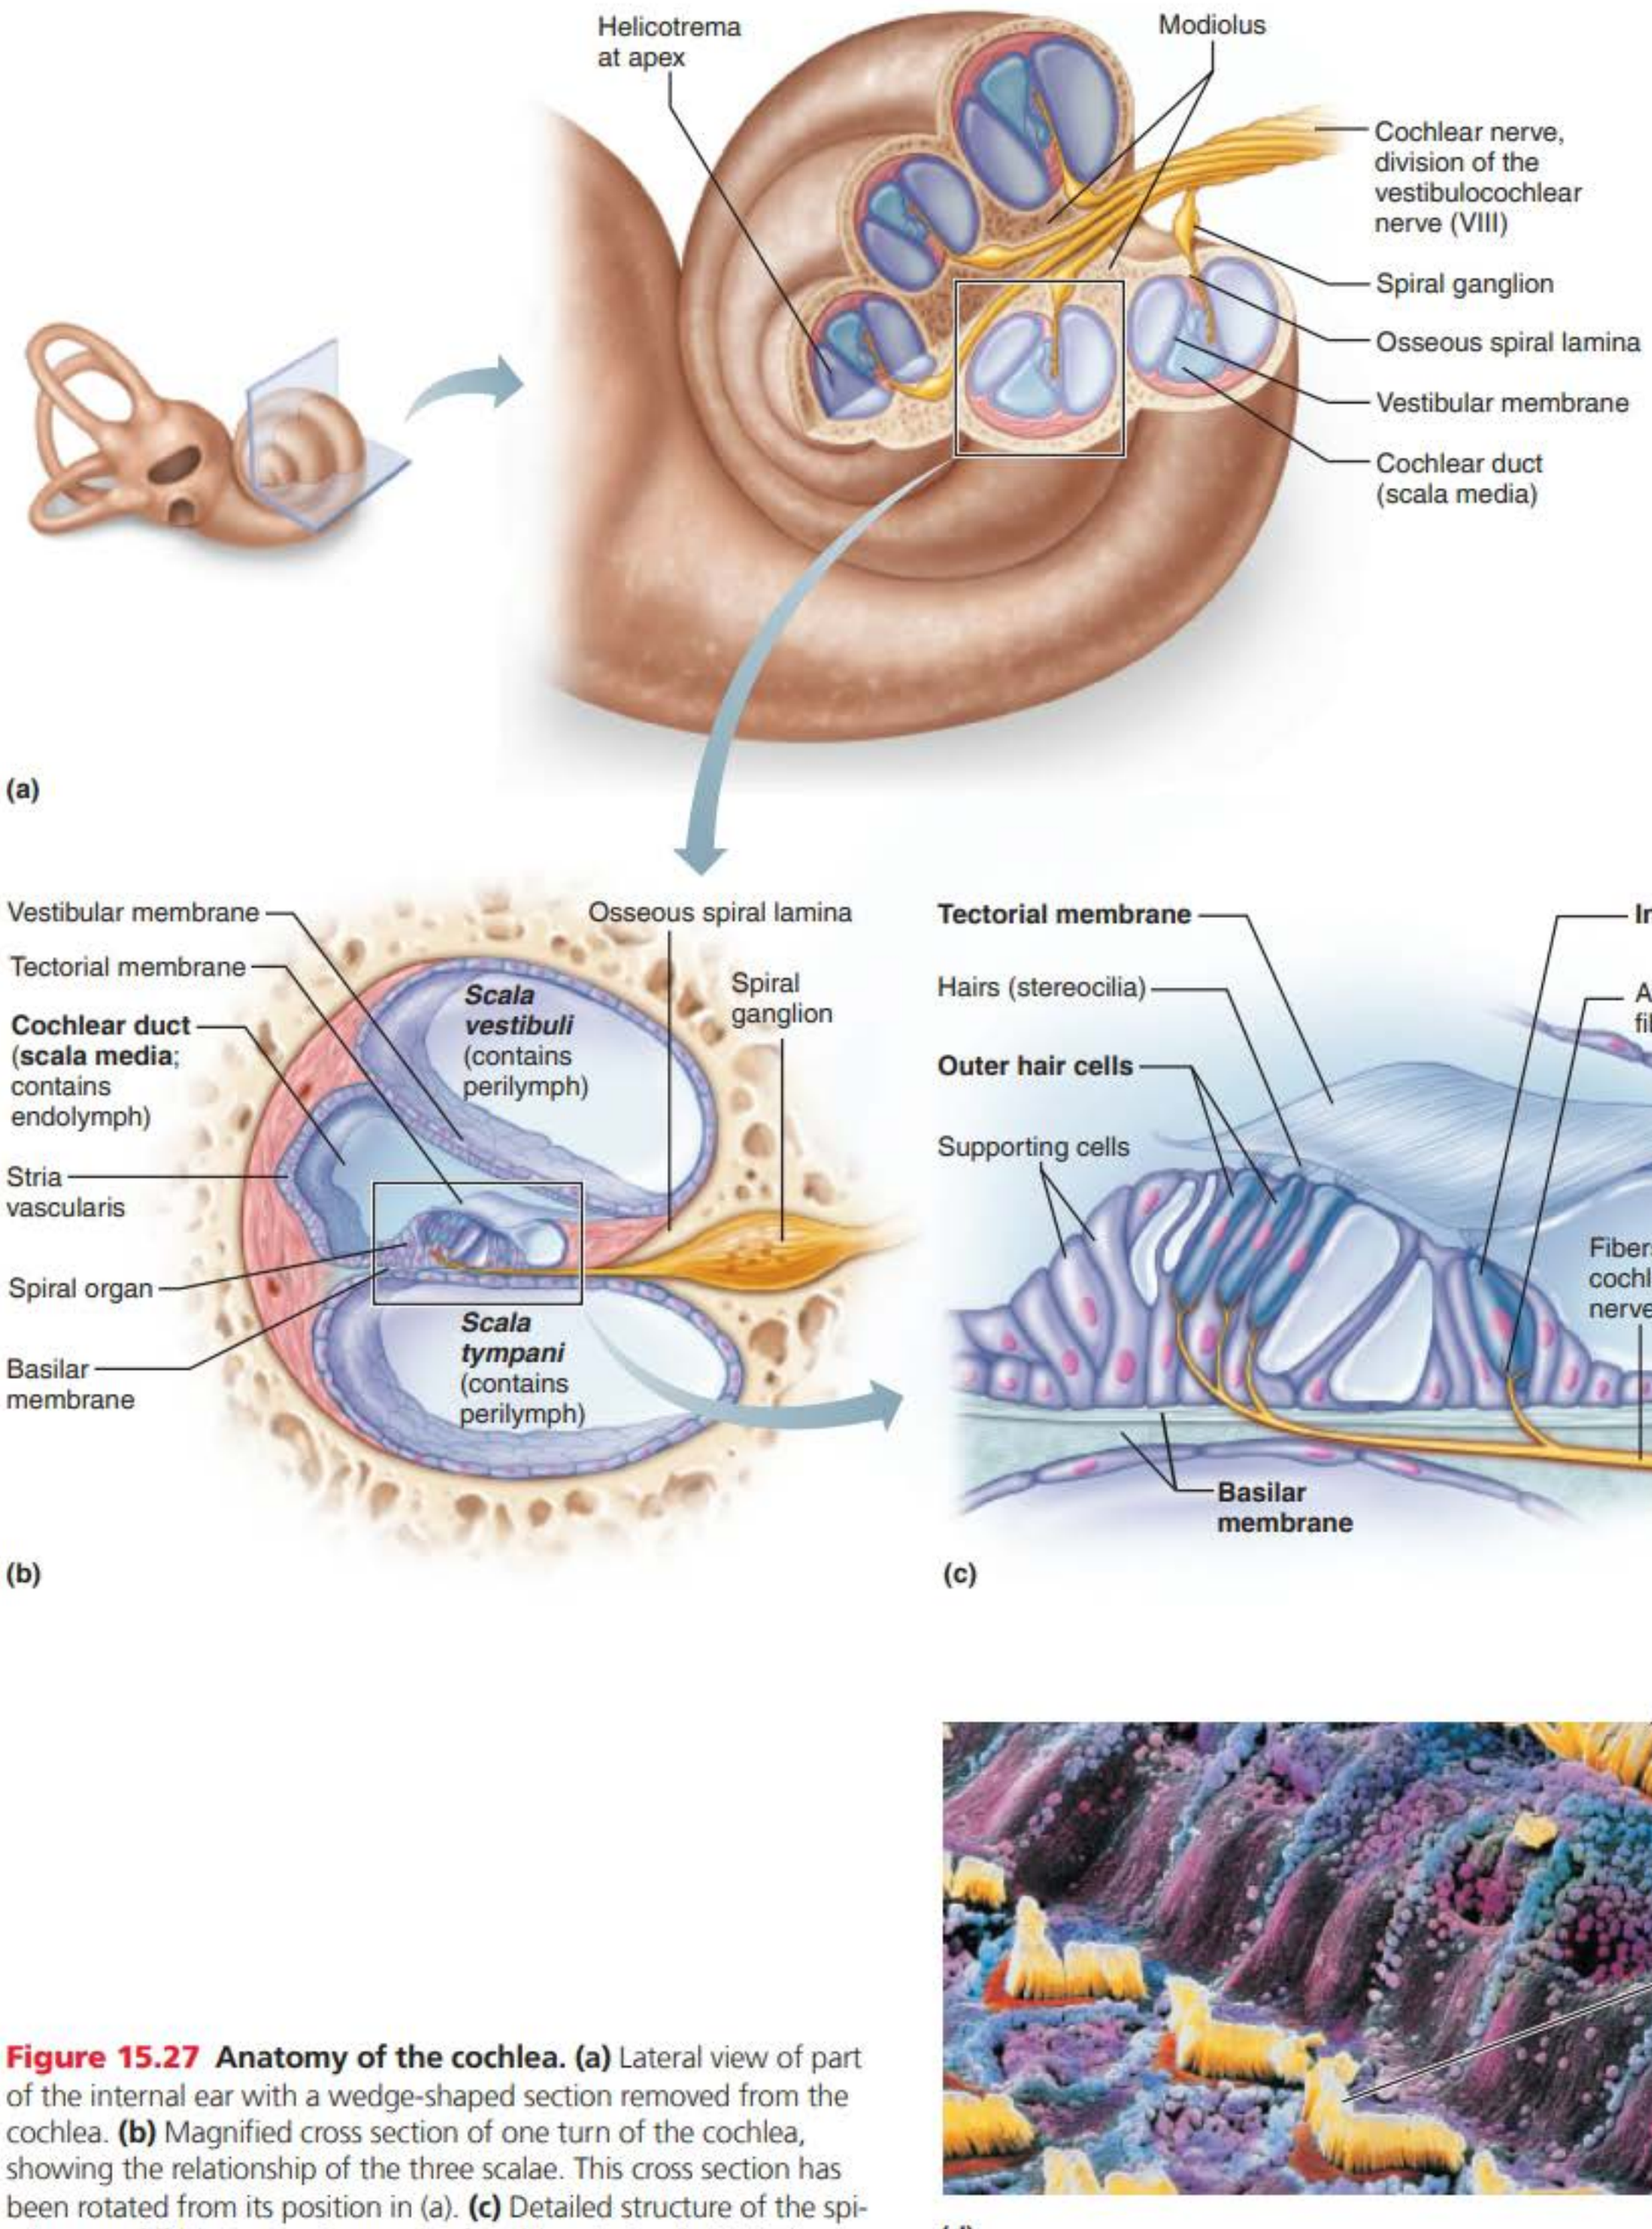

Figure 15.27 Anatomy of the cochlea. (a) Lateral view of part of the internal ear with a wedge-shaped section removed from the cochlea. **(b)** Magnified cross section of one turn of the cochlea, showing the relationship of the three scalae. This cross section has been rotated from its position in (a). **(c)** Detailed structure of the spiral organ. **(d)** Electron micrograph of cochlear hair cells (550×).

Table 15.2 Summary of the Internal Ear

BONY LABYRINTH	MEMBRANOUS LABYRINTH	FUNCTION	RECEPTOR REGION
Semicircular canals	Semicircular ducts	Equilibrium: rotational (angular) acceleration	Crista ampullaris
Vestibule	Utricle and saccule	Equilibrium: head position relative to gravity, linear acceleration	Macula
Cochlea	Cochlear duct (scala media)	Hearing	Spiral organ

receptor region called a *crista ampullaris* (literally, crest of the ampulla). These receptors respond to rotational (angular) movements of the head.

Cochlea

The **cochlea** (kok′le-ah), from the Latin "snail," is a spiral, conical, bony chamber about the size of a split pea. It extends from the anterior part of the vestibule and coils for about 2½ turns around a bony pillar called the **modiolus** (mo-di′o-lus) (**Figure 15.27a**). Running through its center like a wedge-shaped worm is the membranous **cochlear duct**, which ends blindly at the cochlear apex (Figure 15.26). The cochlear duct houses the receptor organ of hearing, called the **spiral organ** or the *organ of Corti* (Figure 15.27b).

The cochlear duct and the **osseous spiral lamina**, a thin shelflike extension of bone that spirals up the modiolus like the thread on a screw, together divide the cavity of the bony cochlea into three separate chambers or **scalae** (*scala* = ladder).

- The **scala vestibuli** (ska′lah ves-tĭ′bu-li), part of the bony labyrinth, is continuous with the vestibule and begins at the oval window. It contains perilymph.
- The middle **scala media**, part of the membranous labyrinth, is the cochlear duct itself. It contains endolymph.
- The **scala tympani**, part of the bony labyrinth, terminates at the membrane-covered round window. It contains perilymph.

The perilymph-containing chambers are continuous with each other at the cochlear apex, a region called the **helicotrema** (hel″ĭ-ko-tre′mah; "the hole in the spiral") (see Figure 15.30 on p. 587).

The "roof" of the cochlear duct, separating the scala media from the scala vestibuli, is the **vestibular membrane** (Figure 15.27b). The duct's external wall, the **stria vascularis**, is composed of an unusual richly vascularized mucosa that secretes endolymph. The "floor" of the cochlear duct is composed of the osseous spiral lamina and the flexible, fibrous basilar membrane, which supports the spiral organ. The **basilar membrane**, which plays a critical role in sound reception, is narrow and thick near the oval window and gradually widens and thins as it approaches the cochlear apex.

The spiral organ, which rests atop the basilar membrane, is composed of supporting cells and hearing receptor cells called *cochlear hair cells*. The hair cells are arranged functionally—specifically, one row of **inner hair cells** and three rows of **outer hair cells**—sandwiched between the tectorial and basilar membranes (Figure 15.27c). (We will describe the tectorial membrane and hair cells further when we discuss sound transduction.) Afferent fibers of the **cochlear nerve** [a division of the vestibulocochlear nerve (VIII)] coil about the bases of the hair cells and run from the spiral organ through the modiolus to the brain.

Table 15.2 summarizes the structures of the internal ear and their functions.

14. Apart from the bony boundaries, which structure separates the external from the middle ear? Which two (nonbone) structures separate the middle from the inner ear?

For answers, see Answers Appendix.

15.8 Sound is a pressure wave that stimulates mechanosensitive cochlear hair cells

Learning Outcomes

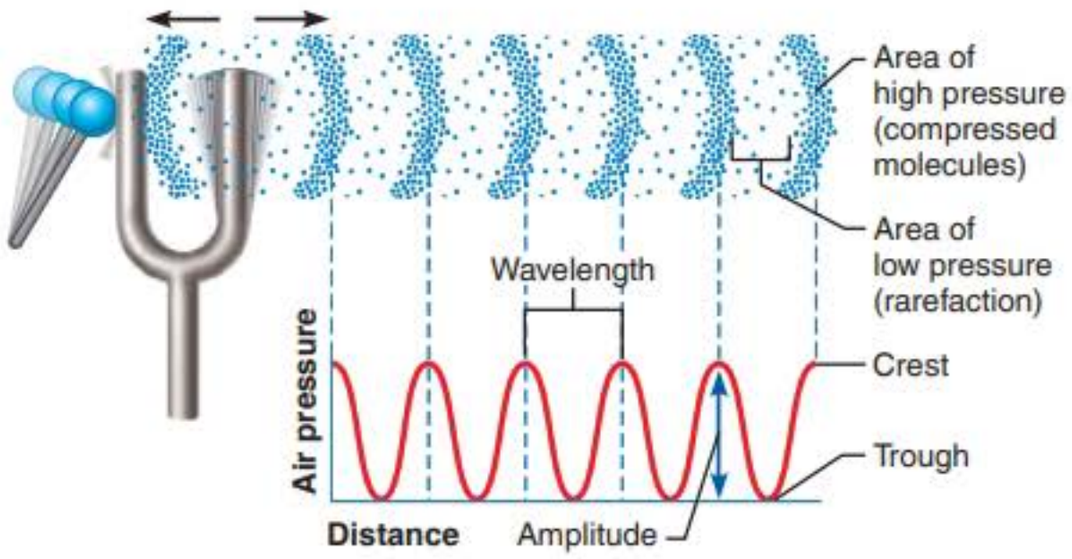
- **Describe the sound conduction pathway to the fluids of the internal ear.**
- **Describe sound transduction.**

We can summarize human hearing in a single sprawling sentence: Sounds set up vibrations in air that beat against the eardrum that pushes a chain of tiny bones that press fluid in the internal ear against membranes that set up shearing forces that pull on the tiny hair cells that stimulate nearby neurons that give rise to action potentials that travel to the brain, which interprets them—and you hear. Before we unravel this intriguing sequence, let us describe sound, the stimulus for hearing.

Properties of Sound

Light can be transmitted through a vacuum (for instance, outer space), but sound depends on an *elastic* medium—one that physically transmits vibrations. Sound also travels much more slowly than light. Its speed in dry air is only about 331 m/s (0.2 mi/s), as opposed to about 300,000 km/s (186,000 mi/s) for light. A lightning flash is almost instantly visible, but the sound it creates (thunder) reaches our ears much more slowly. (For each second between the lightning bolt and the roll of thunder, the storm is 1/5 mile farther away.) The speed of sound is fastest in solids and slowest in gases, but it is constant in a given medium.

Sound is a pressure disturbance—alternating areas of high and low pressure—produced by a vibrating object and propagated by the molecules of the medium. Consider a vibrating tuning fork



(a) A struck tuning fork alternately compresses and rarefies the air molecules around it.

(b) Sound waves radiate outward in all directions.

Figure 15.28 Sound: Source and propagation. The graph in (a) shows that plotting the oscillating air pressures yields a sine wave.

(**Figure 15.28a**). If the tuning fork is struck on the left, its prongs will move first to the right, creating an area of high pressure by compressing the air molecules there. Then, as the prongs rebound to the left, the air on the left will be compressed, and the region on the right will be a *rarefied*, or low-pressure, area (since most of its air molecules have been pushed farther to the right).

As the fork vibrates alternately from right to left, it produces a series of compressions and rarefactions, collectively called a *sound wave*, which moves outward in all directions (Figure 15.28b). However, the individual air molecules just vibrate back and forth for short distances as they bump other molecules and rebound. Because the outward-moving molecules give up kinetic energy to the molecules they bump, energy is always transferred in the direction the sound wave is traveling. For this reason, the energy of the wave declines with time and distance (just as ripples in a pond get smaller as they move away from the pebble you threw).

We can illustrate a sound wave as an S-shaped curve, or *sine wave*, in which the compressed areas are crests and the rarefied areas are troughs (Figure 15.28a). Sound can be described in terms of two physical properties: frequency and amplitude.

Frequency

Frequency is defined as the number of waves that pass a given point in a given time. The sine wave of a pure tone has crests and troughs that repeat at specific intervals. The distance between two consecutive crests (or troughs) is the **wavelength** of the sound and is constant for a particular tone. The shorter the wavelength, the higher the frequency of the sound (Figure 15.28 and **Figure 15.29a**).

The frequency range of human hearing is from 20 to 20,000 waves per second, or *hertz* (*Hz*). Our ears are most sensitive to frequencies between 1500 and 4000 Hz and, in that range, we can distinguish frequencies differing by only 2–3 Hz. We perceive different sound frequencies as differences in **pitch**: the higher the frequency, the higher the pitch.

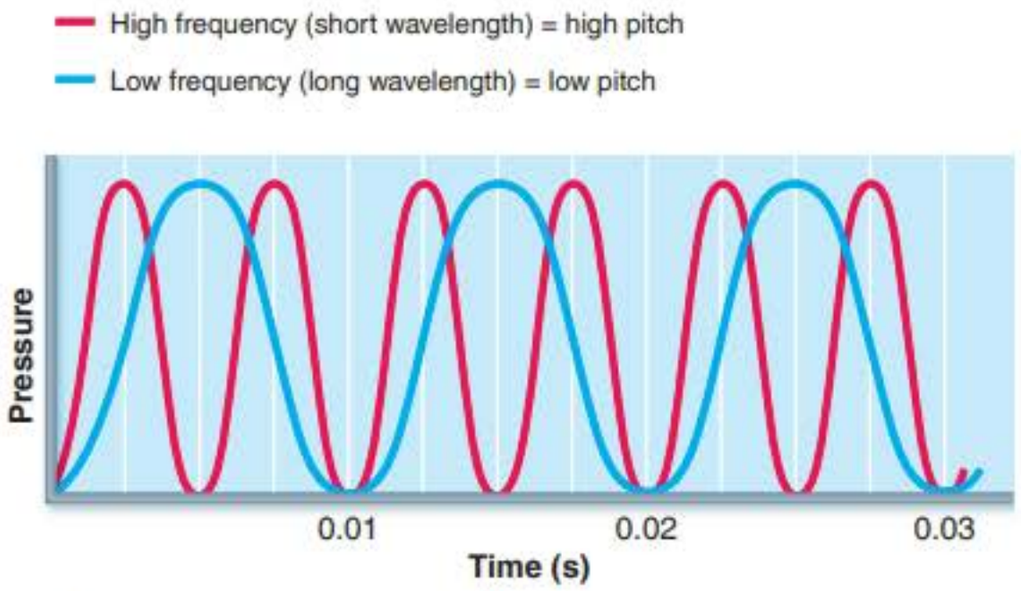
A tuning fork produces a *tone*—a pure (but bland) sound with a single frequency—but most sounds are mixtures of several frequencies. This characteristic of sound, called **quality**, enables us to distinguish between the same musical note—say, high C—sung by a soprano or played on a piano. Sound quality also provides the richness and complexity of sounds (and music) that we hear.

Amplitude

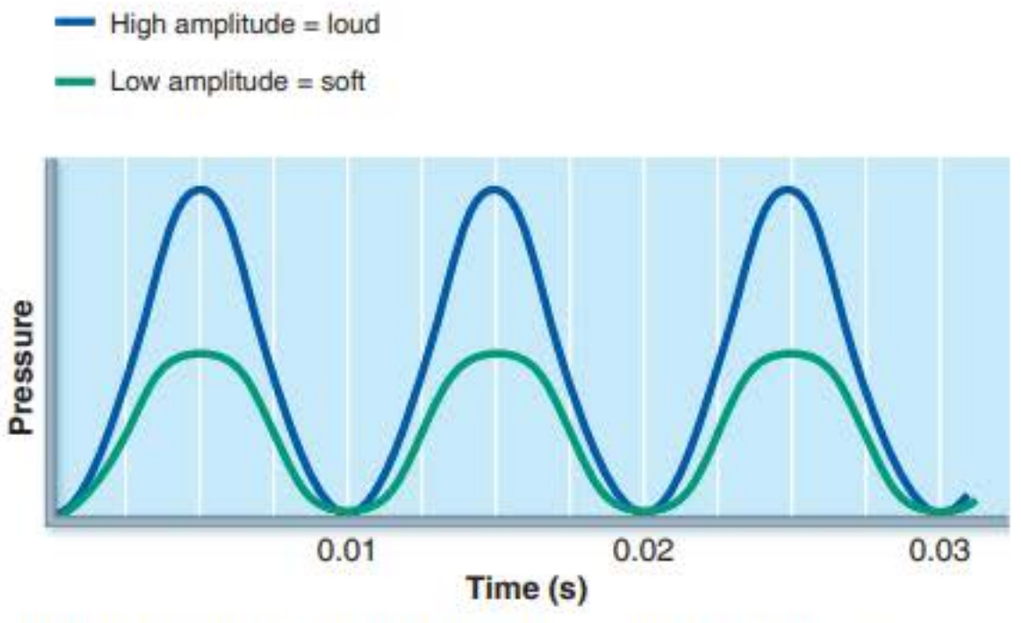
The **amplitude**, or height, of the sine wave crests reveals a sound's intensity, which is related to its energy, or the pressure differences between its compressed and rarefied areas (Figures 15.28 and 15.29b).

Loudness refers to our subjective interpretation of sound intensity. Because we can hear such an enormous range of intensities, from the proverbial pin drop to a jet engine 10 million times more intense, sound intensity (and loudness) is measured in logarithmic units called **decibels (dB)** (des′ĭ-belz).

On a clinical audiometer, the decibel scale is arbitrarily set to begin at 0 dB, which is the threshold of hearing (barely audible

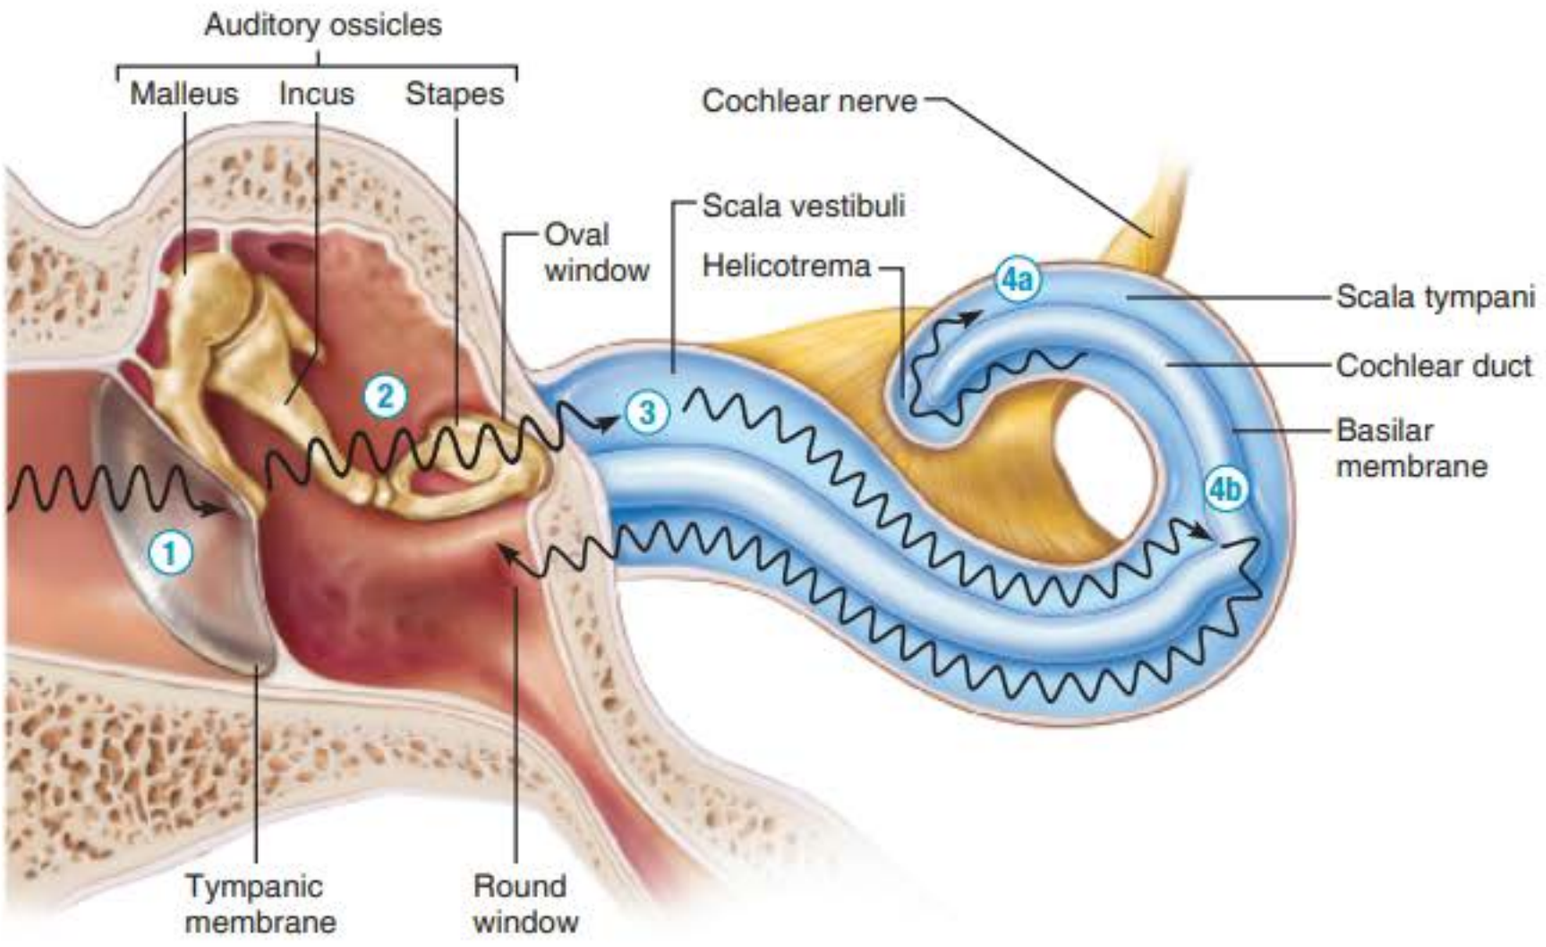


(a) Frequency is perceived as pitch.



(b) Amplitude (size or intensity) is perceived as loudness.

Figure 15.29 Frequency and amplitude of sound waves.



1 Sound waves vibrate the tympanic membrane.

2 Auditory ossicles vibrate. Pressure is amplified.

3 Pressure waves created by the stapes pushing on the oval window move through fluid in the scala vestibuli.

4a Sounds with frequencies below the hearing range travel through the helicotrema and do not excite hair cells.

4b Sounds in the hearing range go through the cochlear duct, vibrating the basilar membrane and deflecting hairs on inner hair cells.

Figure 15.30 Pathway of sound waves. The cochlea is drawn as if uncoiled.

sound) for normal ears. Each 10-dB increase represents a tenfold increase in sound intensity. A sound of 10 dB has 10 times more energy than one of 0 dB, and a 20-dB sound has 100 times (10 × 10) more energy. However, the same 10-dB increase represents only a twofold increase in loudness. In other words, most people would report that a 20-dB sound seems about twice as loud as a 10-dB sound. The normal range of hearing (from barely audible to the loudest sound we can process without excruciating pain) extends over a range of 120 dB. (The threshold of pain is 120 dB.)

Severe hearing loss occurs with frequent or prolonged exposure to sounds with intensities greater than 90 dB. That number becomes more meaningful when you realize that a normal conversation is in the 50-dB range, a noisy restaurant has 70-dB levels, and amplified concert music is often 120 dB or more, far above the 90-dB danger zone.

Transmission of Sound to the Internal Ear

Hearing occurs when the auditory area of the temporal lobe cortex is stimulated. However, before this can happen, sound waves must be propagated through air, membranes, bones, and fluids to stimulate receptor cells in the spiral organ (**Figure 15.30**).

1 **Tympanic membrane.** Sound waves entering the external acoustic meatus strike the tympanic membrane and set it vibrating at the same frequency. The greater the intensity, the farther the membrane is displaced in its vibratory motion.

2 **Auditory ossicles.** The motion of the tympanic membrane is amplified and transferred to the oval window by the ossicle lever system, which acts much like a piston to transfer the force striking the eardrum to the oval window. Because the tympanic membrane is 17–20 times larger than the oval window, the pressure (force per unit area) actually exerted on the oval window is about 20 times that on the tympanic membrane. This increased pressure overcomes the stiffness and inertia of cochlear fluid and sets it into wave motion.

This situation can be roughly compared to the difference in pressure relayed to the floor by the broad rubber heels of a man's shoes versus a woman's tiny spike heels. The man's weight is spread over several square inches, and his heels will not make dents in a pliable vinyl floor. But spike heels concentrate the same force in an area of about 2.5 cm^2 (1 square inch) and *will* dent the floor.

3 **Scala vestibuli.** As the stapes rocks back and forth against the oval window, it sets the perilymph in the scala vestibuli into a similar back-and-forth motion. A pressure wave travels through the perilymph from the basal end toward the helicotrema, much as a piece of rope held horizontally can be set into wave motion by movements initiated at one end. Fluids cannot be compressed, so each time the stapes forces the fluid adjacent to the oval window medially, the membrane of the round window bulges laterally into the middle ear cavity and acts as a pressure valve.

4a **Helicotrema path.** Sounds of very low frequency (below 20 Hz) create pressure waves that take the complete route through the cochlea—up the scala vestibuli, around the helicotrema, and back toward the round window through the scala tympani (Figure 15.30). These low-frequency sounds do not activate the spiral organ and so are below the range of hearing.

4b **Basilar membrane path.** In contrast, sounds with frequencies high enough to hear create pressure waves that take a "shortcut" and are transmitted through the cochlear duct into the perilymph of the scala tympani. As a pressure wave descends through the flexible cochlear duct, it vibrates the basilar membrane. This vibration activates hair cells (receptor cells) at the site of this "shortcut" through the basilar membrane, causing action potentials to be sent to the brain.

Resonance of the Basilar Membrane

Sound waves make the basilar membrane vibrate. Maximal displacement of the membrane occurs where the fibers of the basilar membrane are "tuned" to a particular sound frequency (**Figure 15.31**). This characteristic of maximum movement at a particular frequency is called *resonance*. The fibers of the basilar membrane span its width like the strings of a harp. The fibers near the oval window (cochlear base) are short and stiff, and they resonate in response to high-frequency pressure waves (Figure 15.31). The longer, more floppy basilar membrane fibers near the cochlear apex resonate in time with lower-frequency pressure waves. As a result, the resonance of the basilar membrane mechanically processes sound signals before the signals ever reach the receptors.

Sound Transduction

Excitation of Inner Hair Cells

How does movement of the basilar membrane result in action potentials being sent to the brain? Transduction of sound stimuli occurs after localized movements of the basilar membrane "tweak" or deflect the hairs of the inner hair cells (**Figure 15.32**). The hairs of the hair cells protrude into the K^+-rich endolymph and the longest are enmeshed in the overlying stiff gel-like **tectorial membrane**. As the basilar membrane vibrates, the hair cells move with it. Their hairs pivot, opening and closing ion channels and generating an electrical signal. Let's look at how this happens in more detail.

The "hairs" protruding from the apex of a cochlear hair cell are actually microvilli called **stereocilia**. These stereocilia are longest on one side of the cell and shortest on the other. The stereocilia of the hair cells are stiffened by actin filaments so they bend *only* at their bases—that is, they pivot. The stereocilia are bound together by fine fibers called *tip links* that connect to mechanically gated ion channels. Pulling on the tip links opens the ion channels.

Pivoting the stereocilia toward the tallest stereocilium increases the distance between the tips of adjacent stereocilia and so puts tension on the tip links. Like a rope pulling on a trap door, this opens cation channels in the adjacent shorter stereocilia. K^+ and Ca^{2+} from the endolymph flow through the open channels, creating a graded depolarization (receptor potential). Pivoting the stereocilia toward the shortest stereocilium relaxes the tip links, closes the mechanically gated ion channels, and allows repolarization and even a graded hyperpolarization (Figure 15.32).

Depolarization increases intracellular Ca^{2+} and so increases the hair cells' release of neurotransmitter (glutamate). This causes the afferent cochlear fibers to transmit more impulses to the brain. Hyperpolarization produces the exact opposite effect.

The vast majority of the sensory fibers of the spiral ganglia (90–95%) service the inner hair cells, which shoulder nearly the entire responsibility for sending auditory messages to the brain.

Role of Outer Hair Cells

Most fibers coiling around the more numerous outer hair cells are *efferent* fibers that convey messages from brain to ear. So what do the outer hair cells do? The outer hair cells act on the basilar membrane itself. When outer hair cells depolarize and hyperpolarize as the basilar membrane moves, they contract and stretch in a type of cellular dance called *fast motility*. Their strange behavior changes the stiffness of the basilar membrane.

Outer hair cell motility serves two functions:

- It increases the responsiveness of the inner hair cells by amplifying the motion of the basilar membrane—a kind of cochlear tuning that increases the cochlea's ability to distinguish small differences in frequency.
- It may help protect the inner hair cells from damage. Loud sounds activate a negative feedback loop from the brain stem to the outer hair cells via the efferent fibers, which release

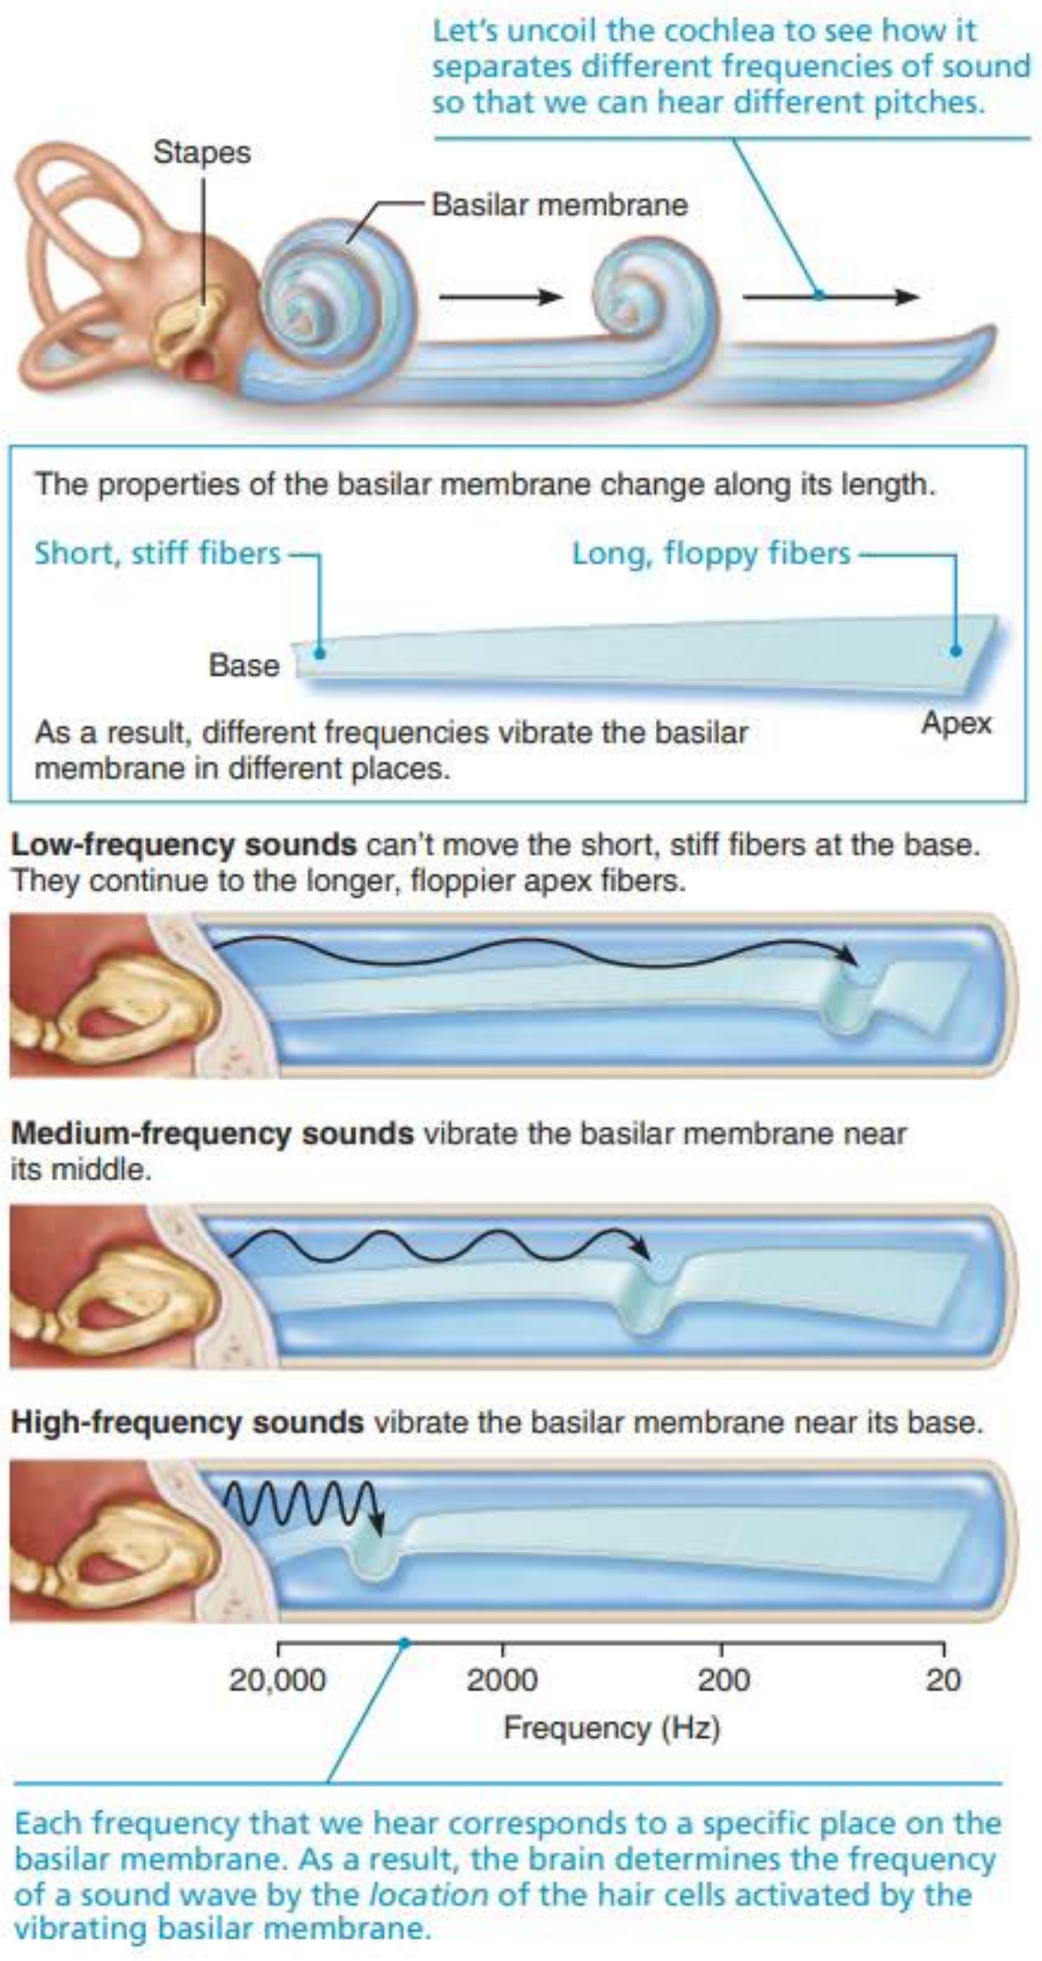


Figure 15.31 Basilar membrane function. The basilar membrane separates sound frequencies, allowing pitch discrimination.

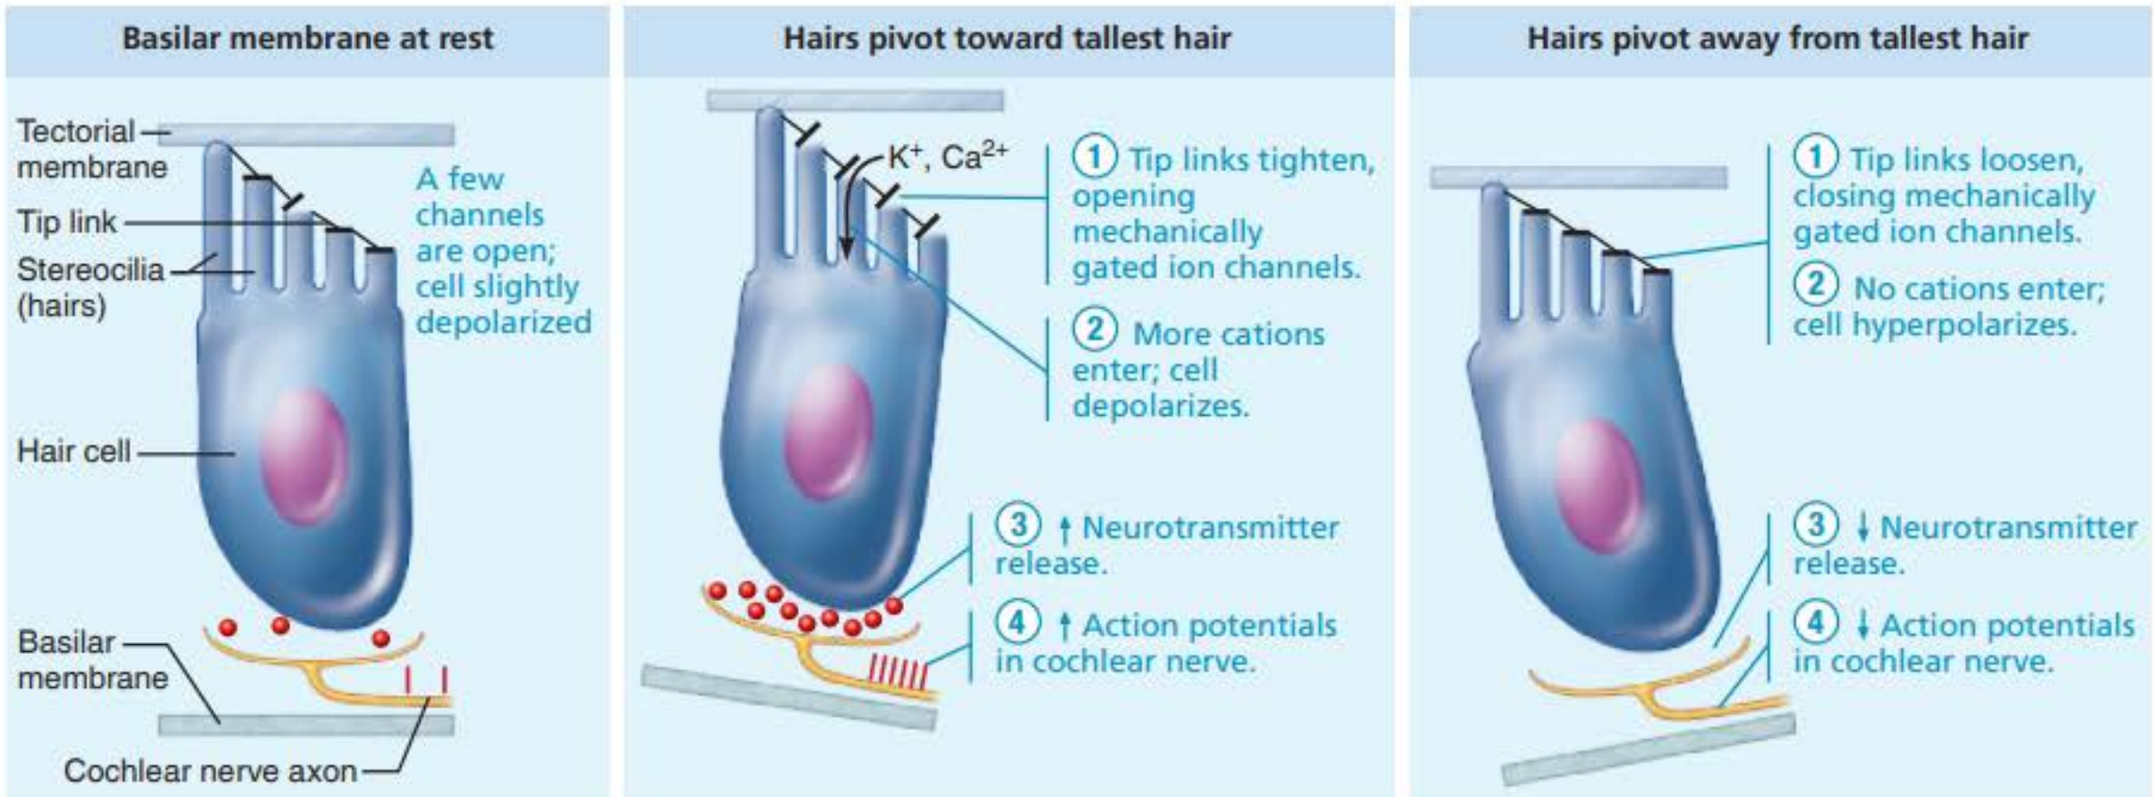

Figure 15.32 Pivoting of stereocilia (hairs) opens or closes mechanically gated ion channels in hair cells.

neurotransmitters that cause the outer hair cells to stiffen. This dampens the motion of the basilar membrane and spreads the sound energy over a wider area.

Check Your Understanding

15. Which structure inside the spiral organ allows us to differentiate sounds of different pitch?

16. The stapes pushes on the fluid in the scala vestibuli but cannot compress the fluid. What is the "pressure valve" that allows fluid to move within the cochlea?

17. PREDICT Sound frequencies too low to hear pass through the helicotrema without displacing the basilar membrane. Sound frequencies that we hear do displace the basilar membrane. Predict what happens to high-frequency sound waves that we cannot hear.

18. MAKE CONNECTIONS Opening cation channels causes depolarization. The influx of which ion usually causes this? (Hint: See the discussion on p. 417 of Chapter 11.) Which ions cause depolarization in hair cells? Why does K^+ move into these cells, rather than out?

For answers, see Answers Appendix.

15.9 Sound information is processed and relayed through brain stem and thalamic nuclei to the auditory cortex

Learning Outcomes

- **Describe the pathway of impulses traveling from the cochlea to the auditory cortex.**
- **Explain how we are able to differentiate pitch and loudness, and to localize the source of sounds.**

The Auditory Pathway

The ascending auditory pathway transmits auditory information primarily from the cochlear receptors (the inner hair cells) to the cerebral cortex. Action potentials generated in the cochlea pass through the **spiral ganglion**, where the auditory bipolar cell bodies reside, and along the afferent fibers of the cochlear nerve to the **cochlear nuclei** of the medulla (**Figure 15.33**).

From there, neurons project to the **superior olivary nucleus**, which lies at the junction of the medulla and pons. Beyond this,

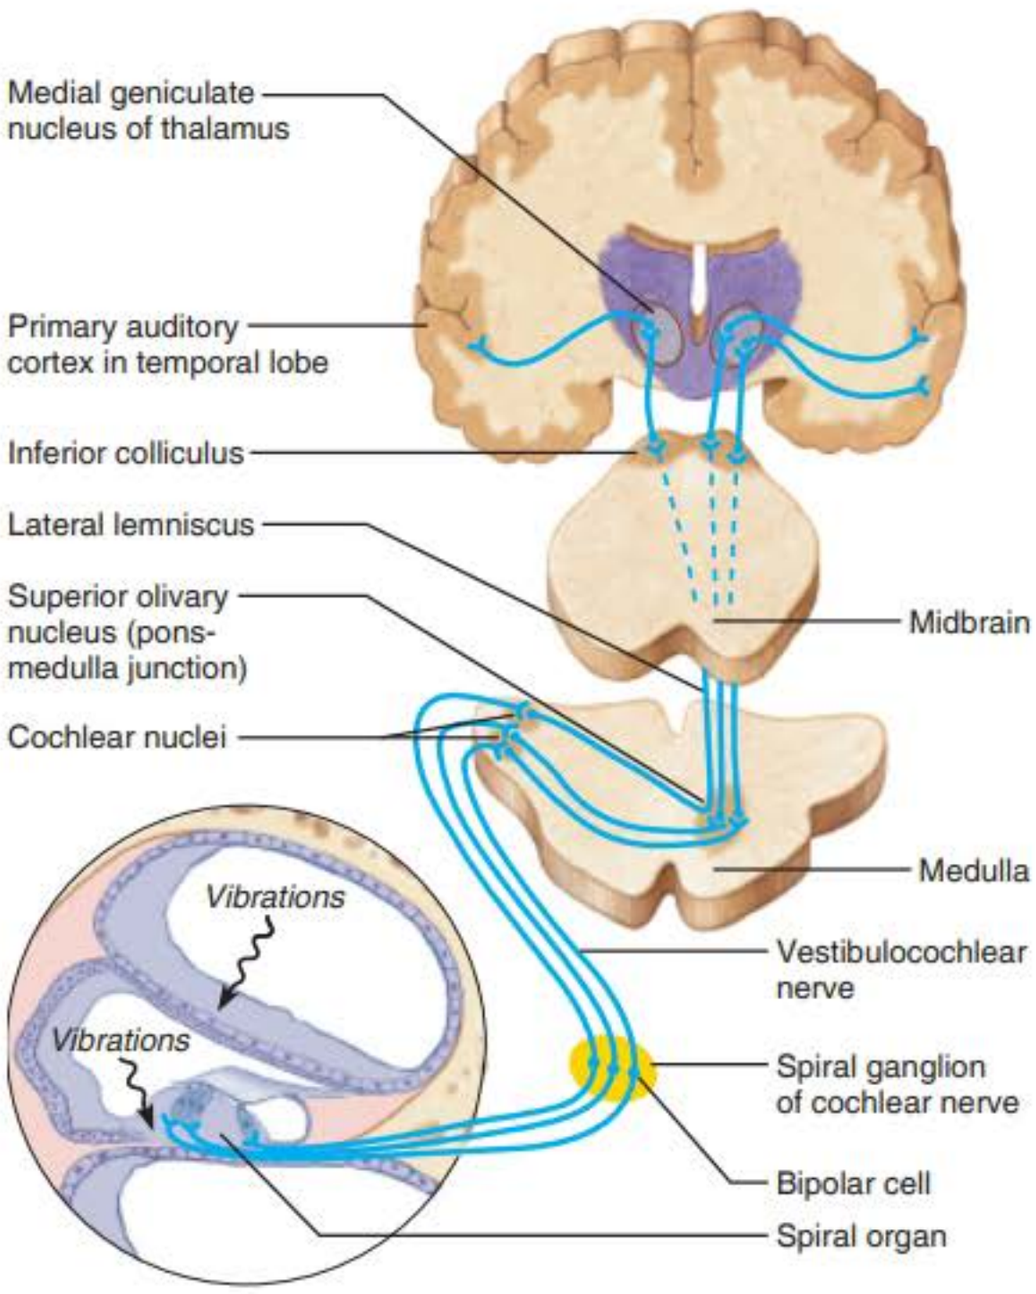

Figure 15.33 The auditory pathway. This simplified diagram shows only the pathway from the right ear.

axons ascend in the **lateral lemniscus** (a fiber tract) to the **inferior colliculus** (auditory reflex center in the midbrain), which projects to the **medial geniculate nucleus** of the thalamus. Axons of the thalamic neurons then project to the **primary auditory cortex**, which provides conscious awareness of sound.

The auditory pathway is unusual because not all of the fibers from each ear cross over to the other side of the brain. For this reason, each auditory cortex receives impulses from both ears.

Auditory Processing

If you are at a Broadway musical, the sound of the instruments, the actors' voices, rustling of clothing, and closing of doors are all intermingled in your awareness. Yet, your auditory cortex can distinguish the separate parts of this auditory jumble. Whenever the difference between sound wavelengths is sufficient for discrimination, you hear two separate and distinct tones.

Cortical processing of sound stimuli is complex. For example, certain cortical cells depolarize at the beginning of a particular tone, and others depolarize when the tone ends. Some cortical cells depolarize continuously, and others appear to have high thresholds (low sensitivity), and so on. Here we will concentrate on the more straightforward aspects of cortical perception of pitch, loudness, and sound location.

Perception of Pitch

As we explained, sound waves of different frequencies activate hair cells in different positions along the length of the basilar membrane (Figure 15.31). Impulses from specific hair cells are interpreted as specific pitches. When a sound is composed of tones of many frequencies, it activates several populations of cochlear hair cells and cortical cells simultaneously, and we perceive multiple tones.

Detection of Loudness

Louder sounds cause larger movements of the tympanic membrane, auditory ossicles, and oval window, and pressure waves of greater amplitude in the fluids of the cochlea. These larger waves in turn cause larger movements of the basilar membrane, larger deflections of the hairs on the hair cells, and larger graded potentials in the hair cells. As a result, they release more neurotransmitter and generate more frequent action potentials. The brain interprets more frequent action potentials as greater loudness. In addition, as more neurotransmitter is released, more of the 10 or so bipolar cells connected to a given hair cell are recruited to fire action potentials.

Localization of Sound

Several brain stem nuclei (most importantly the superior olivary nuclei) help us localize a sound's source in space by means of two cues: the *relative intensity* and the *relative timing* of sound waves reaching the two ears. If the sound source is directly in front, in back, or overhead, the intensity and timing cues are the same for both ears. However, when sound comes from one side, it activates the receptors of the nearer ear slightly earlier and also more vigorously.

Check Your Understanding

19. WHAT IF? If the brain stem did not receive input from both ears, what would you not be able to do?

For answers, see Answers Appendix.

15.10 Hair cells in the maculae and cristae ampullares monitor head position and movement

Learning Outcome

- **Explain how the balance organs of the semicircular canals and the vestibule help maintain equilibrium.**

The equilibrium sense is not easy to describe because it does not "see," "hear," or "feel," but responds (frequently without our awareness) to various head movements. Furthermore, this sense depends not only on inputs from the internal ear but also on vision and information from stretch receptors of muscles and tendons.

The **vestibular apparatus** consists of the semicircular canals, the vestibule (utricle and saccule), and the receptors that they contain. Under normal conditions, they send signals to the brain that initiate reflexes needed to make the simplest changes in position as well as more complex movements such as pitching a baseball.

The equilibrium receptors of the vestibular apparatus can be divided into two functional arms. The receptors in the vestibule monitor linear acceleration and the position of the head with respect to gravity. Because gravity is constant, this is called our sense of *static equilibrium*. The semicircular canals monitor changes in head rotation, called our sense of *dynamic equilibrium*.

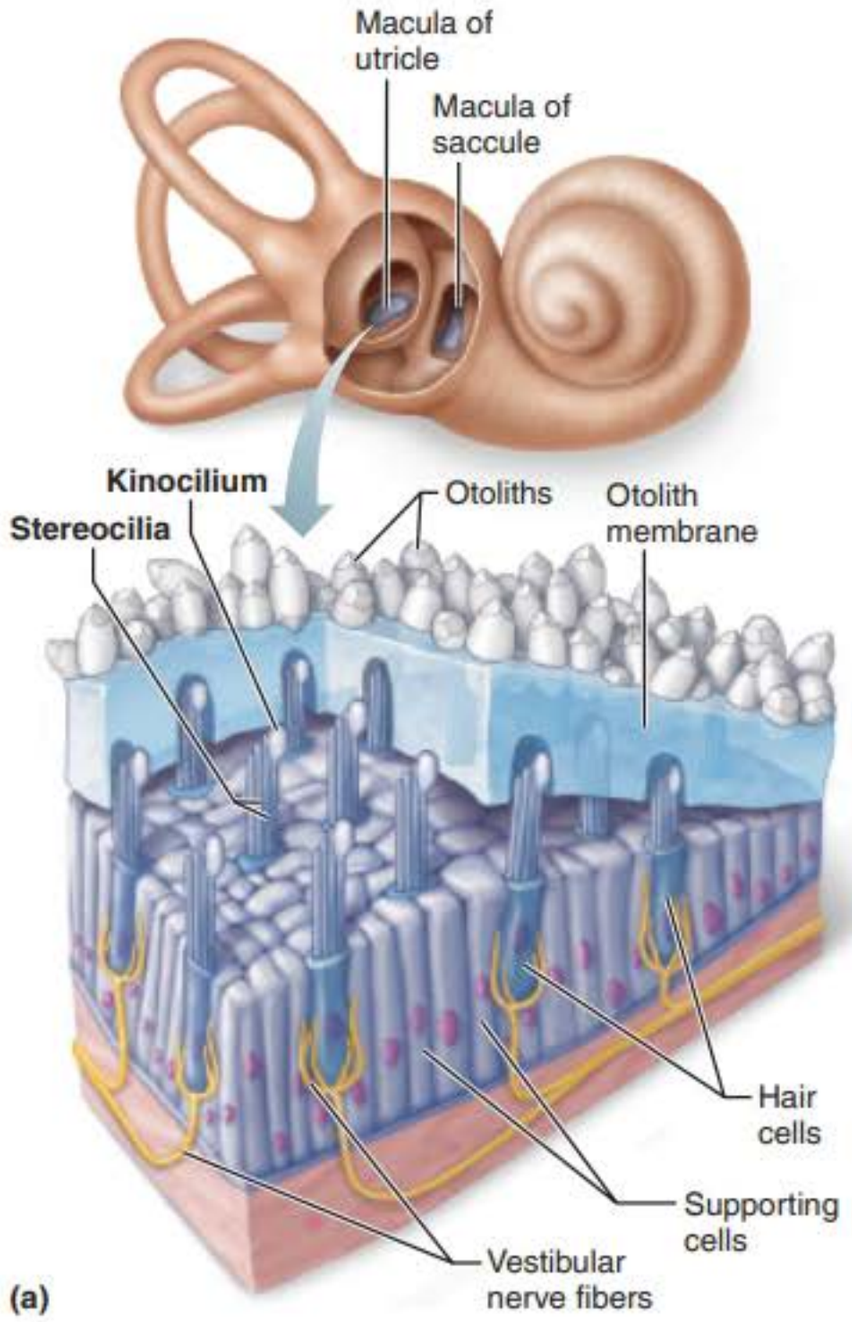
The Maculae

The **maculae** (mak′u-le; "spots"), one in each saccule wall and one in each utricle wall (**Figure 15.34**), are sensory receptor organs that monitor the position of the head in space. In so doing, they play a key role in controlling posture. They respond to *linear* acceleration, that is, changes in straight-line speed and direction, but not rotation.

Anatomy of a Macula

Each macula is a flat epithelial patch containing **hair cells**. Like the cochlear hair cells, vestibular hair cells have stereocilia (microvilli). In addition, they have a true cilium, called a **kinocilium**, next to the tallest stereocilia. **Supporting cells** surround the macula's scattered hair cells (Figure 15.34). The "hairs" of the hair cells are embedded in the overlying **otolith membrane** (o′to-lith), a jellylike mass studded with tiny stones (calcium carbonate crystals) called **otoliths** ("ear stones"). The otoliths, though small, are dense and they increase the membrane's weight and its inertia (resistance to changes in motion).

In the utricle, the macula is horizontal, and the hairs are vertically oriented when the head is upright (Figure 15.34). For this reason, the utricular maculae respond best to acceleration in the horizontal plane and tilting the head, because vertical



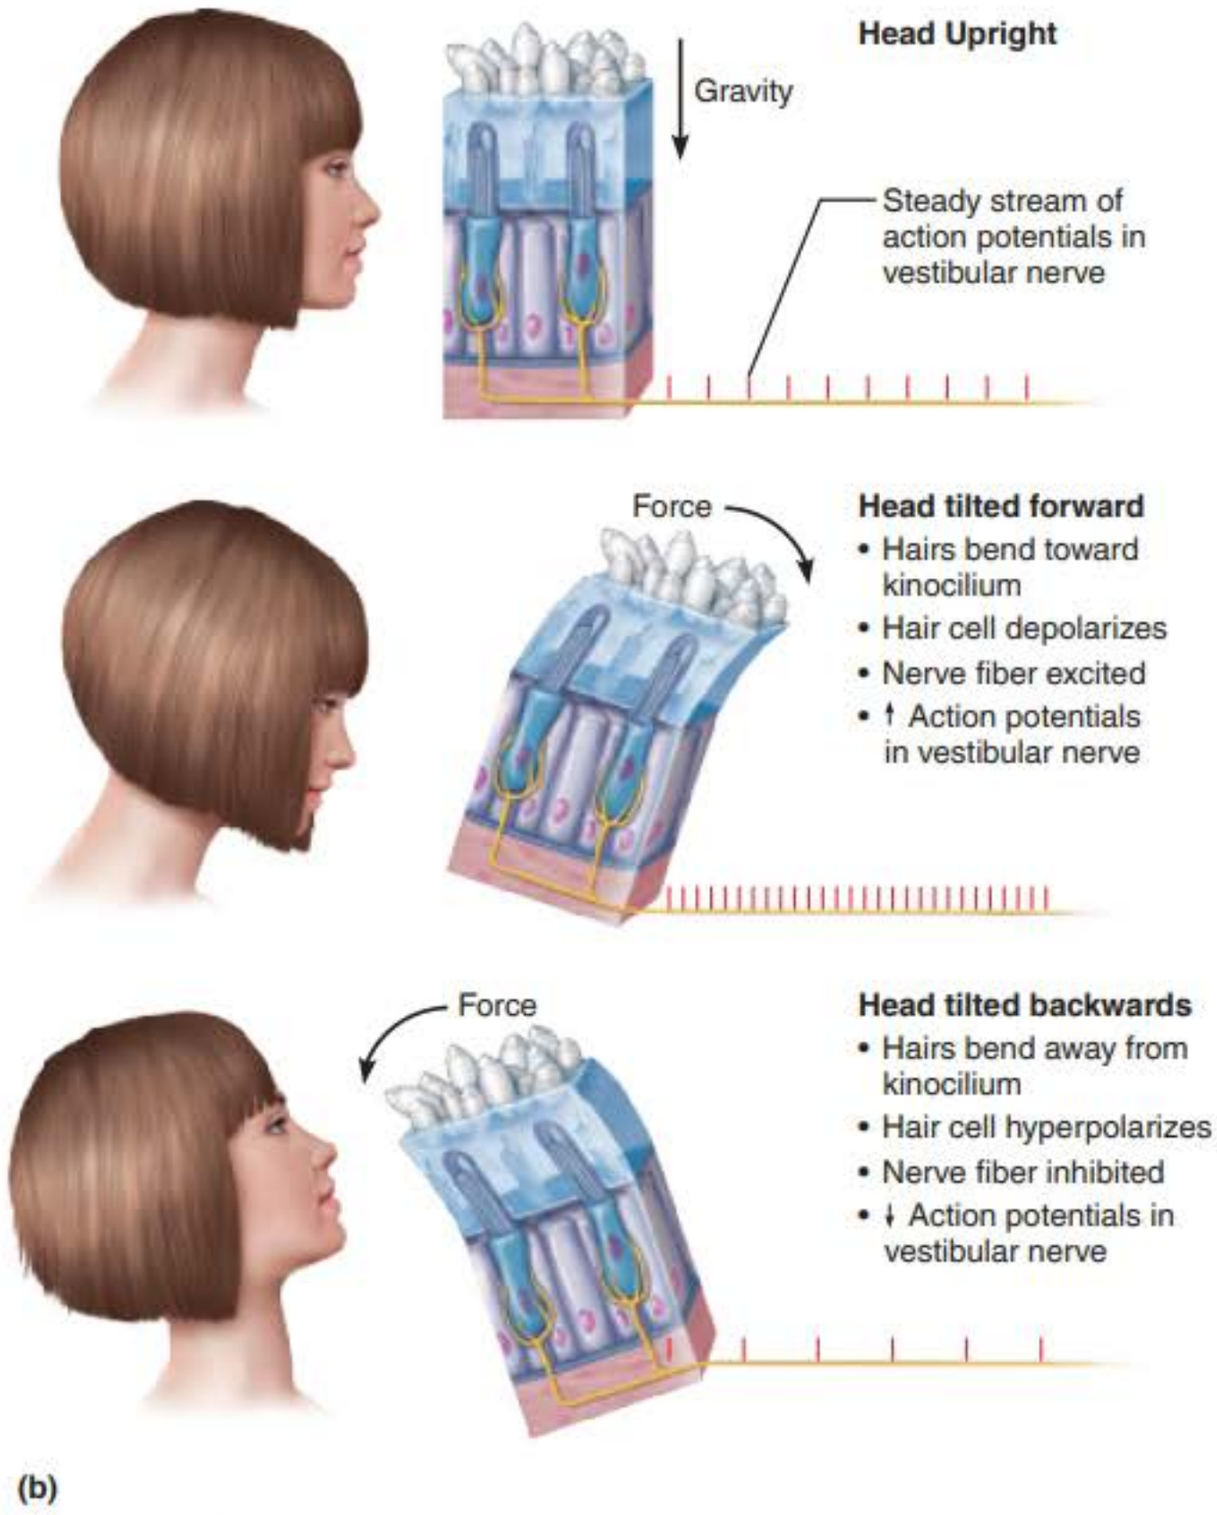


Figure 15.34 Structure and function of a macula. (a) Structure. **(b)** Function of a macula of the utricle in signaling head position.

(up-down) movements do not displace their horizontal otolith membrane.

In the saccule, on the other hand, the macula is nearly vertical, and the hairs protrude horizontally into the otolith membrane. The saccular maculae respond best to vertical movements, such as the sudden acceleration of an elevator.

The hair cells synapse with fibers of the **vestibular nerve**, whose endings coil around their bases. Like the cochlear nerve, the vestibular nerve is a subdivision of the vestibulocochlear nerve (VIII). The cell bodies of the sensory neurons are located in the nearby **superior** and **inferior vestibular ganglia** (see Figure 15.26).

Activating Receptors of a Macula

What happens in the maculae that leads to sensory transduction? When your head starts or stops moving in a linear direction, inertia causes the otolith membrane to slide backward or forward like a greased plate over the hair cells, bending the hairs. For example, when you start to run, the otolith membranes of the utricle maculae lag behind, bending the hairs backward. When you suddenly stop, the otolith membrane slides abruptly forward (just as you slide forward in your car when you brake), bending the hairs forward. Likewise, when you nod your head or fall, the otoliths sag inferiorly, bending the hairs of the maculae in the saccules.

The hair cells release neurotransmitter continuously, but movement of their hairs modifies the amount they release just as it does in the cochlea (see Figure 15.32).

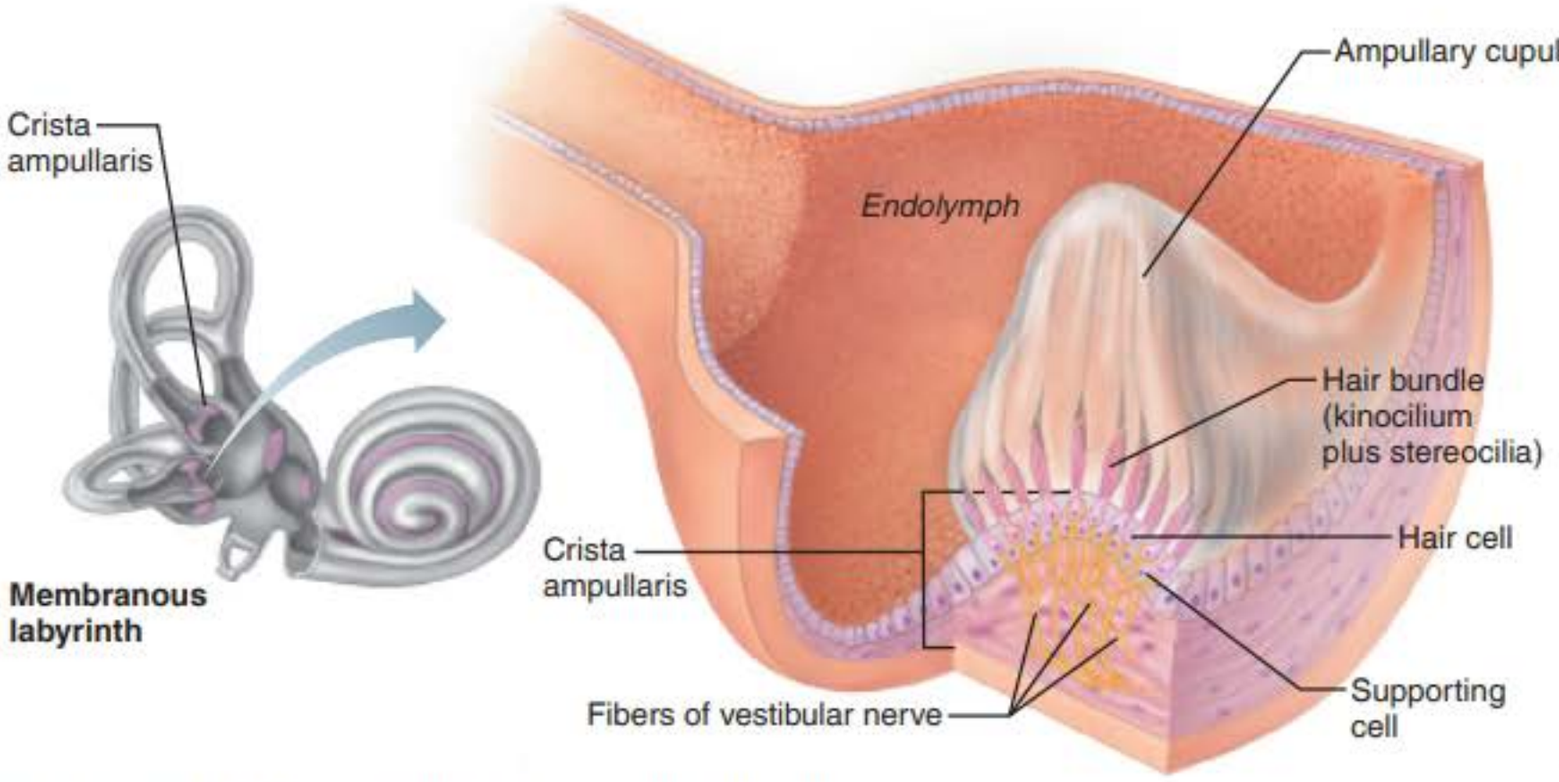
- When the hairs bend toward the kinocilium, the hair cells depolarize, stepping up their pace of neurotransmitter release, and more impulses travel up the vestibular nerve to the brain.
- When the hairs bend away from the kinocilium, the receptors hyperpolarize and release less neurotransmitter, generating fewer impulses.

In either case, the brain is informed of the changing position of the head in space (Figure 15.34b).

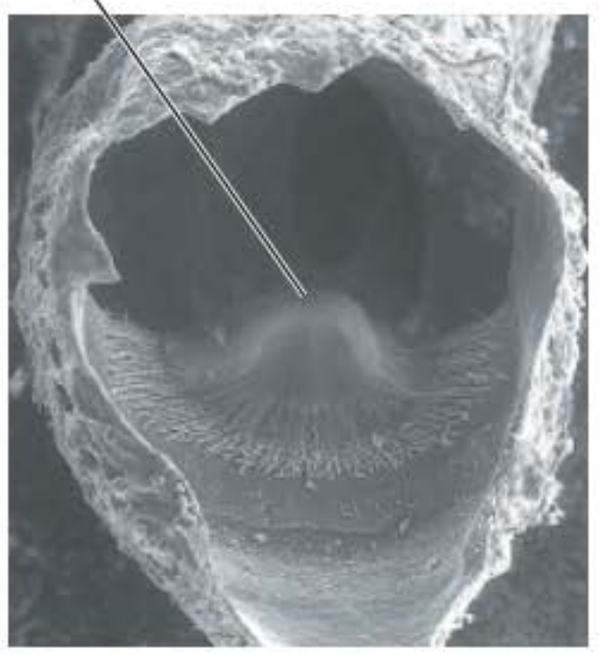
It is important to understand that the maculae respond to *changes* in the velocity of head movement (linear acceleration or deceleration). Because most hair cells adapt quickly (resuming their basal level of neurotransmitter release), they do not report on unchanging head positions. In this way, the maculae help us to maintain normal head position with respect to gravity.

The Cristae Ampullares

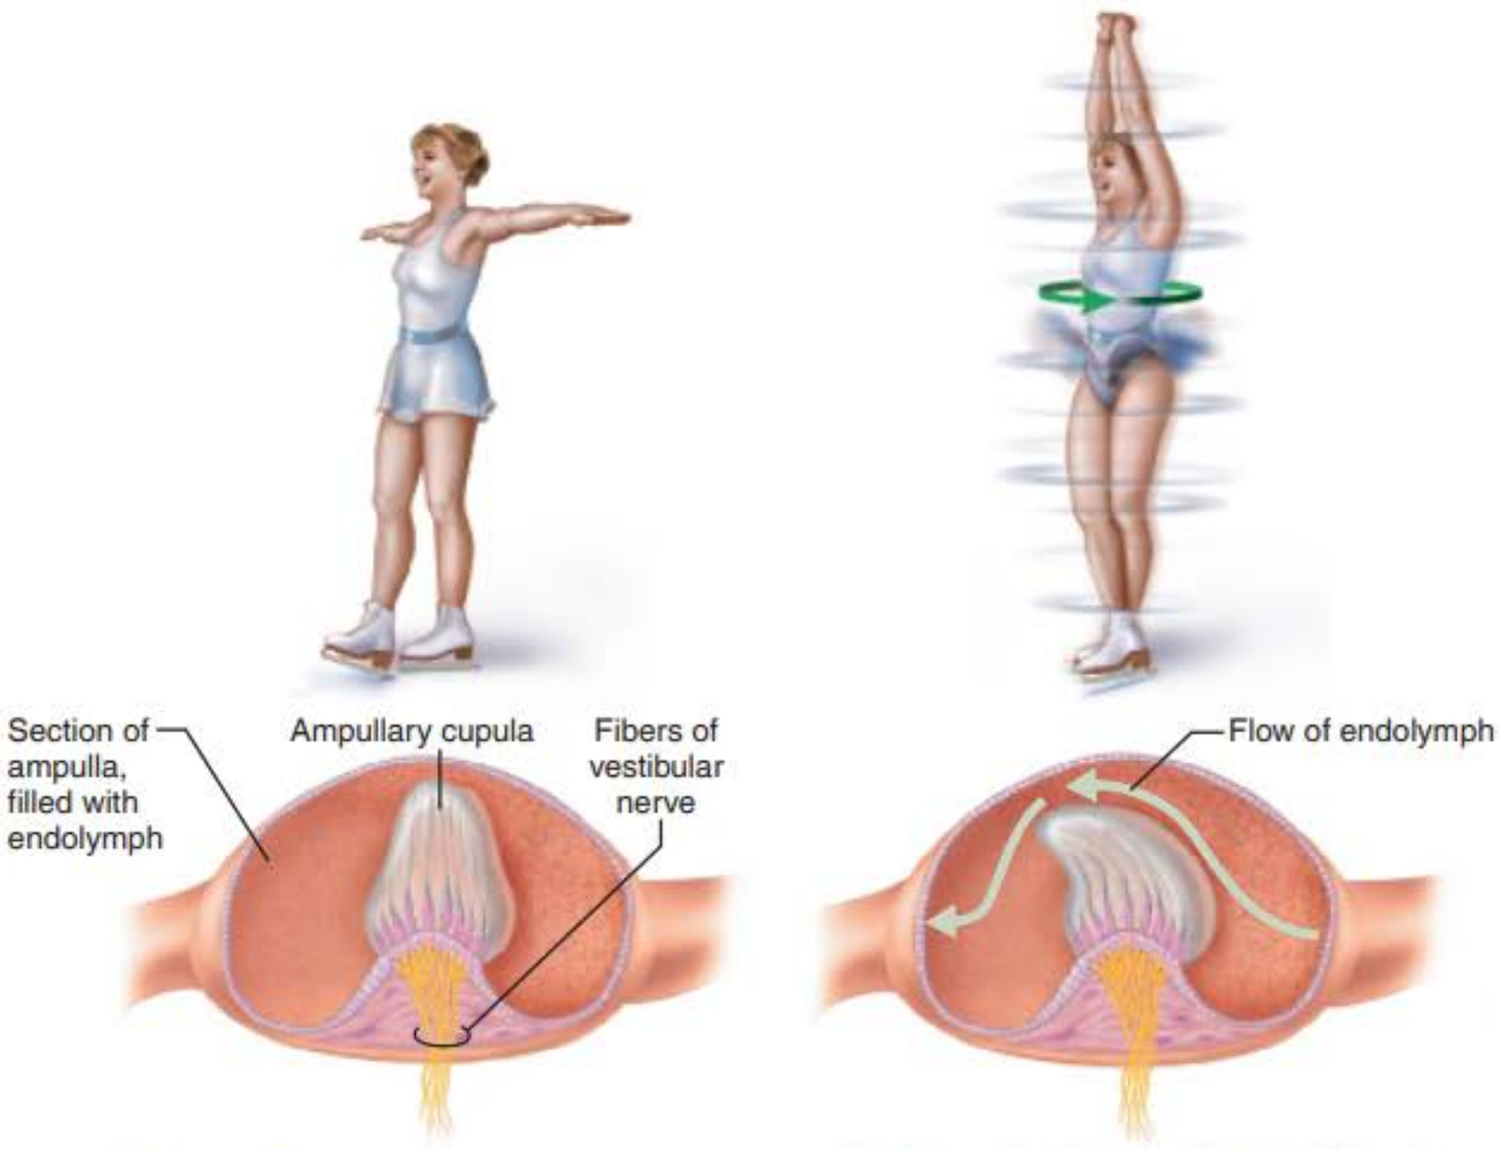
The receptor for rotational acceleration, called the **crista ampullaris** or simply *crista*, is a minute elevation in the ampulla of each semicircular duct (see Figure 15.26). Like the maculae, the cristae are excited by head movement (acceleration and deceleration), but in this case the major stimuli are rotational (angular) movements. When you twirl on the dance floor or suffer through a rough boat ride, these gyroscope-like receptors are working overtime. Since the semicircular canals are located in all three planes of space, all rotational movements of the head disturb one or another *pair* of cristae (one in each ear).



(a) Anatomy of a crista ampullaris in a semicircular duct



(b) Scanning electron micrograph of a crista ampullaris (200×)



At rest, the cupula stands upright.

During rotational acceleration, endolymph moves inside the semicircular canals in the direction opposite the rotation (it lags behind due to inertia). Endolymph flow bends the cupula and excites the hair cells.

As rotational movement slows, endolymph keeps moving in the direction of rotation. Endolymph flow bends the cupula in the opposite direction from acceleration and inhibits the hair cells.

(c) Movement of the ampullary cupula during rotational acceleration and deceleration

Figure 15.35 Location, structure, and function of a crista ampullaris in the internal ear.

Anatomy of a Crista Ampullaris

Each crista is composed of supporting cells and hair cells whose structure and function are basically the same as the hair cells of the cochlea and maculae. In this case, the gelled mass is an **ampullary cupula** (ku′pu-lah), which resembles a pointed cap (**Figure 15.35**). The cupula is a delicate, loosely organized network of gelatinous strands that radiate outward to contact the "hairs" of each hair cell. Dendrites of vestibular nerve fibers encircle the base of the hair cells.

Activating Receptors of the Crista Ampullaris

The cristae respond to *changes* in the velocity of rotational movements of the head. Because of its inertia, the endolymph in the semicircular ducts moves briefly in the direction *opposite* the body's rotation, deforming the crista in the duct. As the hairs bend, the hair cells depolarize and impulses reach the brain at a faster rate (Figure 15.35c, center). Bending the cilia in the opposite direction causes hyperpolarization and generates fewer impulses. Because the axes of the hair cells in the complementary semicircular ducts are opposite, rotation in a given direction depolarizes the receptors in one ampulla of the pair, and hyperpolarizes the receptors in the other.

If the body continues to rotate at a constant rate, the endolymph eventually comes to rest—it moves along at the same speed as the body, and the hair cells are no longer stimulated. Consequently, if we are blindfolded, we cannot tell whether we are moving at a constant speed or not moving at all after the first few seconds of rotation. However, when we suddenly stop moving, the endolymph keeps on going, in effect reversing its direction within the canal. This sudden reversal in the direction of hair bending alters membrane voltage in the receptor cells and modifies the rate of impulse transmission, which tells the brain that we have slowed or stopped (Figure 15.35c, right).

The key point to remember when considering both types of equilibrium receptors is that the rigid bony labyrinth moves with the body, while the fluids (and gels) within the membranous labyrinth are free to move at various rates, depending on the forces (gravity, acceleration, and so on) acting on them.

Vestibular Nystagmus

Information transmitted from the semicircular canals is particularly important to reflex movements of the eyes. **Vestibular nystagmus** is a complex of rather strange eye movements that occurs during and immediately after rotation.

As you rotate, your eyes slowly drift in the opposite direction, as though fixed on some object in the environment. This reaction relates to the backflow of endolymph in the semicircular ducts. Then, because of CNS compensating mechanisms, the eyes jump rapidly toward the direction of rotation to establish a new fixation point. These alternating eye movements continue until the endolymph comes to rest.

When you stop rotating, at first your eyes continue to move in the direction of the previous spin, and then they jerk rapidly in the opposite direction. This sudden change is caused by the change in the direction in which the cristae bend after you stop. Nystagmus is often accompanied by vertigo, a false sensation of movement.

The Equilibrium Pathway to the Brain

Our responses to body imbalance, such as when we stumble, must be fast and reflexive. By the time we "thought about" correcting our fall, we would already be on the ground! Accordingly, information from equilibrium receptors goes directly to reflex centers in the brain stem, rather than to the cerebral cortex as with the other special senses.

The nerve pathways connecting the vestibular apparatus with the brain are complex. The transmission sequence begins when the hair cells in the vestibular apparatus are activated. As depicted in **Figure 15.36**, impulses travel initially to one of two destinations: the **vestibular nuclei** in the brain stem or the **cerebellum**. The vestibular nuclei, the major integrative center for balance, also receive inputs from the visual and somatic receptors, particularly

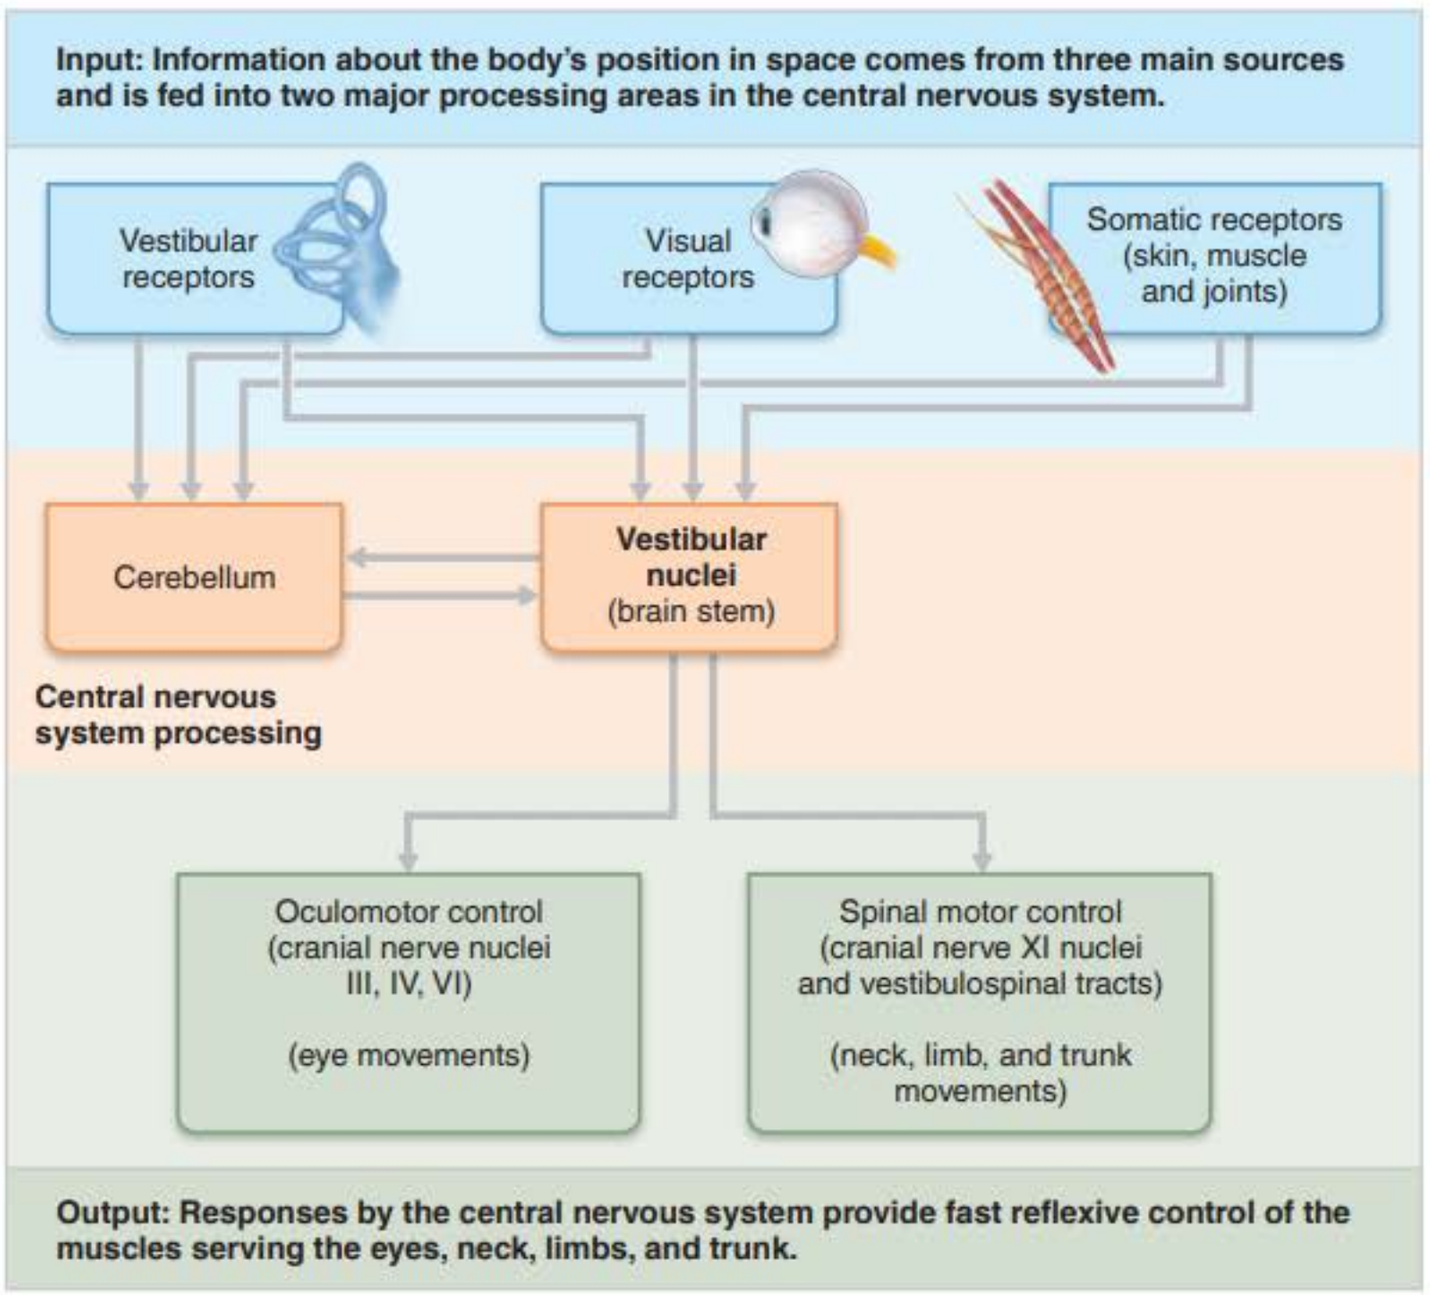


Figure 15.36 Neural pathways of the balance and orientation system.

from proprioceptors in neck muscles that report on the position of the head. These nuclei integrate this information and then send commands to brain stem motor centers that control the extrinsic eye muscles (cranial nerve nuclei III, IV, and VI) and reflex movements of the neck, limb, and trunk muscles (via the vestibulospinal tracts). The ensuing reflex movements of the eyes (the *vestibulo-ocular reflex*) and body allow us to remain focused on the visual field and quickly adjust our body position to maintain or regain balance. The vestibulo-ocular reflex is a normal reflex that occurs when the head rotates. Involuntary eye movements compensate for the head movement so as to keep the image steady.

The cerebellum also integrates inputs from the eyes and somatic receptors (as well as from the cerebrum). It coordinates skeletal muscle activity and regulates muscle tone to maintain head position, posture, and balance, often in the face of rapidly changing inputs. Its "specialty" is fine control of delicate postural movements and timing.

Notice that the vestibular apparatus *does not automatically compensate* for forces acting on the body. Its job is to send warning signals to the CNS, which initiates the appropriate compensations.

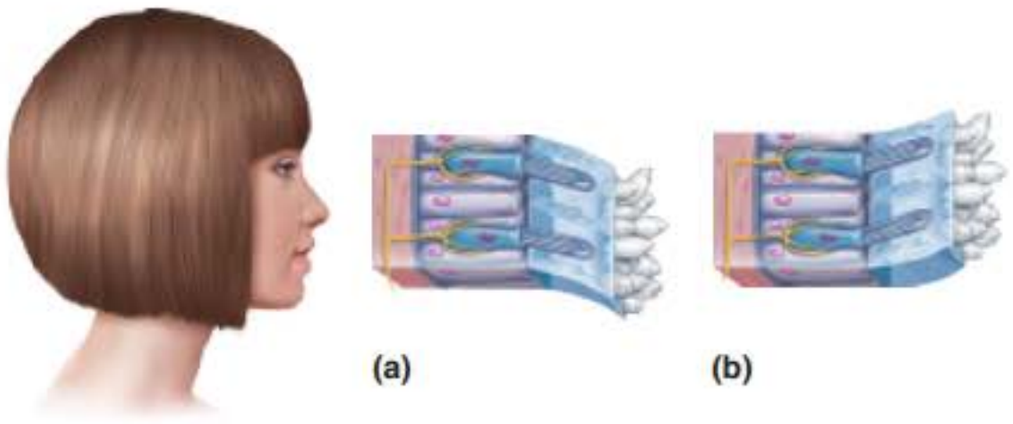
HOMEOSTATIC IMBALANCE 15.15 CLINICAL

Equilibrium problems are usually obvious and unpleasant. Nausea, dizziness, and loss of balance are common and there may be nystagmus in the absence of rotational stimuli.

Motion sickness appears to be due to sensory input mismatches. For example, if you are inside a ship during a storm, visual inputs indicate that your body is fixed with reference to a stationary environment (your cabin). But as rough seas toss the ship about, your vestibular apparatus detects movement and sends impulses that disagree with the visual information. The brain thus receives conflicting signals, and its "confusion" somehow leads to motion sickness. Warning signals include excessive salivation, pallor, rapid deep breathing, and profuse sweating. Removal of the stimulus usually ends the symptoms. Over-the-counter drugs, such as meclizine, depress vestibular inputs and help alleviate the symptoms.

Check Your Understanding

20. For the maculae shown below, which best shows the position of the otolith membrane in the saccule of a person in an elevator that is just beginning to go up? Will this cause an increase or decrease in action potential frequency in the axons of the vestibular nerve from this saccule? How can you tell?



21. For each of the following phrases, indicate whether it applies to a macula or a crista ampullaris: inside a semicircular canal; contains otoliths; responds to linear acceleration and deceleration; has a cupula; responds to rotational acceleration and deceleration; inside a saccule.

For answers, see Answers Appendix.

15.11 Ear abnormalities can affect hearing, equilibrium, or both CLINICAL

Learning Outcome

- **List possible causes and symptoms of otitis media, deafness, and Ménière's syndrome.**

Deafness

Any hearing loss, no matter how slight, is **deafness** of some sort. Deafness is classified as conduction or sensorineural deafness, according to its cause.

Conduction deafness occurs when something hampers sound conduction to the fluids of the internal ear. For example, compacted earwax can block the external acoustic meatus, or a *perforated* (*ruptured*) eardrum can prevent sound conduction from the eardrum to the ossicles. But the most common causes of conduction deafness are middle ear inflammations (otitis media) and **otosclerosis** (o″to-sklĕ-ro′sis) of the ossicles.

Otosclerosis ("hardening of the ear") occurs when overgrowth of bony tissue fuses the base of the stapes to the oval window or welds the ossicles to one another. In such cases, vibrations of the skull bones conduct sound to the receptors of that ear, which is far less satisfactory. Otosclerosis is treated surgically.

Sensorineural deafness results from damage to neural structures at any point from the cochlear hair cells to and including the auditory cortical cells. This type of deafness typically results from the gradual loss of hair cells throughout life. Hair cells can also be destroyed by a single explosively loud noise or prolonged exposure to high-intensity sounds, such as music or industrial noise, which literally tear off their cilia. Other causes of sensorineural deafness are degeneration of the cochlear nerve, strokes, and tumors in the auditory cortex.

Hair cells don't normally regenerate in mammals, but researchers are seeking ways to prod supporting cells into becoming hair cells. For congenital defects or age- or noise-related cochlear damage, cochlear implants (devices that convert sound energy into electrical signals) can be inserted into the temporal bone. Modern

Figure 15.37 Boy with a cochlear implant. The parts visible on the boy's head are a microphone and processor that transmit signals to electrodes embedded in the temporal bone.

implants are so effective that even children born deaf can hear well enough to learn to speak well (**Figure 15.37**).

Tinnitus

Tinnitus (tĭ-ni′tus) is a ringing, buzzing, or clicking sound in the ears in the absence of auditory stimuli. It is usually a symptom rather than a disease. For example, tinnitus is one of the first symptoms of cochlear nerve degeneration. It may also signal inflammation of the middle or internal ears and is a side effect of some medications, such as aspirin.

Recent evidence suggests that tinnitus is analogous to phantom limb pain. In other words, it is "phantom cochlear noise" caused by destruction of some neurons in the auditory pathway and the subsequent ingrowth of nearby neurons whose signals are interpreted as noise by the CNS.

Ménière's Syndrome

Classic **Ménière's syndrome** (men″ē-ārz′) is a labyrinth disorder that seems to affect all three parts of the internal ear. The afflicted person has repeated attacks of vertigo, nausea, and vomiting. Balance is so disturbed that standing erect is nearly impossible. Tinnitus may be present, and hearing may be impaired or lost completely.

Mild cases can usually be managed by antimotion drugs or a low-salt diet and diuretics to decrease endolymph fluid volume. In severe cases, draining the excess endolymph from the internal ear may help. A last resort is removal of the entire malfunctioning labyrinth.

Check Your Understanding

22. Six-year-old Mohammed has a cold and says his ears feel "full" and he "can't hear well." Explain what has happened in Mohammed's ears. Which type of deafness does Mohammed have—conduction or sensorineural?

For answers, see Answers Appendix.

Developmental Aspects of the Special Senses

Taste and Smell

All the special senses are functional, to a greater or lesser degree, at birth. Smell and taste are sharp, and infants relish food that adults consider bland. Some researchers claim that smell is just as important as touch in guiding newborn infants to their mother's breast. However, very young children seem indifferent to odors.

There are few problems with the chemical senses during childhood and young adulthood. Women generally have a more acute sense of smell than men, and nonsmokers have a sharper sense of smell than smokers.

Beginning in the fourth decade of life, our ability to taste and smell declines due to the gradual loss of receptors, which are replaced more slowly as we age. More than half of people over age 65 have serious problems detecting odors, and their sense of taste is poor. This makes food taste bland and contributes to loss of appetite.

Vision

By the fourth week of development, the eyes begin forming as the **optic vesicles** that protrude from the diencephalon (◀ Figure 12.1c, p. 435). Soon these hollow vesicles indent to form double-layered **optic cups**, and their stalks form the optic nerves and provide a pathway for blood vessels to reach the eye interior.

Once an optic vesicle reaches the overlying surface ectoderm, it induces the ectoderm to thicken and then form a **lens vesicle** that pinches off into the cavity of the optic cup, where it becomes the lens. The lining (internal layer) of the optic cup becomes the neural layer of the retina, and the outer layer forms the pigmented layer. The rest of the eye tissues and the vitreous humor are formed by mesenchymal cells derived from the mesoderm that surrounds the optic cup.

In the darkness of the uterus, the fetus cannot see. Nonetheless, even before the light-sensitive portions of the photoreceptors develop, the central nervous system connections have been made and are functional. During infancy, synaptic connections are fine-tuned, and the typical cortical fields that allow binocular vision are established.

HOMEOSTATIC IMBALANCE 15.16 CLINICAL

Congenital problems of the eyes are relatively uncommon, but their incidence is dramatically increased by certain maternal infections, particularly rubella (German measles) during the critical first three months of pregnancy. Common rubella sequels include blindness and cataracts.

As a rule, vision is the only special sense not fully functional at birth. Because the eyeballs are foreshortened, most babies are hyperopic. The newborn sees only in gray tones, eye movements are uncoordinated, and often only one eye at a time is used. The lacrimal glands are not completely developed until about two weeks after birth, so babies are tearless for this period, even though they may cry lustily. By 5 months, infants can follow moving objects with their eyes, but visual acuity is still poor.

By the age of 3 years, depth perception is present and color vision is well developed. Because the eyeball has grown, visual acuity has improved, providing a readiness to begin reading. The eye reaches its adult size at 8–9 years of age. Presbyopia begins to set in around age 40 owing to decreasing lens elasticity.

With age, the lens loses its clarity and discolors. As a result, it begins to scatter light, causing a glare that is distressing when driving at night. The dilator pupillae muscles become less efficient, so the pupils stay partly constricted. These two changes decrease the amount of light reaching the retina, and visual acuity is dramatically lower in people over 70. In addition, the lacrimal glands are less active and the eyes tend to be dry and more susceptible to infection. Elderly persons are also at risk for certain conditions that cause blindness, such as macular degeneration, glaucoma, cataracts, atherosclerosis, and diabetes mellitus.

Hearing and Balance

The ear begins to develop in the three-week embryo. The internal ears develop first, from thickenings of the surface ectoderm called the **otic placodes** (o′tik plak′ōds), which lie lateral to the hindbrain on each side. The otic placode invaginates, forming the **otic pit** and then the **otic vesicle**, which detaches from the surface epithelium. The otic vesicle develops into the membranous labyrinth. The surrounding mesenchyme forms the bony labyrinth.

The middle ear cavity and pharyngotympanic tube of the middle ear develop from **pharyngeal pouches**, lateral outpocketings of the endoderm lining the pharynx. The auditory ossicles develop from neural crest cells.

The external acoustic meatus and external face of the tympanic membrane of the external ear differentiate from the **pharyngeal cleft** (*branchial groove*), an indentation of the surface ectoderm, and the auricle develops from swellings of the surrounding tissue.

Newborn infants can hear, but early responses to sound are mostly reflexive—for example, crying in response to a startling noise. By the fourth month, infants will turn to the voices of family members. Critical listening begins as toddlers increase their vocabulary, and good language skills are closely tied to the ability to hear well.

HOMEOSTATIC IMBALANCE 15.17 — CLINICAL

Congenital abnormalities of the ears are fairly common. Examples include partly or completely missing pinnae and closed or absent external acoustic meatuses. Maternal rubella during the first trimester commonly results in sensorineural deafness.

Except for ear inflammations, mostly due to infections, few problems affect the ears during childhood and adult life. By the 60s, however, deterioration of the spiral organ becomes noticeable. We are born with approximately 30,000 hair cells, but their number declines as they are damaged or destroyed by loud noises, disease, or drugs (for example, the antibiotic streptomycin). The hair cells *are* replaced, but at such a slow rate that there really is no functional regeneration.

The ability to hear high-pitched sounds leaves us first. This condition, called **presbycusis** (pres″bĭ-ku′sis), is a type of sensorineural deafness. Although presbycusis is considered a disability of old age, it is becoming much more common in younger people as our world grows noisier.

RELATED CLINICAL TERMS

Ageusia (ah-gu′ze-ah) Loss or impairment of the taste sense.

Age-related macular degeneration (ARMD) Progressive deterioration of the macula lutea that destroys central vision; the main cause of vision loss in those over age 65. Buildup of pigments in the macula impairs functioning of the pigmented epithelium. Continued accumulation of pigment leads to the "dry" form of ARMD, in which many pigment cells and macular photoreceptors die. The dry form is largely untreatable, although a specific cocktail of vitamins and zinc slows its progression. Less common is the "wet" form in which new blood vessels from the choroid grow into the retina. Blood and fluids leak from these vessels, scarring and detaching the retina. The cause of wet ARMD is unknown, but several treatment options can slow its progression—laser treatments that destroy some of the invading vessels and drugs that prevent blood vessel growth.

Blepharitis (blef″ah-ri′tis; *blephar* = eyelash; *itis* = inflammation) Inflammation of the margins of the eyelids.

Enucleation (e-nu″kle-a′shun) Surgical removal of an eyeball.

Exophthalmos (ek″sof-thal′mos; *ex* = out; *ophthalmo* = the eye) Anteriorly bulging eyeballs. Seen in some cases of hyperthyroidism. See Figure 16.10b on p. 620.

Labyrinthitis Inflammation of the labyrinth.

Ophthalmology (of″thal-mol′o-je) The science that studies the eye and eye diseases. An ophthalmologist is a medical doctor who specializes in treating eye disorders.

Optometrist A licensed nonphysician who measures vision and prescribes corrective lenses.

Otalgia (o-tal′je-ah; *algia* = pain) Earache.

Otitis externa Inflammation and infection of the external acoustic meatus, caused by bacteria or fungi that enter the canal from outside, especially when the canal is moist (e.g., after swimming).

Otoacoustic emissions Sounds generated by the movement of outer hair cells in the cochlea. Stimulated otoacoustic emissions are an inexpensive way to screen newborns for hearing defects.

Papilledema (pap″il-ĕ-de′mah; *papill* = nipple; *edema* = swelling) Protrusion of the optic disc into the eyeball, which can be observed by ophthalmoscopic examination; caused by conditions that increase intracranial pressure.

Scotoma (sko-to′mah; *scoto* = darkness) A blind spot other than the normal (optic disc) blind spot. Has many causes, including stroke or a brain tumor pressing on fibers of the visual pathway.

Trachoma (trah-ko′mah; *trach* = rough) A highly contagious bacterial (chlamydial) infection of the conjunctiva and cornea. Common worldwide, it blinds millions of people in poor countries of Africa and Asia. Treated with eye ointments containing antibiotic drugs.

Weber's test Hearing test during which a sounding tuning fork is held to the forehead. In those with normal hearing, the tone is heard equally in both ears. The tone will be heard best in the "good" ear if sensorineural deafness is present, and in the "bad" ear if conduction deafness is present.

CHAPTER SUMMARY

PART 1
THE EYE AND VISION

15.1 The eye has three layers, a lens, and humors, and is surrounded by accessory structures (pp. 554–563)

1. The eyes are enclosed in bony orbits and cushioned by fat.

Accessory Structures of the Eye (pp. 554–557)

2. Eyebrows help to shade and protect the eyes.
3. Eyelids protect and lubricate the eyes by reflex blinking. Within the eyelids are the orbicularis oculi and levator palpebrae superioris muscles, and modified sebaceous and sweat glands.
4. The conjunctiva is a mucosa that lines the eyelids and covers the anterior eyeball surface. Its mucus lubricates the eyeball surface.
5. The lacrimal apparatus consists of the lacrimal gland (which produces a saline solution containing mucus, lysozyme, and antibodies), the lacrimal canaliculi, the lacrimal sac, and the nasolacrimal duct.
6. The extrinsic eye muscles (superior, inferior, lateral, and medial rectus and superior and inferior oblique) move the eyeballs.

Structure of the Eyeball (pp. 558–563)

7. The wall of the eyeball is made up of three layers. The outermost fibrous layer consists of the sclera and the cornea. The sclera protects the eye and gives it shape; the cornea allows light to enter the eye.
8. The middle, pigmented vascular layer (uvea) consists of the choroid, the ciliary body, and the iris. The choroid provides nutrients to the eye and prevents light scattering within the eye. The ciliary muscles of the ciliary body control lens shape; the iris controls the size of the pupil.
9. The inner layer, or retina, consists of an outer pigmented layer and an inner neural layer. The neural layer contains photoreceptors (rods and cones), bipolar cells, and ganglion cells. Ganglion cell axons form the optic nerve, which exits via the optic disc ("blind spot").
10. The posterior segment of the eyeball, behind the lens, contains vitreous humor, which helps support the eyeball and keep the retina in place. The anterior segment, anterior to the lens, is filled with aqueous humor, formed by capillaries in the ciliary processes and drained into the scleral venous sinus. Aqueous humor is a major factor in maintaining intraocular pressure.
11. The biconvex lens is suspended within the eye by the ciliary zonule attached to the ciliary body. The lens is the only adjustable refractory structure of the eye.

15.2 The cornea and lens focus light on the retina (pp. 563–567)

1. Visible light is made up of those wavelengths of the electromagnetic spectrum that excite the photoreceptors.
2. Light is refracted (bent) when passing from one transparent medium to another of different density. Concave lenses disperse light; convex lenses converge light and bring its rays to a focal point. The greater the lens curvature, the more light bends.
3. As light passes through the eye, the cornea and lens bend and focus it on the retina. The cornea accounts for most of the refraction, but the lens allows active focusing for different distances.
4. Focusing for distant vision requires no special movements of the eye structures. Focusing for close-up vision requires accommodation (bulging of the lens), pupillary constriction, and convergence of the eyeballs (all controlled by cranial nerve III).
5. Refractory problems include presbyopia, myopia, hyperopia, and astigmatism.

15.3 Phototransduction begins when light activates visual pigments in retinal photoreceptors (pp. 567–573)

1. The outer segments of the photoreceptors contain light-absorbing visual pigment in membrane-bounded discs.
2. The light-absorbing molecule retinal is combined with various opsins to form the visual pigments. Rod visual pigment, rhodopsin, is a combination of retinal and opsin. The three types of cones all contain retinal, but each has a different type of opsin. Each cone type responds maximally to one color of light: red, blue, or green.
3. Rods respond to low-intensity light and provide night and peripheral vision. Cones are bright-light, high-discrimination receptors that provide color vision. Anything that must be viewed precisely is focused on the cone-rich fovea centralis.
4. When struck by light, retinal changes shape (11-*cis* to all-*trans*) and activates opsin. Activated opsin activates transducin (a G protein) which in turn activates PDE, an enzyme that breaks down cGMP, allowing the cation channels to close. This hyperpolarizes the receptor cells and inhibits their release of neurotransmitter.
5. Photoreceptors and bipolar cells generate graded potentials only; ganglion cells generate action potentials.
6. During light adaptation, visual pigments are bleached and rods are inactivated; then, as cones decrease their light sensitivity, high-acuity vision ensues. In dark adaptation, cones cease functioning, and visual acuity decreases; rod function begins when sufficient rhodopsin has accumulated.

15.4 Visual information from the retina passes through relay nuclei to the visual cortex (pp. 573–575)

1. The visual pathway to the brain begins with the optic nerve fibers (ganglion cell axons) from the retina. At the optic chiasma, fibers from the medial half of each retina cross over and continue in the optic tracts to the thalamus. Thalamic neurons project to the visual cortex via the optic radiation. Fibers also project from the retina to the midbrain pretectal nuclei and the superior colliculi, and to the suprachiasmatic nucleus of the hypothalamus.
2. Each eye receives a slightly different view of the visual field. The visual cortices fuse these views to provide depth perception.
3. Retinal processing involves the selective destruction of inputs so as to emphasize bright/dark or color contrasts (edges). Thalamic processing subserves high-acuity color vision and depth perception. Cortical processing involves color, form, and movement. Visual processing proceeds anteriorly in the "what" and "where" streams.

PART 2
THE CHEMICAL SENSES: SMELL AND TASTE

15.5 Airborne chemicals are detected by olfactory receptors in the nose (pp. 575–578)

1. The olfactory epithelium is located in the roof of the nasal cavity. The olfactory sensory neurons are ciliated bipolar neurons. Their axons are the filaments of the olfactory nerve (cranial nerve I).
2. Individual olfactory neurons have one type of receptor protein that can respond to more than one chemical. Olfactory neurons bearing the same odorant receptors synapse in the same glomerulus type.
3. Olfactory neurons are excited by volatile chemicals that bind to receptors in the olfactory cilia.
4. Action potentials of the olfactory nerve filaments are transmitted to the olfactory bulb where the filaments synapse with mitral cells. The mitral cells send impulses via the olfactory tract to the olfactory cortex. Fibers carrying impulses from the olfactory bulb also project to the limbic system.

15.6 Dissolved chemicals are detected by receptor cells in taste buds (pp. 578–580)

1. The taste buds are scattered in the oral cavity and pharynx but are most abundant on the tongue papillae.
2. Gustatory epithelial cells, the receptor cells of the taste buds, have gustatory hairs (microvilli) that serve as the receptor regions. The gustatory epithelial cells are excited by the binding of tastants (food chemicals) to receptors on their microvilli.
3. The five basic taste qualities are sweet, sour, salty, bitter, and umami. Lipid may be a sixth taste quality.
4. The taste sense is served by cranial nerves VII, IX, and X, which send impulses to the solitary nucleus of the medulla. From there, impulses are sent to the thalamus and the gustatory cortex.

PART 3
THE EAR: HEARING AND BALANCE

15.7 The ear has three major areas (pp. 580–585)

1. The auricle and external acoustic meatus compose the external ear. The tympanic membrane, the boundary between the outer and middle ears, transmits sound waves to the middle ear.
2. The middle ear is a small chamber within the temporal bone, connected by the pharyngotympanic tube to the nasopharynx. The ossicles, which help amplify sound, span the middle ear cavity and transmit sound vibrations from the tympanic membrane to the oval window.
3. The internal ear consists of the bony labyrinth, within which the membranous labyrinth is suspended. The bony labyrinth chambers contain perilymph; the membranous labyrinth ducts and sacs contain endolymph.
4. The vestibule contains the saccule and utricle. The semicircular canals extend posteriorly from the vestibule in three planes. They contain the semicircular ducts.
5. The cochlea houses the cochlear duct (scala media), containing the spiral organ, the receptor organ for hearing. Within the cochlear duct, the hair (receptor) cells rest on the basilar membrane, and their hairs project into the gelatinous tectorial membrane.

15.8 Sound is a pressure wave that stimulates mechanosensitive cochlear hair cells (pp. 585–589)

1. Sound originates from a vibrating object and travels in waves consisting of alternating areas of compression and rarefaction of the medium.
2. The distance from crest to crest on a sine wave is the sound's wavelength; the shorter the wavelength, the higher the frequency (measured in hertz). Frequency is perceived as pitch.
3. The amplitude of sound is the height of the peaks of the sine wave, which reflect the sound's intensity. Sound intensity is measured in decibels. Intensity is perceived as loudness.
4. Sound passing through the external acoustic meatus sets the tympanic membrane into vibration at the same frequency. The ossicles amplify and deliver the vibrations to the oval window.
5. Pressure waves in cochlear fluids set specific locations on the basilar membrane into resonance. At points of maximal membrane vibration, the vibratory motion alternately depolarizes and hyperpolarizes the hair cells of the spiral organ. Movements of the stereocilia toward the tallest cilium depolarize the hair cells and increase the rate of impulse generation in the auditory nerve fibers. Movements away from the tallest cilium have the opposite effect. High-frequency sounds stimulate hair cells near the oval window; low-frequency sounds stimulate hair cells near the apex. Inner hair cells send most auditory inputs to the brain. Outer hair cells amplify the inner hair cells' responsiveness.

15.9 Sound information is processed and relayed through brain stem and thalamic nuclei to the auditory cortex (pp. 589–590)

1. Impulses generated along the cochlear nerve travel to the cochlear nuclei of the medulla and from there through several brain stem nuclei to the medial geniculate nucleus of the thalamus and then the auditory cortex. Each auditory cortex receives impulses from both ears.
2. Auditory processing is analytic; each tone is perceived separately. Perception of pitch is related to the position of the excited hair cells along the basilar membrane. Intensity perception reflects the fact that as sound intensity increases, basilar membrane motion increases, and the frequency of impulse transmission to the cortex increases. Cues for sound localization include the intensity and timing of sound arriving at each ear.

15.10 Hair cells in the maculae and cristae ampullares monitor head position and movement (pp. 590–594)

1. The equilibrium receptor regions of the internal ear are called the vestibular apparatus.
2. The receptors for linear acceleration and gravity are the maculae of the saccule and utricle. A macula consists of hair cells with stereocilia and a kinocilium embedded in an overlying otolith membrane. Linear movements cause the otolith membrane to move, pulling on the hair cells and changing the rate of impulse generation in the vestibular nerve fibers.
3. The receptor within each semicircular duct, the crista ampullaris, responds to angular or rotational acceleration in one plane. It consists of a tuft of hair cells whose stereocilia are embedded in the gelatinous ampullary cupula. Rotational movements cause the endolymph to flow in the opposite direction, bending the cupula and either exciting or inhibiting the hair cells.
4. Impulses from the vestibular apparatus are sent via vestibular nerve fibers mainly to the vestibular nuclei of the brain stem and the cerebellum. These centers initiate responses that fix the eyes on objects and activate muscles to maintain balance.

15.11 Ear abnormalities can affect hearing, equilibrium, or both (pp. 594–595)

1. Conduction deafness results from interference with conduction of sound vibrations to the fluids of the internal ear. Sensorineural deafness reflects damage to neural structures.

2. Tinnitus is an early sign of sensorineural deafness; it may also result from inflammation or certain drugs.
3. Ménière's syndrome is a disorder of the membranous labyrinth. Symptoms include tinnitus, deafness, and vertigo. Excessive endolymph accumulation is the suspected cause.

Developmental Aspects of the Special Senses (pp. 595–596)

Taste and Smell (p. 595)

1. The chemical senses are sharpest at birth and gradually decline with age as receptor cells are replaced more slowly.

Vision (p. 595)

2. Congenital eye problems are uncommon, but maternal rubella can cause blindness.
3. The eye starts as an optic vesicle, an outpocketing of the diencephalon that invaginates to form the optic cup, which becomes the retina. Overlying ectoderm folds to form the lens vesicle, which gives rise to the lens. The remaining eye tissues and the accessory structures are formed by mesenchyme.
4. The eye is foreshortened at birth and reaches adult size at the age of 8–9 years. Depth perception and color vision develop before age 3.
5. With age, the lens loses its elasticity and clarity, there is a decline in the ability of the iris to dilate, and visual acuity decreases. The elderly are at risk for eye problems resulting from dry eyes and disease.

Hearing and Balance (p. 596)

6. The membranous labyrinth develops from the otic placode, an ectodermal thickening lateral to the hindbrain. Mesenchyme forms the surrounding bony structures. Pharyngeal pouch endoderm, in conjunction with mesenchyme, forms most middle ear structures; the external ear is formed largely by ectoderm.
7. Congenital ear problems are fairly common. Maternal rubella can cause deafness.
8. Response to sound in infants is reflexive. By the fourth month, an infant can locate sound. Critical listening develops in toddlers.
9. The spiral organ deteriorates throughout life as noise, disease, and drugs destroy cochlear hair cells. Age-related loss of hearing (presbycusis) occurs in the 60s and 70s.

REVIEW QUESTIONS

To access additional practice questions using your smartphone, tablet, or computer: MasteringA&P® > Study Area > Practice Tests & Quizzes

15

Level 1 Remember/Understand

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Accessory glands that produce an oily secretion are the **(a)** conjunctiva, **(b)** lacrimal glands, **(c)** tarsal glands.
2. The portion of the fibrous layer that is white and opaque is the **(a)** choroid, **(b)** cornea, **(c)** retina, **(d)** sclera.
3. Which sequence best describes a normal route for the flow of tears from the eyes into the nasal cavity? **(a)** lacrimal canaliculi, lacrimal sacs, nasolacrimal ducts; **(b)** lacrimal ducts, lacrimal canaliculi, nasolacrimal ducts; **(c)** nasolacrimal ducts, lacrimal canaliculi, lacrimal sacs.
4. The phenomenon of dark adaptation is best explained by the fact that **(a)** rhodopsin does not function in dim light, **(b)** rhodopsin breakdown occurs slowly, **(c)** rods exposed to intense light need time to generate rhodopsin, **(d)** cones are stimulated to function by bright light.
5. Nearsightedness is more properly called **(a)** myopia, **(b)** hyperopia, **(c)** presbyopia, **(d)** emmetropia.
6. Of the neurons in the retina, the axons of which of these form the optic nerve? **(a)** bipolar cells, **(b)** ganglion cells, **(c)** cone cells, **(d)** horizontal cells.
7. Which reactions occur when a person looks at a distant object? **(a)** pupils constrict, ciliary zonule (suspensory ligament) relaxes, lenses become less convex; **(b)** pupils dilate, ciliary zonule becomes taut, lenses become less convex; **(c)** pupils dilate, ciliary zonule becomes taut, lenses become more convex; **(d)** pupils constrict, ciliary zonule relaxes, lenses become more convex.
8. The blind spot of the eye is **(a)** where more rods than cones are found, **(b)** where the macula lutea is located, **(c)** where only cones occur, **(d)** where the optic nerve leaves the eye.
9. Taste buds are found on the **(a)** anterior part of the tongue, **(b)** posterior part of the tongue, **(c)** palate, **(d)** all of these.
10. Olfactory nerve filaments are found **(a)** in the optic bulbs, **(b)** passing through the cribriform plate of the ethmoid bone, **(c)** in the optic tracts, **(d)** in the olfactory cortex.
11. The transmission of sound vibrations through the internal ear occurs chiefly through **(a)** nerve fibers, **(b)** air, **(c)** fluid, **(d)** bone.
12. Which of the following statements does *not* correctly describe the spiral organ? **(a)** Sounds of high frequency stimulate hair cells at the basal end, **(b)** the "hairs" of the receptor cells are embedded in the tectorial membrane, **(c)** the basilar membrane acts as a resonator, **(d)** the more numerous outer hair cells are largely responsible for our perception of sound.
13. The structure that allows pressure in the middle ear to be equalized with atmospheric pressure is the **(a)** pinna, **(b)** pharyngotympanic tube, **(c)** tympanic membrane, **(d)** oval window.
14. Otoliths (ear stones) are **(a)** a cause of deafness, **(b)** a type of hearing aid, **(c)** important in equilibrium, **(d)** the rock-hard petrous part of the temporal bones.
15. How do rods and cones differ functionally?
16. Name the cranial nerves that serve the sense of taste.

Level 2 Apply/Analyze

17. Damage to the medial recti muscles would probably affect **(a)** accommodation, **(b)** refraction, **(c)** convergence, **(d)** pupil constriction.
18. Blockage of the scleral venous sinus might result in **(a)** a sty, **(b)** glaucoma, **(c)** conjunctivitis, **(d)** a cataract.
19. Pitch is to frequency of sound as loudness is to **(a)** quality, **(b)** intensity, **(c)** overtones, **(d)** all of these.
20. Which of the following is important in maintaining the balance of the body? **(a)** visual cues, **(b)** semicircular canals, **(c)** the saccule, **(d)** proprioceptors, **(e)** all of these.
21. Which of the following is not a possible cause of conduction deafness? **(a)** impacted cerumen, **(b)** middle ear infection, **(c)** cochlear nerve degeneration, **(d)** otosclerosis.

22. Why do you often have to blow your nose after crying?
23. Where are the olfactory sensory neurons, and why is that site poorly suited for their job?
24. David Norris, an engineering student, has been working in a nightclub to earn money to pay for his education. After about eight months, he notices that he is having problems hearing high-pitched tones. What is the cause-and-effect relationship here?

Level 3 Evaluate/Synthesize

25. Describe the response of rhodopsin to light stimuli. What is the outcome of this cascade of events?
26. Since there are only three types of cones, how can you explain the fact that we see many more colors?
27. Describe the effect of aging on the special sense organs.
28. During an ophthalmoscopic examination, Mrs. James was found to have bilateral papilledema. Further investigation indicated that this condition resulted from a rapidly growing intracranial tumor. First, define papilledema (see Related Clinical Terms). Then explain its presence in terms of Mrs. James's diagnosis.
29. Maria, a 9-year-old girl, told the clinic physician that her "ear lump hurt" and she kept "getting dizzy and falling down." As she told her story, she pointed to her mastoid process. An otoscopic examination of the external acoustic meatus revealed a red, swollen eardrum, and her throat was inflamed. Her condition was described as mastoiditis with secondary labyrinthitis (inflammation of the labyrinth). Describe the most likely route of infection and the infected structures in Maria's case. Also explain the cause of her dizziness and falling.
30. Mrs. Orlando has been noticing flashes of light and tiny specks in her right visual field. When she begins to see a "veil" floating before her right eye, she makes an appointment to see the eye doctor. What is your diagnosis? Is the condition serious? Explain.
31. Assume that a tumor in the pituitary gland or hypothalamus is protruding inferiorly and compressing the optic chiasma. What could be the visual outcome?
32. Henri, a chef in a five-star French restaurant, has been diagnosed with leukemia. He is about to undergo chemotherapy, which will kill rapidly dividing cells in his body. He needs to continue working between bouts of chemotherapy. What consequences of chemotherapy would you predict that might affect his job as a chef?

CLINICAL CASE STUDY

42-Year-Old Male with Recurring Vertigo

Brian Rhen, 42, has experienced recurring episodes of vertigo and so was referred to a neurologist. (Vertigo is a sensation of motion or movement while the person is stationary, and can be accompanied by nausea and vomiting.)

Mr. Rhen was diagnosed with benign paroxysmal positional vertigo (BPPV). With this condition, which can be caused by head trauma, vertigo can be provoked by specific changes in head position. Mr. Rhen reported that his vertigo usually occurred when rolling over in bed, or when turning his head from side to side while sitting up, and that these movements provoked the sensation of a spinning room, which led to nausea. The neurologist confirmed the diagnosis of BPPV by using a test called the Dix-Hallpike maneuver. During this test, the neurologist looks for nystagmus (involuntary, jerking eye movements) as he makes specific rotational changes to Mr. Rhen's head position.

1. The ear is divided into three major areas (compartments). What are these three areas, and which of these areas is involved in Mr. Rhen's BPPV?
2. ✚ NCLEX-STYLE Which of the following mechanisms is a likely explanation for Mr. Rhen's condition?
   a. Damage to the stereocilia of all the hair cells in his internal ear
   b. Damage to the tectorial membrane
   c. An abnormal buildup of endolymph in the cochlear duct
   d. Dislodged otoliths pressing against a cupula
3. What are the three main sources of sensory input that the body uses in order to control balance and equilibrium?
4. Name the two functional divisions of the vestibular apparatus. Identify the sensory receptor associated with each division, and state which aspect of equilibrium each receptor senses.
5. ✚ NCLEX-STYLE As you discuss Mr. Rhen's condition with him, he makes several statements. Which of these statements indicates the need for further education about his problem?
   a. "I guess this was coming, I always have trouble clearing my ears when I go up in an airplane. This is just the same thing, getting worse."
   b. "My wife always said I had rocks in my head!"
   c. "I was reading this web site called Wobblers Anonymous, and they said my problem could give me some trouble with vision as well."
   d. "I'm afraid I'll get seasick whenever I walk."
6. Explain why nystagmus is associated with the Dix-Hallpike maneuver.

16 The Endocrine System

In this chapter you will learn that

- **16.1 The endocrine system is one of two major control systems of the body**
  - by first examining
    - **16.2 Hormone chemical structure**
      - and asking
        - **16.3 How do hormones act?**
        - **16.4 What stimuli cause hormone release?**
        - **16.5 What determines cell responses to hormones?**
  - then looking at
    - **16.6 The hypothalamus**
      - part of **Central nervous system** Ch. 12
      - controls
        - **The posterior pituitary**
        - **The anterior pituitary**
  - then exploring
    - **16.7 The thyroid gland**
    - **16.8 The parathyroid glands**
    - **16.9 The adrenal glands**
    - **16.10 The pineal gland**
    - and hormones released by
      - **16.11 Organs with other major functions**
    - and finally, exploring

You don't have to watch a blockbuster to experience action-packed drama. Molecules and cells inside your body have dynamic adventures on microscopic levels all the time.

For instance, when insulin molecules carried along in the blood attach to protein receptors of nearby cells, the response is dramatic: Glucose molecules disappear from the blood into the cells, and cellular activity accelerates. Such is the power of the second great control system of the body, the **endocrine system**, which interacts with the nervous system to coordinate and integrate the activity of body cells.

16.1 The endocrine system is one of the body's two major control systems

Learning Outcomes

- **Indicate important differences between hormonal and neural controls of body functioning.**
- **List the major endocrine organs, and describe their body locations.**
- **Distinguish between hormones, paracrines, and autocrines.**

As we have seen, the nervous system regulates the activity of muscles and glands via electrochemical impulses delivered by neurons, and those organs respond within milliseconds. The means of control and speed of the endocrine system are very different: The endocrine system influences metabolic activity by means of *hormones* (*hormone* = to excite). Hormones are chemical messengers secreted by cells into the extracellular fluids. These messengers travel through the blood and regulate the metabolic function of other cells in the body. Binding of a hormone to cellular receptors initiates responses that typically occur after a lag period of seconds or even days. But, once initiated, those responses tend to last much longer than those induced by the nervous system. **Table 16.1** summarizes the differences between the nervous sytem and the endocrine system.

Hormones ultimately target most cells of the body, producing widespread and diverse effects. The major processes that these "mighty molecules" control and integrate include:

- Reproduction
- Growth and development
- Maintenance of electrolyte, water, and nutrient balance of the blood
- Regulation of cellular metabolism and energy balance
- Mobilization of body defenses

As you can see, the endocrine system orchestrates processes that go on for relatively long periods, in some instances continuously. The scientific study of hormones and the endocrine organs is called **endocrinology**.

Compared with other organs, the endocrine system's organs are small and unimpressive, but their influence is powerful.

Table 16.1 Comparison of Nervous and Endocrine Systems

NERVOUS SYSTEM	ENDOCRINE SYSTEM
Initiates responses **rapidly**	Initiates responses **slowly**
Short-duration responses	**Long-duration** responses
Acts via action potentials and **neurotransmitters**	Acts via **hormones** released into the blood
Acts at **specific locations** determined by axon pathways	Acts at **diffuse locations**—targets can be anywhere blood reaches
Neurotransmitters act over very **short distances**	Hormones act over **long distances**

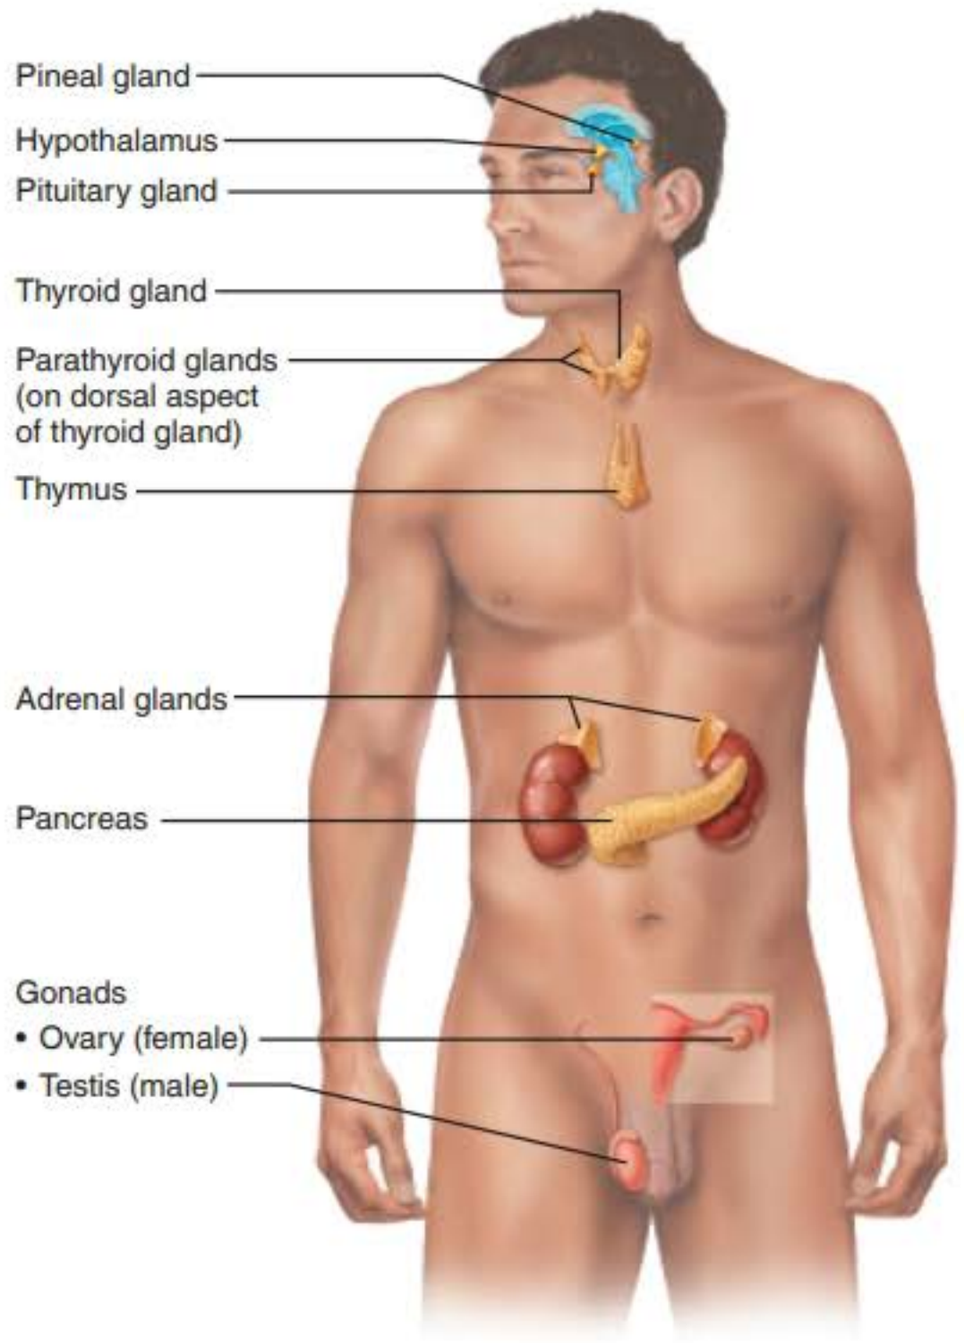

Figure 16.1 Location of selected endocrine organs of the body.

Unlike most organ systems, the endocrine organs are not grouped together but are widely scattered about the body.

As we explained in Chapter 4 (◀ pp. 123–124), there are two kinds of glands:

- *Exocrine glands* produce nonhormonal substances, such as sweat and saliva, and have ducts that carry these substances to a membrane surface.
- **Endocrine glands**, also called *ductless glands*, produce hormones and lack ducts. They release their hormones into the surrounding tissue fluid (*endo* = within; *crine* = to secrete), and typically have a rich vascular and lymphatic drainage that receives their hormones. Most of the hormone-producing cells in endocrine glands are arranged in cords and branching networks, which maximizes contact between them and the surrounding capillaries.

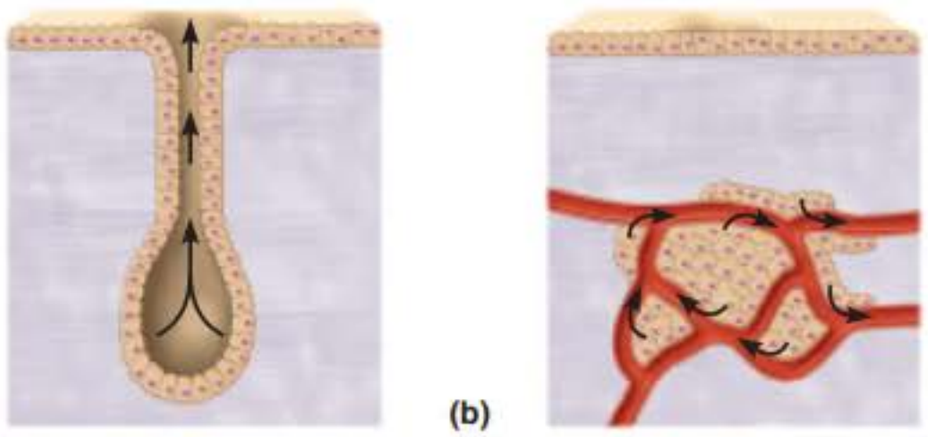
The endocrine glands include the pituitary, thyroid, parathyroid, adrenal, and pineal glands (**Figure 16.1**). The hypothalamus, along with its neural functions, also produces and releases hormones, so we consider the hypothalamus a **neuroendocrine organ**. In addition, several organs, such as the pancreas, gonads (ovaries and testes), and placenta, contain endocrine tissue. Most other organs also contain scattered endocrine cells or small clusters of endocrine cells.

Some physiologists include local chemical messengers—autocrines and paracrines—as part of the endocrine system, but that is not the consensus.

- **Hormones** are long-distance chemical signals that travel in blood or lymph throughout the body.
- **Autocrines** are short-distance chemical signals that exert their effects on the same cells that secrete them. For example, certain prostaglandins released by smooth muscle cells cause those smooth muscle cells to contract.
- **Paracrines** are also short-distance chemical signals. They act locally (within the same tissue) but affect cell types other than those releasing the paracrine chemicals. For example, somatostatin released by one population of pancreatic cells inhibits the release of insulin by a different population of pancreatic cells.

Check Your Understanding

1. For each of the following statements, indicate whether it applies more to the endocrine system or the nervous system: rapid; discrete responses; controls growth and development; long-lasting responses.
2. Which two endocrine glands are found in the neck?
3. What is the difference between a hormone and a paracrine?
4. MAKE CONNECTIONS Which gland below is an endocrine gland and which is an exocrine gland? How can you tell? (Hint: See Chapter 4.)



For answers, see Answers Appendix.

16.2 The chemical structure of a hormone determines how it acts

Learning Outcome

▶ **Describe how hormones are classified chemically.**

A hormone's chemical structure determines one of its critical properties: its solubility in water. Its water solubility in turn affects how that hormone is transported in the blood (which is mostly water), how long it lasts before it is degraded, and what receptors it can act upon. Although a large variety of hormones are produced, nearly all of them can be classified chemically either as based on amino acids or as steroids.

- **Amino acid based:** Most hormones are based on amino acids (◀ p. 48). Molecular size varies widely in this group—from simple amino acid derivatives [which include biogenic amines (e.g., epinephrine), and thyroxine], to peptides (short chains of amino acids), to proteins (long polymers of amino acids). These hormones are usually water soluble and cannot cross the plasma membrane.
- **Steroids:** Steroid hormones are synthesized from cholesterol (◀ pp. 47–48). Of the hormones produced by the major endocrine organs, only gonadal and adrenocortical hormones are steroids. These hormones are all lipid soluble and can cross the plasma membrane.

Some researchers add a third class, **eicosanoids** (i-ko′să-noyds), which include *leukotrienes* and *prostaglandins* (◀ p. 48). Nearly all cell membranes release these biologically active lipids (made from arachidonic acid). Leukotrienes are signaling chemicals that mediate inflammation and some allergic reactions. Prostaglandins have multiple targets and effects, ranging from raising blood pressure and increasing the expulsive uterine contractions of birth to enhancing blood clotting, pain, and inflammation.

Because the effects of eicosanoids are typically highly localized, affecting only nearby cells, they generally act as paracrines and autocrines and do not fit the definition of true hormones, which influence distant targets. For this reason, we will not consider these hormonelike chemicals here, but will discuss them in later chapters as appropriate.

Check Your Understanding

5. MAKE CONNECTIONS Where in the cell are steroid hormones synthesized? (Hint: Recall cell components from Chapter 3.) Where are peptide hormones synthesized? Which of these two types of hormone could be stored in vesicles and released by exocytosis?

For answers, see Answers Appendix.

16

16.3 Hormones act through second messengers or by activating specific genes

Learning Outcome

▶ **Describe the two major mechanisms by which hormones bring about their effects on their target tissues.**

All major hormones circulate to virtually all tissues, but a hormone influences the activity of only those tissue cells that have receptors for it. These cells are its **target cells**. Hormones bring about their characteristic effects by *altering* target cell activity, increasing or decreasing the rates of normal cellular processes.

The precise response depends on the target cell type. For example, when the hormone epinephrine binds to certain smooth muscle cells in blood vessel walls, it stimulates them to contract. Epinephrine binding to cells other than muscle cells does not cause those cells to contract and instead has a totally different effect.

A hormone typically produces one or more of the following changes:

- Alters plasma membrane permeability or membrane potential, or both, by opening or closing ion channels
- Stimulates synthesis of enzymes and other proteins within the cell

- Activates or deactivates enzymes
- Induces secretory activity
- Stimulates mitosis

How does a hormone communicate with its target cell? In other words, how is hormone receptor binding harnessed to the intracellular machinery needed for hormone action? The answer depends on the chemical nature of the hormone and the cellular location of the receptor. In general, hormones act at receptors in one of two ways.

- *Water-soluble hormones* (all amino acid–based hormones except thyroid hormone) act on *receptors in the plasma membrane*. These receptors are usually coupled via regulatory molecules called G proteins to one or more intracellular second messengers, which mediate the target cell's response.
- *Lipid-soluble hormones* (steroid and thyroid hormones) act on *receptors inside the cell*, which directly activate genes.

This will be easy for you to remember if you think about why the hormones must bind where they do. Receptors for water-soluble hormones must be in the plasma membrane since these hormones *cannot* diffuse across the plasma membrane, and receptors for lipid-soluble steroid and thyroid hormones are inside the cell because these hormones *can* diffuse across the plasma membrane into the cell.

16

Plasma Membrane Receptors and Second-Messenger Systems

With the exception of thyroid hormone, amino acid–based hormones exert their signaling effects through intracellular **second messengers** generated when a hormone binds to a receptor in the plasma membrane. You are already familiar with one of these second messengers, **cyclic AMP (cAMP)**, which is used by neurotransmitters (◀ p. 425) and olfactory receptors (◀ p. 577).

The Cyclic AMP Signaling Mechanism

As you recall, this mechanism involves the interaction of three plasma membrane components—a hormone receptor, a G protein, and an effector enzyme (adenylate cyclase)—to determine intracellular levels of cyclic AMP. **Figure 16.2** illustrates these steps:

Watch a 3-D animation of this process: MasteringA&P® > Study Area > Animations & Videos > A&P Flix

1. **Hormone binds receptor.** The hormone, acting as the **first messenger**, binds to its receptor in the plasma membrane.
2. **Receptor activates G protein.** Hormone binding causes the receptor to change shape, allowing it to bind a nearby inactive **G protein**. This in turn allows the G protein to be activated as the guanosine diphosphate (GDP) bound to it is displaced by the high-energy compound *guanosine triphosphate* (*GTP*). The G protein behaves like a light switch: It is "off" when GDP is bound to it, and "on" when GTP is bound.
3. **G protein activates adenylate cyclase.** The activated G protein (moving along the membrane) binds to the effector enzyme **adenylate cyclase**. Some G proteins (G_s) *stimulate* adenylate cyclase (as shown in Figure 16.2), but others (G_i) *inhibit* adenylate cyclase. Eventually, the GTP bound to the G protein is hydrolyzed to GDP and the G protein becomes inactive once again. (The G protein splits the terminal phosphate group off GTP in much the same way that ATPase enzymes hydrolyze ATP.)
4. **Adenylate cyclase converts ATP to cyclic AMP.** For as long as activated G_s is bound to it, adenylate cyclase generates the *second messenger* cAMP from ATP.
5. **Cyclic AMP activates protein kinases.** cAMP, which is free to diffuse throughout the cell, triggers a cascade of chemical reactions by activating protein kinases. **Protein kinases** are enzymes that *phosphorylate* (add a phosphate group to) various proteins, many of which are other enzymes. Because phosphorylation activates some of these proteins and inhibits others, it may affect a variety of processes in the same target cell at the same time.

This type of intracellular enzymatic cascade has a huge amplification effect. Each activated adenylate cyclase generates large numbers of cAMP molecules, and a single kinase enzyme can catalyze hundreds of reactions. As the reaction cascades through one enzyme intermediate after another, the number of product molecules increases dramatically at each step. A single hormone molecule binding to a receptor can generate millions of final product molecules!

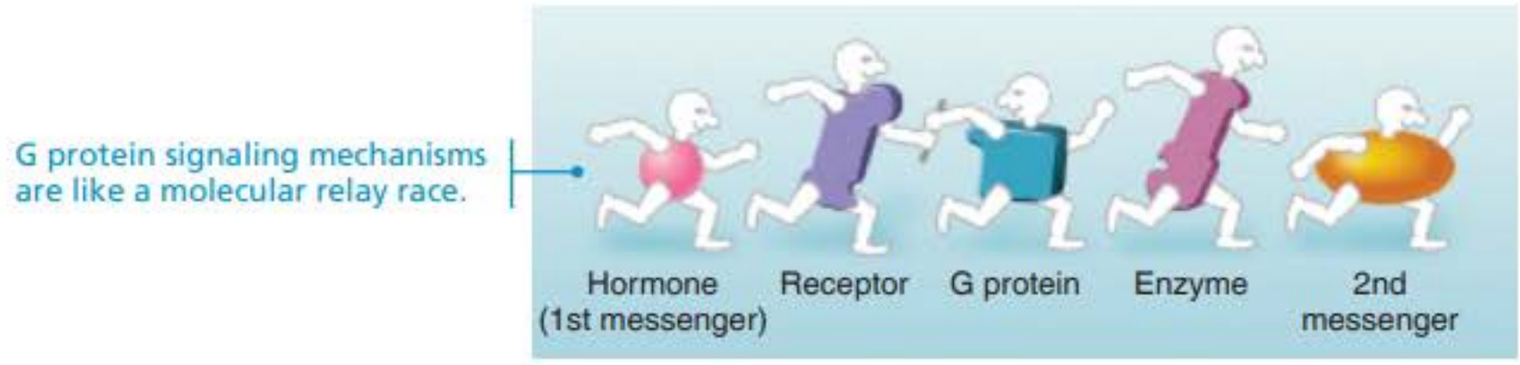
Cyclic AMP is a very common second messenger that has many different effects in many different cells. What determines the effect that cAMP has in a given cell? This is determined by the specific protein kinases that cell contains, and the substrates within that cell available for phosphorylation. For example, a hormone that increases cAMP in thyroid cells triggers the synthesis of the thyroid hormone thyroxine. A hormone that increases cAMP in liver cells, on the other hand, activates enzymes that break down glycogen, releasing glucose to the blood. Since some G proteins inhibit rather than activate adenylate cyclase, thereby reducing the cytoplasmic concentration of cAMP, even slight changes in levels of hormones that have opposite effects on cAMP levels can influence a target cell's activity.

The action of cAMP persists only briefly because the molecule is rapidly degraded by the intracellular enzyme **phosphodiesterase**. While at first glance this may appear to be a problem, it is quite the opposite. Because of the amplification effect, most hormones need to be present only briefly to cause results, and the quick work of phosphodiesterase means that no extracellular controls are necessary to stop the activity.

The PIP_2-Calcium Signaling Mechanism

Certain hormones use second messengers other than cAMP. For example, in the PIP_2-calcium signaling mechanism, intracellular calcium ions act as a second messenger.

Like the cAMP signaling mechanism, the PIP_2-calcium signaling mechanism involves a G protein (G_q) and



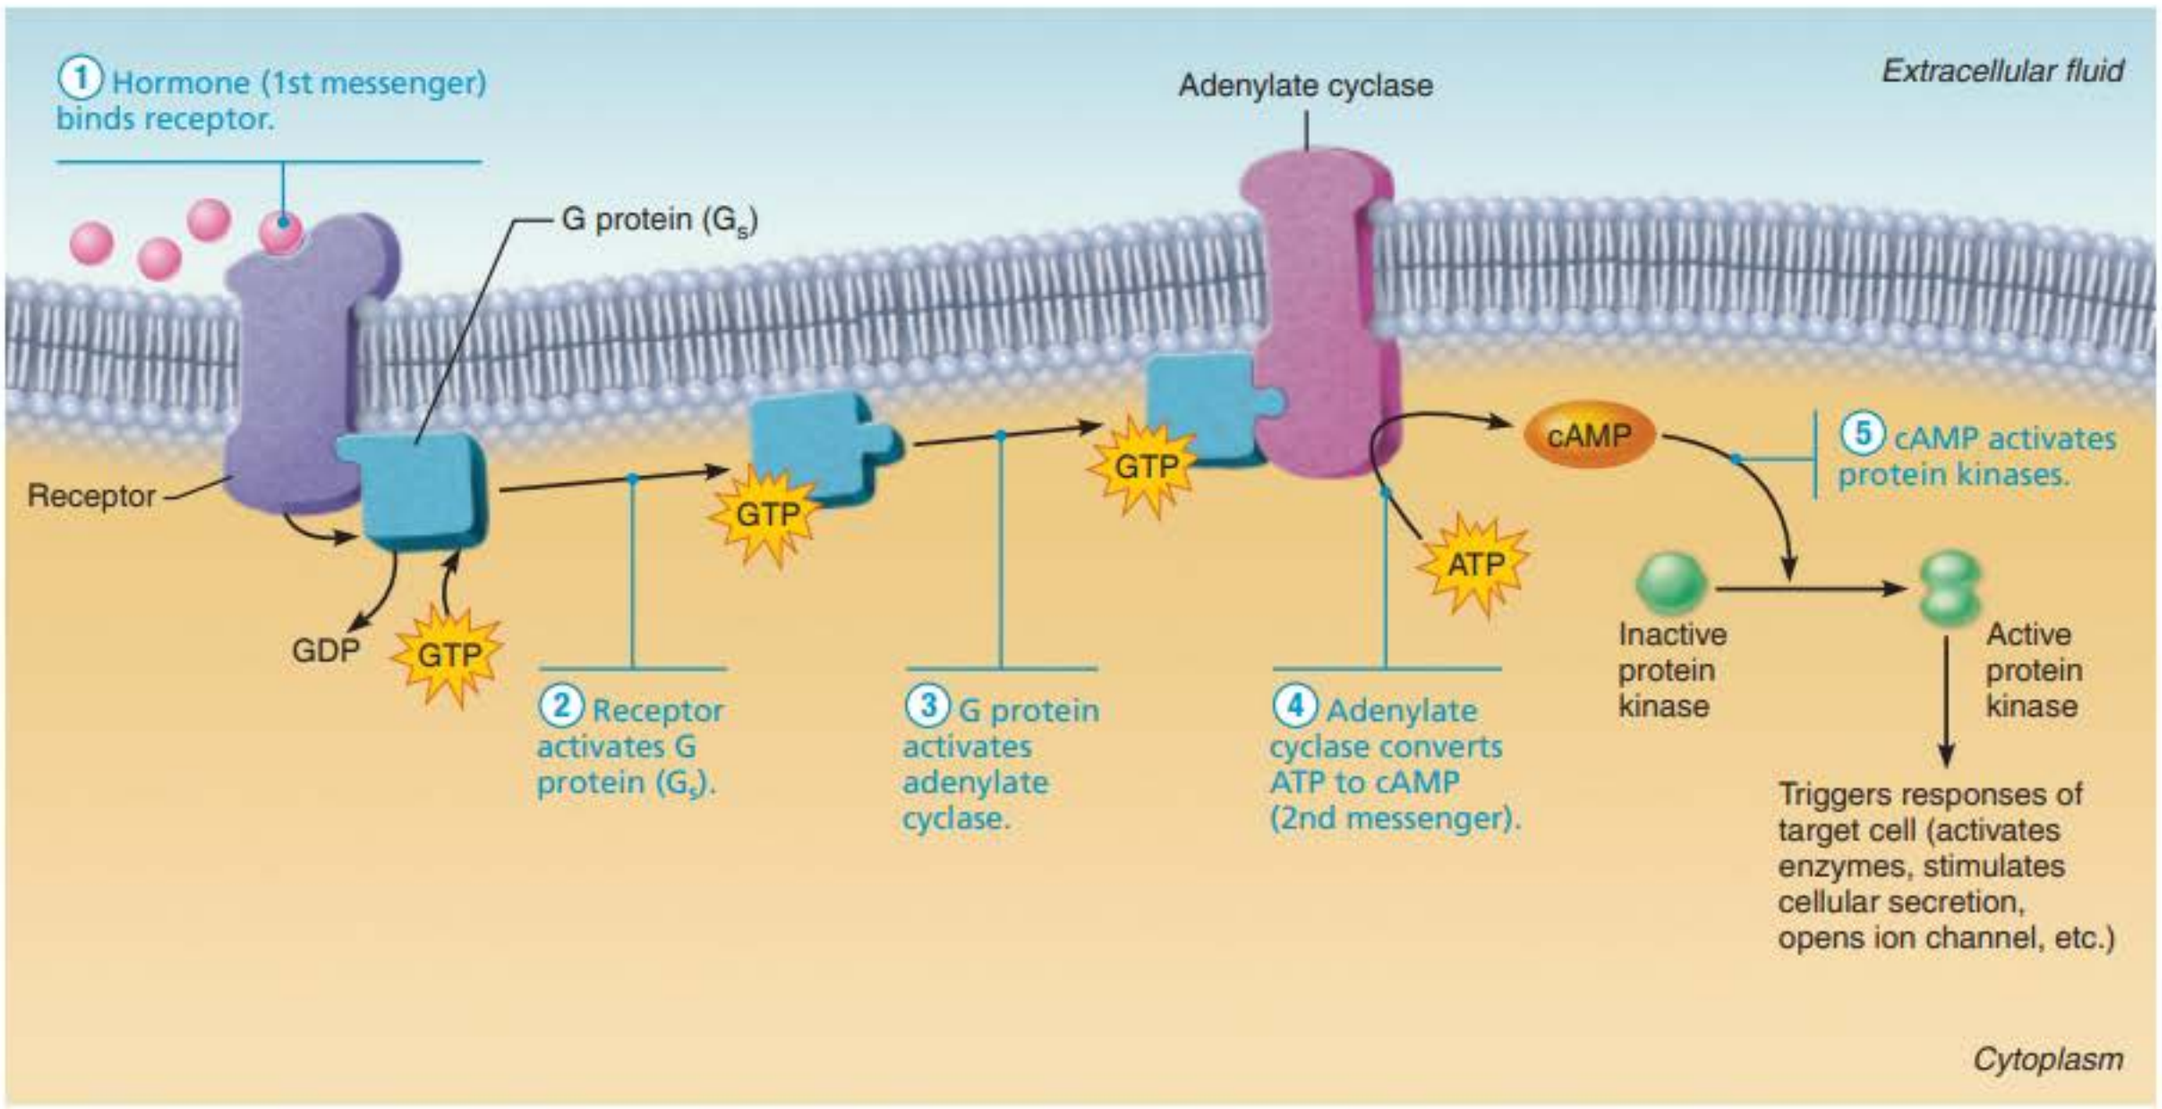


Figure 16.2 Cyclic AMP second-messenger mechanism of water-soluble hormones.
(For the basics of G protein signaling mechanisms, see Focus Figure 3.3 on p. 82.)

a membrane-bound effector, in this case an enzyme called **phospholipase C**. Phospholipase C splits a plasma membrane phospholipid called **PIP_2** (**p**hosphatidyl **i**nositol bis**p**hosphate) into two second messengers: **diacylglycerol (DAG)** and **inositol trisphosphate (IP_3)**. DAG, like cAMP, activates a protein kinase enzyme, which triggers responses within the target cell. In addition, IP_3 releases Ca^{2+} from intracellular storage sites.

The liberated Ca^{2+} also takes on a second-messenger role, either by directly altering the activity of specific enzymes and channels or by binding to the intracellular regulatory protein **calmodulin**. Once Ca^{2+} binds to calmodulin, it activates enzymes that amplify the cellular response.

Other Signaling Mechanisms

Other hormones that bind plasma membrane receptors act on their target cells through different signaling mechanisms. For example, cyclic guanosine monophosphate (cGMP) is a second messenger for selected hormones.

Still other hormones, such as insulin and certain growth factors, work without second messengers. The insulin receptor is a *tyrosine kinase* enzyme that is activated by adding phosphates to several of its own tyrosines when insulin binds. The activated insulin receptor provides docking sites for intracellular *relay proteins* that, in turn, initiate a series of protein phosphorylations that trigger specific cell responses.

Intracellular Receptors and Direct Gene Activation

Unlike water-soluble hormones, the lipid-soluble steroid hormones and thyroid hormone are able to diffuse through the plasma membrane into their target cells. There, they bind to and activate intracellular receptors (**Figure 16.3**). The activated receptor-hormone complex then makes its way to the nuclear chromatin and binds to a specific region of DNA. (There are exceptions to these generalizations. For example, thyroid hormone receptors are always bound to DNA even in the absence of thyroid hormone.)

When the receptor-hormone complex binds to DNA, it "turns on" a gene; that is, it prompts transcription of DNA to produce a messenger RNA (mRNA). The mRNA is then translated on the cytoplasmic ribosomes, producing specific proteins. These proteins include enzymes that promote the metabolic activities induced by that particular hormone and, in some cases, promote synthesis of either structural proteins or proteins to be exported from the target cell.

Check Your Understanding

6. Which class of hormones consists entirely of lipid-soluble hormones? Name the only hormone in the other chemical class that is lipid soluble.
7. DRAW Make a simple drawing of a cell. Draw and label a receptor for a lipid-soluble hormone and one for a water-soluble hormone in their correct locations in the cell. State what happens as a result of a hormone binding to each receptor.

For answers, see Answers Appendix.

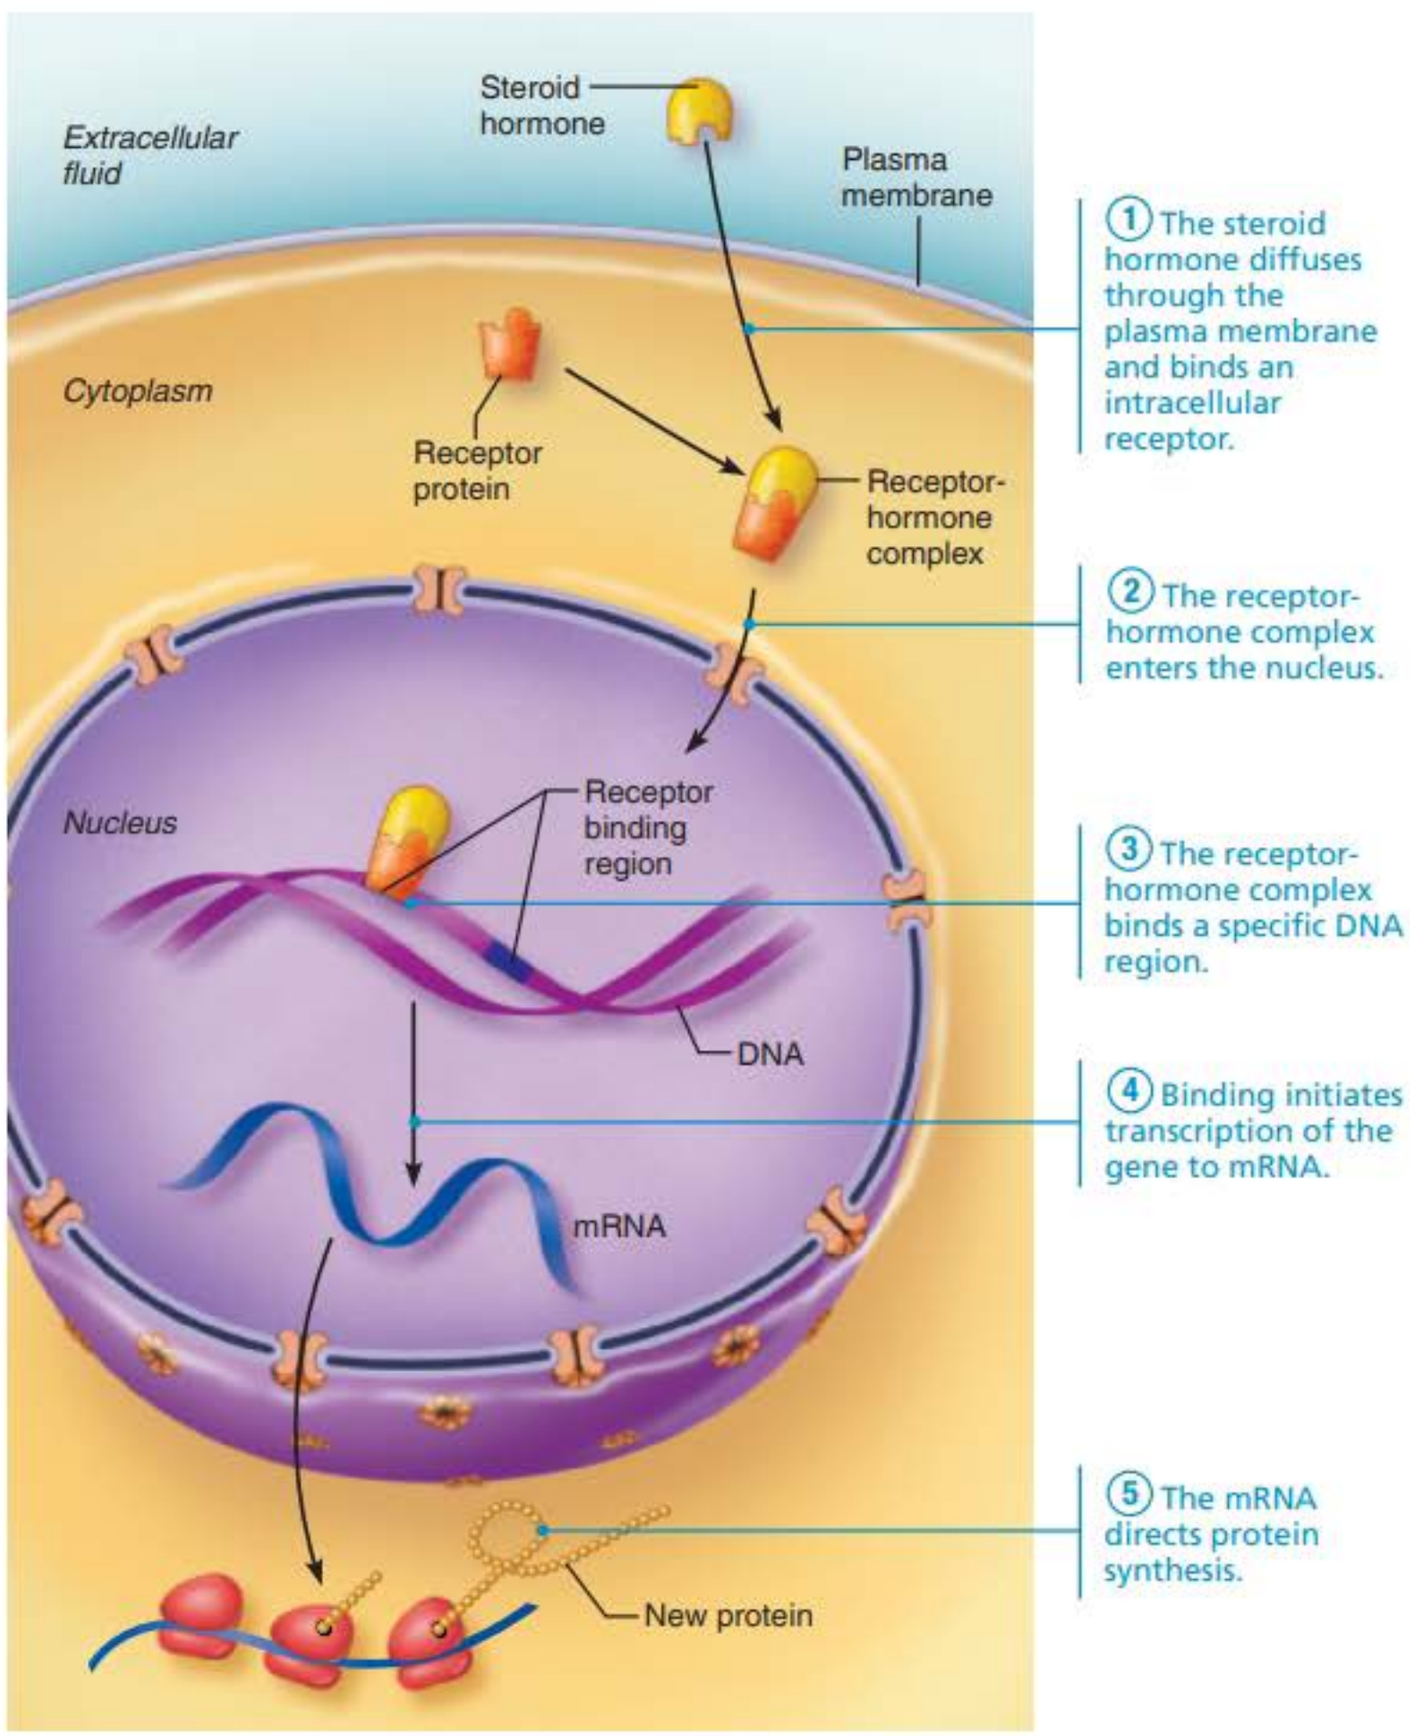

Figure 16.3 Direct gene activation mechanism of lipid-soluble hormones. Receptors may be located in the nucleus, or in the cytoplasm as shown.

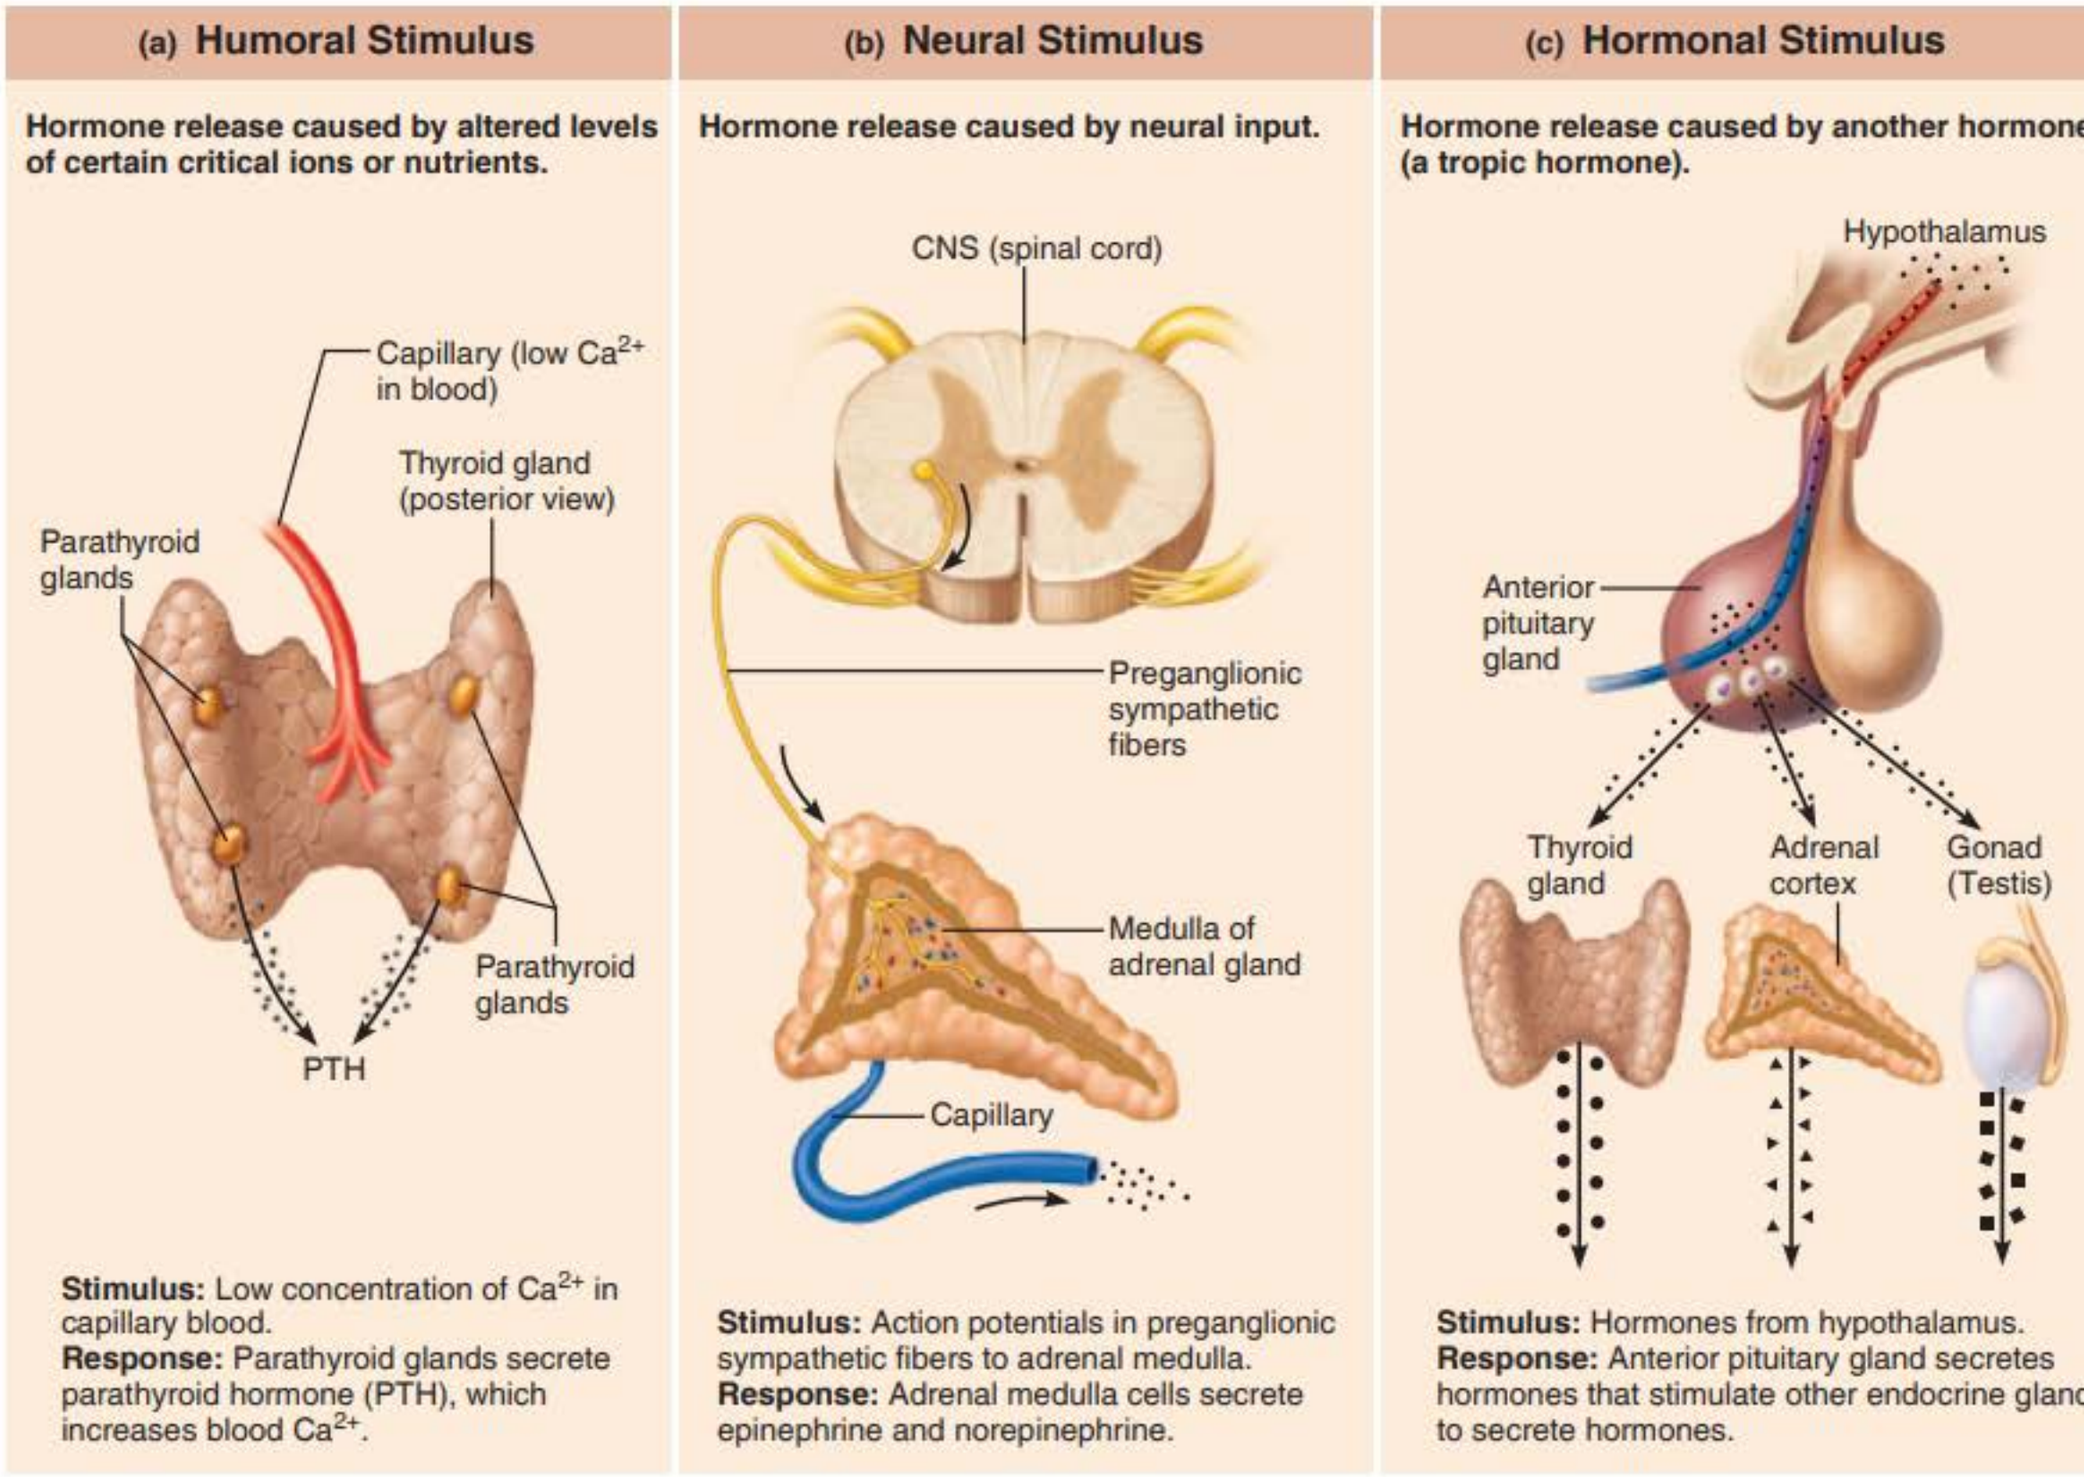

Figure 16.4 Three types of endocrine gland stimuli.

16.4 Three types of stimuli cause hormone release

Learning Outcome

- **Explain how hormone release is regulated.**

The synthesis and release of most hormones are regulated by some type of **negative feedback mechanism** (◀ p. 10). In such a mechanism, some internal or external stimulus triggers hormone secretion. As levels of a hormone rise, it causes target organ effects, which then feed back to inhibit further hormone release. As a result, blood levels of many hormones vary only within a narrow range.

Endocrine Gland Stimuli

Three types of stimuli trigger endocrine glands to manufacture and release their hormones: *humoral* (hu′mer-ul), *neural*, and *hormonal stimuli*. Some endocrine organs respond to more than one type of stimulus.

Humoral Stimuli

Some endocrine glands secrete their hormones in direct response to changing blood levels of certain critical ions and nutrients. These stimuli are called *humoral stimuli* (from the Latin term *humor*, which refers to moisture or bodily fluids).

Humoral stimuli are the simplest endocrine controls. For example, cells of the parathyroid glands monitor the body's crucial blood Ca^{2+} levels and release parathyroid hormone as needed (**Figure 16.4a**). Other hormones released in response to humoral stimuli include insulin (released in response to increased blood glucose) and aldosterone (released in response to low Na^+ or high K^+ blood levels).

Neural Stimuli

In a few cases, nerve fibers stimulate hormone release. The classic example of neural stimuli is the response to stress, in which the sympathetic nervous system stimulates the adrenal medulla to release norepinephrine and epinephrine (Figure 16.4b).

Hormonal Stimuli

Many endocrine glands release their hormones in response to hormones produced by other endocrine organs. For example,

releasing and inhibiting hormones produced by the hypothalamus regulate the secretion of most anterior pituitary hormones, and many anterior pituitary hormones in turn stimulate other endocrine organs to release their hormones (Figure 16.4c). As blood levels of the hormones produced by the final target glands increase, they inhibit the release of anterior pituitary hormones and thus their own release.

This hypothalamic–pituitary–target endocrine organ feedback loop lies at the very core of endocrinology, and it will come up many times in this chapter. Hormonal stimuli promote rhythmic hormone release, with hormone blood levels rising and falling in a specific pattern.

Nervous System Modulation

The nervous system can modify both "turn-on" factors (hormonal, humoral, and neural stimuli) and "turn-off" factors (feedback inhibition and others) that affect the endocrine system. Without this added safeguard, endocrine system activity would be strictly mechanical, much like a household thermostat. A thermostat can maintain the temperature at or around its set value, but it cannot sense that your grandmother visiting from Florida feels cold at that temperature and reset itself accordingly. You must make that adjustment. In your body, it is the nervous system that makes certain adjustments to maintain homeostasis by overriding normal endocrine controls.

For example, the action of insulin and several other hormones normally keeps blood glucose levels in the range of 90–110 mg/100 ml of blood. However, when your body is under severe stress, blood glucose levels rise because the hypothalamus and sympathetic nervous system centers are strongly activated. In this way, the nervous system ensures that body cells have sufficient fuel in case vigorous activity is required.

Check Your Understanding

8. What are the three types of stimuli that control hormone release?

For answers, see Answers Appendix.

16.5 Cells respond to a hormone if they have a receptor for that hormone

Learning Outcomes

- **Identify factors that influence activation of a target cell by a hormone.**
- **List three kinds of interaction of different hormones acting on the same target cell.**

In order for a target cell to respond to a hormone, the cell must have *specific* receptor proteins on its plasma membrane or in its interior to which that hormone can bind. For example, receptors for adrenocorticotropic hormone (ACTH) are normally found only on certain cells of the adrenal cortex. By contrast, thyroxine is the principal hormone stimulating cellular metabolism, and nearly all body cells have thyroxine receptors.

A hormone receptor responds to hormone binding by prompting the cell to perform, or turn on, some gene-determined "preprogrammed" function. As such, hormones are molecular triggers rather than informational molecules. Although binding of a hormone to a receptor is *required*, the degree of target cell activation depends equally on three other factors:

- Blood levels of the hormone
- Relative numbers of receptors for that hormone on or in the target cells
- *Affinity* (strength) of the binding between the hormone and the receptor

The first two factors change rapidly in response to various stimuli and changes within the body. As a rule, for a given level of hormone in the blood, having a large number of high-affinity receptors produces a pronounced hormonal effect, and having a smaller number of low-affinity receptors reduces the target cell response or causes outright endocrine dysfunction.

Receptors are dynamic structures. For example, persistently low levels of a hormone can cause its target cells to form additional receptors for that hormone. This is called **up-regulation**. Likewise, prolonged exposure to high hormone concentrations can decrease the number of receptors for that hormone. This **down-regulation** desensitizes the target cells, so they respond less vigorously to hormonal stimulation, preventing them from overreacting to persistently high hormone levels. Receptors can also be uncoupled from their signaling mechanism, altering the sensitivity of the response.

Hormones influence not only the number of their own receptors but also the number of receptors that respond to other hormones. For example, progesterone down-regulates estrogen receptors in the uterus, thus antagonizing estrogens' actions. On the other hand, estrogens cause the same cells to produce more progesterone receptors, enhancing their ability to respond to progesterone.

Half-Life, Onset, and Duration of Hormone Activity

Hormones are potent chemicals, and they exert profound effects on their target organs even at very low concentrations. Hormones circulate in the blood in two forms—free, or bound to a protein carrier. In general, lipid-soluble hormones (steroids and thyroid hormone) are not water soluble. As a result, they must travel in blood attached to proteins of the blood plasma (*plasma proteins*). Most others circulate without carriers.

The concentration of a circulating hormone in blood at any time reflects (1) its rate of release and (2) the speed at which it is inactivated and removed from the body. Some hormones are rapidly degraded by enzymes in their target cells. However, most hormones are removed from the blood by the kidneys or liver, and the body excretes their breakdown products in urine or, to a lesser extent, in feces. As a result, the length of time for a hormone's blood level to decrease by half, referred to as its **half-life**, varies from a fraction of a minute to a week. Water-soluble hormones have the shortest half-lives because they are rapidly removed from the blood by the kidneys.

How long does it take for a hormone to have an effect? It varies. Some hormones provoke target organ responses almost immediately, while others, particularly steroid hormones,

Table 16.2 Comparison between Lipid- and Water-Soluble Hormones

	LIPID-SOLUBLE HORMONES	WATER-SOLUBLE HORMONES
Consist of	All steroid hormones and thyroid hormone	All amino acid–based hormones except thyroid hormone
Sources	Adrenal cortex, gonads, and thyroid gland	All other endocrine glands
Stored in secretory vesicles	No	Yes
Transport in blood	Bound to plasma proteins	Usually free in plasma
Half-life in blood	Long (most need to be metabolized by liver)	Short (most can be removed by kidneys)
Location of receptors	Usually inside cell	On plasma membrane
Mechanism of action at target cell	Activate genes, causing synthesis of new proteins	Usually act through second-messenger systems

require hours to days before their effects are seen. Additionally, some hormones are secreted in a relatively inactive form and must be activated in the target cells.

The duration of hormone action is limited, ranging from 10 seconds to several hours. Effects may disappear rapidly as blood levels drop, or they may persist for hours even at very low levels. Because of these many variations, hormonal blood levels must be precisely and individually controlled to meet the continuously changing needs of the body.

As you can see, many characteristics of a hormone (such as its half-life and the time it takes to have an effect) depend on its solubility in water or lipids. **Table 16.2** compares the characteristics of lipid- and water-soluble hormones.

Interaction of Hormones at Target Cells

Understanding hormonal effects is a bit more complicated than you might expect because multiple hormones may act on the same target cells at the same time. In many cases the result of such an interaction is not predictable, even when you know the effects of the individual hormones. Here we will look at three types of hormone interaction—permissiveness, synergism, and antagonism.

- **Permissiveness** is the situation in which one hormone cannot exert its full effects without another hormone being present. For example, reproductive system hormones largely regulate the development of the reproductive system, as we might expect. However, thyroid hormone is also necessary (has a permissive effect) for normal *timely* development of reproductive structures. Lack of thyroid hormone delays reproductive development.
- **Synergism** occurs when more than one hormone produces the same effects at the target cell and their combined effects are amplified. For example, both glucagon and epinephrine cause the liver to release glucose to the blood. When they act together, the amount of glucose released is about 150% of what is released if each hormone acts independently.
- **Antagonism** occurs when one hormone opposes the action of another. For example, insulin, which lowers blood glucose levels, is antagonized by glucagon, which raises blood glucose levels. How does antagonism occur? Antagonists may compete for the same receptors, act through different metabolic pathways, or even cause down-regulation of the receptors for the antagonistic hormone.

Check Your Understanding

9. Which type of hormone generally stays in the blood longer following its secretion, lipid soluble or water soluble?

For answers, see Answers Appendix.

16.6 The hypothalamus controls release of hormones from the pituitary gland in two different ways

Learning Outcomes

- **Describe structural and functional relationships between the hypothalamus and the pituitary gland.**
- **Discuss the structure of the posterior pituitary, and describe the effects of the two hormones it releases.**
- **List and describe the chief effects of anterior pituitary hormones.**

Securely seated in the sella turcica of the sphenoid bone (◀ p. 209), the tiny **pituitary gland**, or **hypophysis** (hi-pof′ĭ-sis; "to grow under"), secretes at least eight hormones. This gland is the size and shape of a pea on a stalk. Its stalk, the funnel-shaped **infundibulum**, connects the gland to the hypothalamus superiorly as shown in *Focus on Hypothalamus and Pituitary Interactions* (**Focus Figure 16.1** on pp. 610–611).

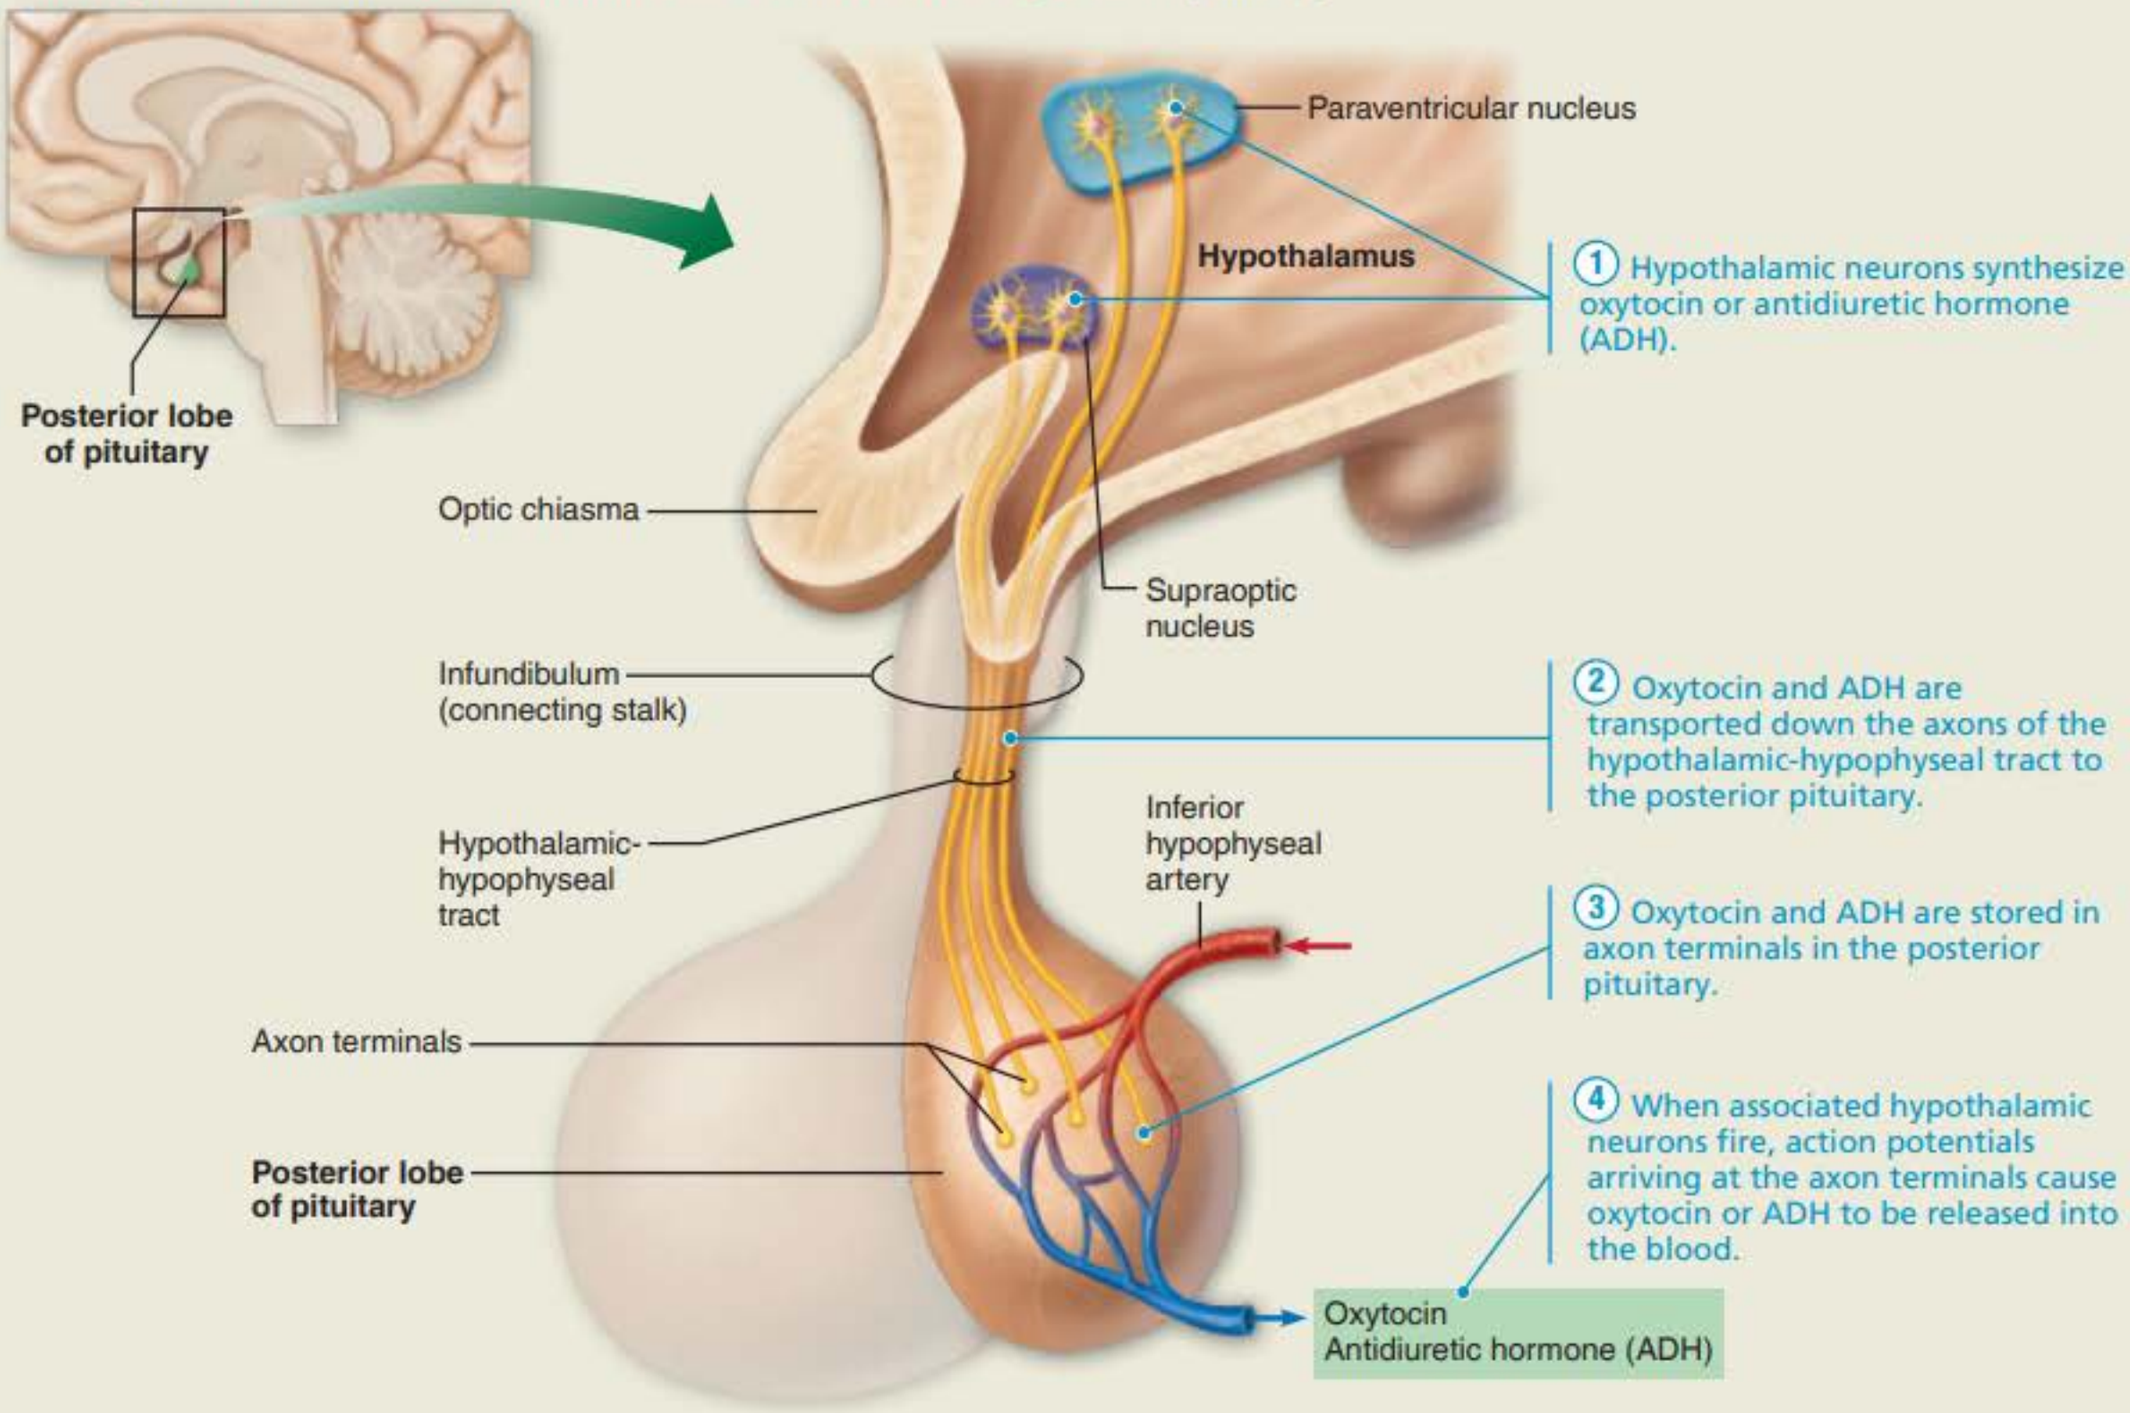
In humans, the pituitary gland has two major lobes.

- The **posterior pituitary** (lobe) is composed largely of neural tissue such as pituicytes (glia-like supporting cells) and nerve fibers. It releases **neurohormones** (hormones secreted by neurons) received ready-made from the hypothalamus. Consequently, this lobe is a hormone-storage area and not a true endocrine gland that manufactures hormones. The posterior lobe plus the infundibulum make up the region called the **neurohypophysis** (nu″ro-hi-pof′ĭ-sis).
- The **anterior pituitary** (lobe), or **adenohypophysis** (ad″ĕ-no-hi-pof′ĭ-sis), is composed of glandular tissue (*adeno* =

FOCUS FIGURE 16.1 Hypothalamus and Pituitary Interactions

The hypothalamus controls release of hormones from the pituitary gland in two different ways.

Posterior Pituitary: *Action potentials* travel down the axons of hypothalamic neurons, causing hormone release from their axon terminals in the posterior pituitary.



gland). It manufactures and releases a number of hormones (**Table 16.3** on pp. 612–613).

Hypophyseal branches of the internal carotid arteries deliver arterial blood to the pituitary. The veins leaving the pituitary drain into the dural sinuses.

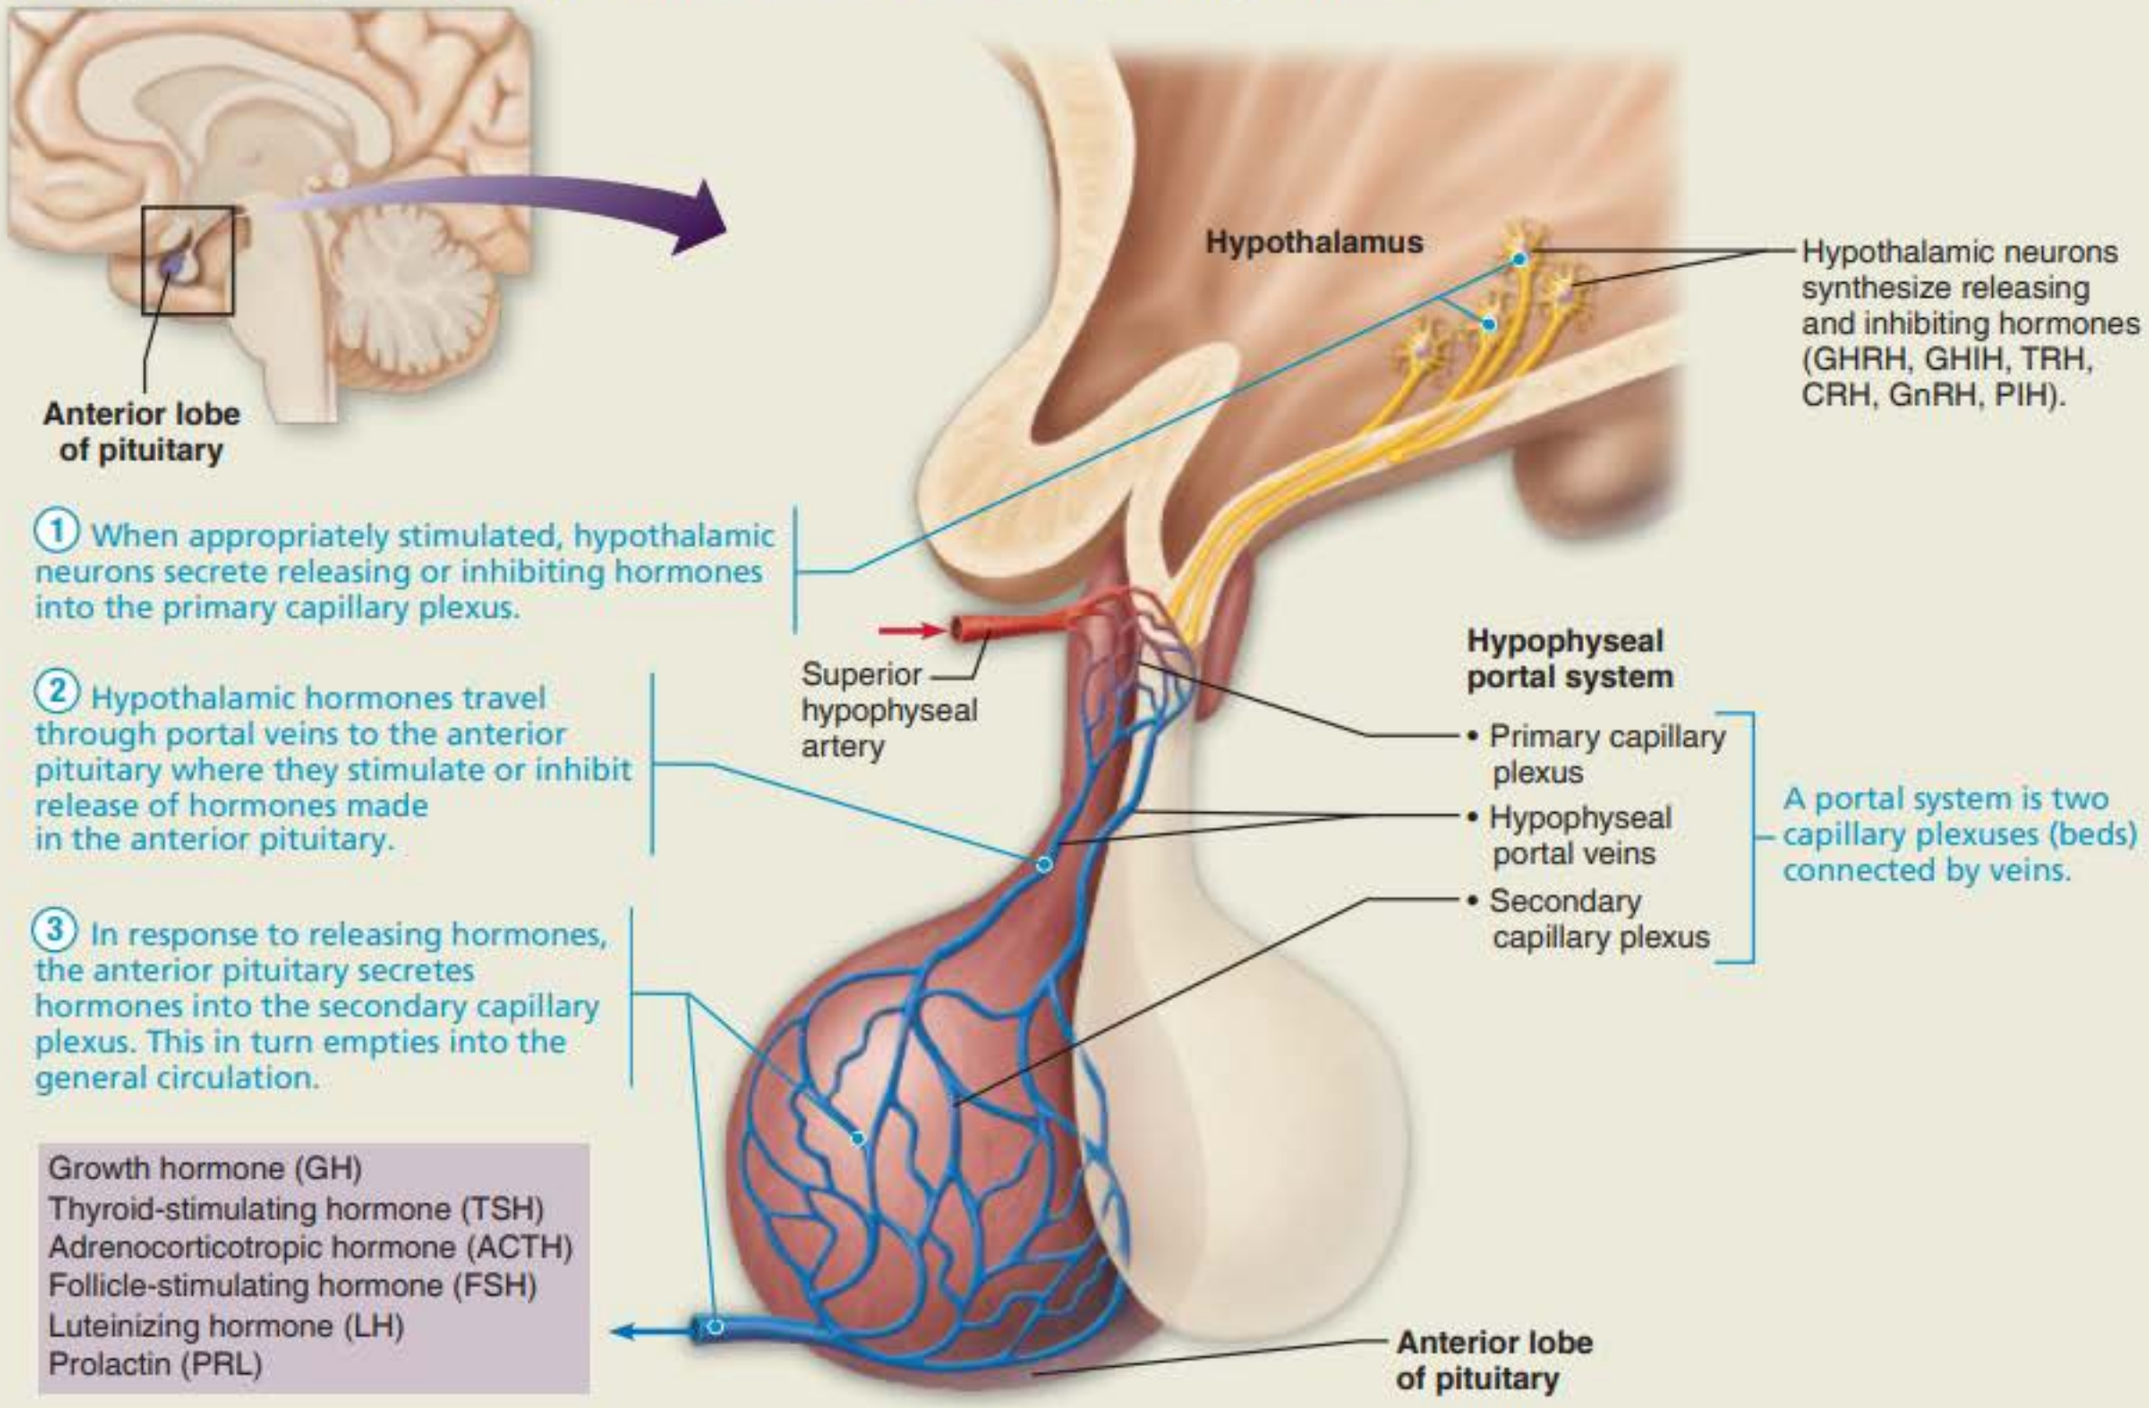
Pituitary-Hypothalamic Relationships

The contrasting histology of the two pituitary lobes reflects the dual origin of this tiny gland during embryonic development. The posterior lobe is actually part of the brain. It derives from hypothalamic tissue that grows downward, maintaining its neural connection with the hypothalamus via a bundle of axons called the **hypothalamic-hypophyseal tract**. This tract runs through the infundibulum (Focus Figure 16.1).

This tract arises from neurons in the **paraventricular** and **supraoptic nuclei** of the hypothalamus. These neurosecretory cells synthesize one of two neurohormones and transport them along their axons to the posterior pituitary. When these hypothalamic neurons fire, they release the stored hormones into a capillary bed in the posterior pituitary for distribution throughout the body.

The glandular anterior lobe originates from epithelial tissue as a superior outpocketing of the oral mucosa. After touching the posterior lobe, the anterior lobe adheres to the neurohypophysis and loses its connection with the oral mucosa. There is no direct neural connection between the anterior lobe and hypothalamus, but there is a vascular connection. Specifically, the **primary capillary plexus** in the infundibulum communicates inferiorly via the small **hypophyseal portal veins** with a

Anterior Pituitary: *Hypothalamic hormones* released into special blood vessels (the hypophyseal portal system) control the release of anterior pituitary hormones.



secondary capillary plexus in the anterior lobe. The primary and secondary capillary plexuses and the intervening hypophyseal portal veins make up the *hypophyseal portal system* (Focus Figure 16.1). Note that a *portal system* is an unusual arrangement of blood vessels in which a capillary bed feeds into veins, which in turn feed into a second capillary bed.

Via the hypophyseal portal system, **releasing** and **inhibiting hormones** secreted by neurons in the ventral hypothalamus circulate to the anterior pituitary, where they regulate secretion of its hormones. The portal system ensures that the minute quantities of hormones released by the hypothalamus arrive rapidly at the anterior pituitary without being diluted by the systemic circulation. All these hypothalamic regulatory hormones are amino acid based, but they vary in size from a single amine to peptides to proteins.

The Posterior Pituitary and Hypothalamic Hormones

The posterior pituitary consists largely of axon terminals of hypothalamic neurons whose cell bodies are located in the supraoptic or paraventricular nuclei. The paraventricular neurons primarily make oxytocin (ok″sĭ-to′sin), and the supraoptic neurons mainly produce antidiuretic hormone (ADH). Axon terminals in the posterior pituitary release these hormones "on demand" in response to action potentials that travel down the axons of these same hypothalamic neurons.

Oxytocin and ADH, each composed of nine amino acids, are almost identical. They differ in only two amino acids, and yet they have dramatically different physiological effects, summarized in Table 16.3 and described next.

Table 16.3 Pituitary Hormones: Summary of Regulation and Effects

HORMONE (CHEMICAL STRUCTURE AND CELL TYPE)	REGULATION OF RELEASE	TARGET ORGAN AND EFFECTS	EFFECTS OF HYPOSECRETION ↓ AND HYPERSECRETION ↑
Posterior Pituitary Hormones (Made by Hypothalamic Neurons and Stored in Posterior Pituitary)			
Oxytocin (Peptide, mostly from neurons in paraventricular nucleus of hypothalamus)	**Stimulated** by impulses from hypothalamic neurons in response to stretching of the uterine cervix or suckling of infant at breast **Inhibited** by lack of appropriate neural stimuli	 Uterus: stimulates uterine contractions; initiates labor Breast: initiates milk ejection	Unknown
Antidiuretic hormone (ADH) or vasopressin (Peptide, mostly from neurons in supraoptic nucleus of hypothalamus)	**Stimulated** by impulses from hypothalamic neurons in response to increased blood solute concentration or decreased blood volume; also stimulated by pain, some drugs, low blood pressure **Inhibited** by adequate hydration of the body and by alcohol	 Kidneys: stimulate kidney tubule cells to reabsorb water from the forming urine back into blood	↓: Diabetes insipidus ↑: Syndrome of inappropriate ADH secretion (SIADH)
Anterior Pituitary Hormones			
Growth hormone (GH) (Protein, somatotropic cells)	**Stimulated** by GHRH* release, which is triggered by low blood levels of GH as well as by a number of secondary triggers including deep sleep, hypoglycemia, increases in blood levels of amino acids, low levels of fatty acids, exercise, and other types of stressors **Inhibited** by feedback inhibition exerted by GH and insulin-like growth factors (IGFs), and by hyperglycemia, hyperlipidemia, obesity, and emotional deprivation via either increased GHIH* (somatostatin) or decreased GHRH* release	 Liver, muscle, bone, cartilage, and other tissues: anabolic hormone; stimulates somatic growth; mobilizes fats; spares glucose Growth-promoting effects mediated indirectly by IGFs	↓: Pituitary dwarfism in children ↑: Gigantism in children; acromegaly in adults

Oxytocin

A strong stimulant of uterine contraction, **oxytocin** is released in significantly higher amounts during childbirth (*oxy* = rapid; *tocia* = childbirth) and in nursing women. The number of oxytocin receptors in the uterus peaks near the end of pregnancy, and uterine smooth muscle becomes more and more sensitive to the hormone's stimulatory effects. Stretching of the cervix of the uterus as birth nears dispatches afferent impulses to the hypothalamus. The hypothalamus responds by synthesizing oxytocin and triggering its release from the posterior pituitary. Oxytocin acts via the PIP_2-Ca^{2+} second-messenger system to mobilize Ca^{2+}, allowing stronger contractions. As blood levels of oxytocin rise, the expulsive contractions of labor gain momentum and finally end in birth.

Oxytocin also acts as the hormonal trigger for milk ejection (the "letdown" reflex) in women whose breasts are producing milk in response to prolactin. Suckling causes a reflex-initiated release of oxytocin, which targets specialized myoepithelial cells surrounding the milk-producing glands. These cells contract and force milk from the breast into the infant's mouth. Both childbirth and milk ejection result from *positive feedback mechanisms*, which Chapter 28 describes in more detail.

Table 16.3 *(continued)*

HORMONE (CHEMICAL STRUCTURE AND CELL TYPE)	REGULATION OF RELEASE	TARGET ORGAN AND EFFECTS	EFFECTS OF HYPOSECRETION ↓ AND HYPERSECRETION ↑
Thyroid-stimulating hormone (TSH) (Glycoprotein, thyrotropic cells)	**Stimulated** by TRH* and in infants indirectly by cold temperature **Inhibited** by feedback inhibition exerted by thyroid hormones on anterior pituitary and hypothalamus and by GHIH*	 Thyroid gland: stimulates thyroid gland to release thyroid hormones	↓: Hypothyroidism; may cause myxedema ↑: Hyperthyroidism; effects similar to those of Graves' disease, in which antibodies mimic TSH
Adrenocorticotropic hormone (ACTH) (Peptide, corticotropic cells)	**Stimulated** by CRH*; stimuli that increase CRH release include fever, hypoglycemia, and other stressors **Inhibited** by feedback inhibition exerted by glucocorticoids	 Adrenal cortex: promotes release of glucocorticoids and androgens (mineralocorticoids to a lesser extent)	↓: Rare ↑: Cushing's disease
Follicle-stimulating hormone (FSH) (Glycoprotein, gonadotropic cells)	**Stimulated** by GnRH* **Inhibited** by feedback inhibition exerted by inhibin, and estrogens in females and testosterone in males	 Ovaries and testes: in females, stimulates ovarian follicle maturation and production of estrogens; in males, stimulates sperm production	↓: Failure of sexual maturation ↑: No important effects
Luteinizing hormone (LH) (Glycoprotein, gonadotropic cells)	**Stimulated** by GnRH* **Inhibited** by feedback inhibition exerted by estrogens and progesterone in females and testosterone in males	 Ovaries and testes: in females, triggers ovulation and stimulates ovarian production of estrogens and progesterone; in males, promotes testosterone production	As for FSH
Prolactin (PRL) (Protein, prolactin cells)	**Stimulated** by decreased PIH*; release enhanced by estrogens, birth control pills, breast-feeding, and dopamine-blocking drugs **Inhibited** by PIH* (dopamine)	 Breast secretory tissue: promotes lactation	↓: Poor milk production in nursing women ↑: Inappropriate milk production (galactorrhea); cessation of menses in females; impotence in males

*Indicates hypothalamic releasing and inhibiting hormones: GHRH = growth hormone–releasing hormone; GHIH = growth hormone–inhibiting hormone; TRH = thyrotropin-releasing hormone; CRH = corticotropin-releasing hormone; GnRH = gonadotropin-releasing hormone; PIH = prolactin-inhibiting hormone

Both natural and synthetic oxytocic drugs are used to induce labor or to hasten labor that is progressing slowly. Less frequently, oxytocic drugs are used to stop postpartum bleeding.

Oxytocin also acts as a neurotransmitter in the brain. There, it is involved in sexual and affectionate behavior (as the "cuddle hormone"), and promotes nurturing, couple bonding, and trust.

Antidiuretic Hormone (ADH)

Diuresis (di″u-re′sis) is urine production, so an *antidiuretic* is a substance that inhibits or prevents urine formation. **Antidiuretic hormone (ADH)** prevents wide swings in water balance, helping the body avoid dehydration and water overload.

Hypothalamic neurons called *osmoreceptors* continually monitor the solute concentration (and thus the water concentration) of the blood. When solutes threaten to become too concentrated (as might follow excessive perspiration or inadequate fluid intake), the osmoreceptors transmit excitatory impulses to the hypothalamic neurons, which release ADH. ADH targets the kidney tubule cells, which respond by reabsorbing more water from the forming urine and returning it to the bloodstream. As a result, less urine is produced and the solute concentration of the blood declines. As solute levels fall, the osmoreceptors stop depolarizing, effectively ending ADH release. Other stimuli triggering ADH release include pain, low blood pressure, and such drugs as nicotine, morphine, and barbiturates.

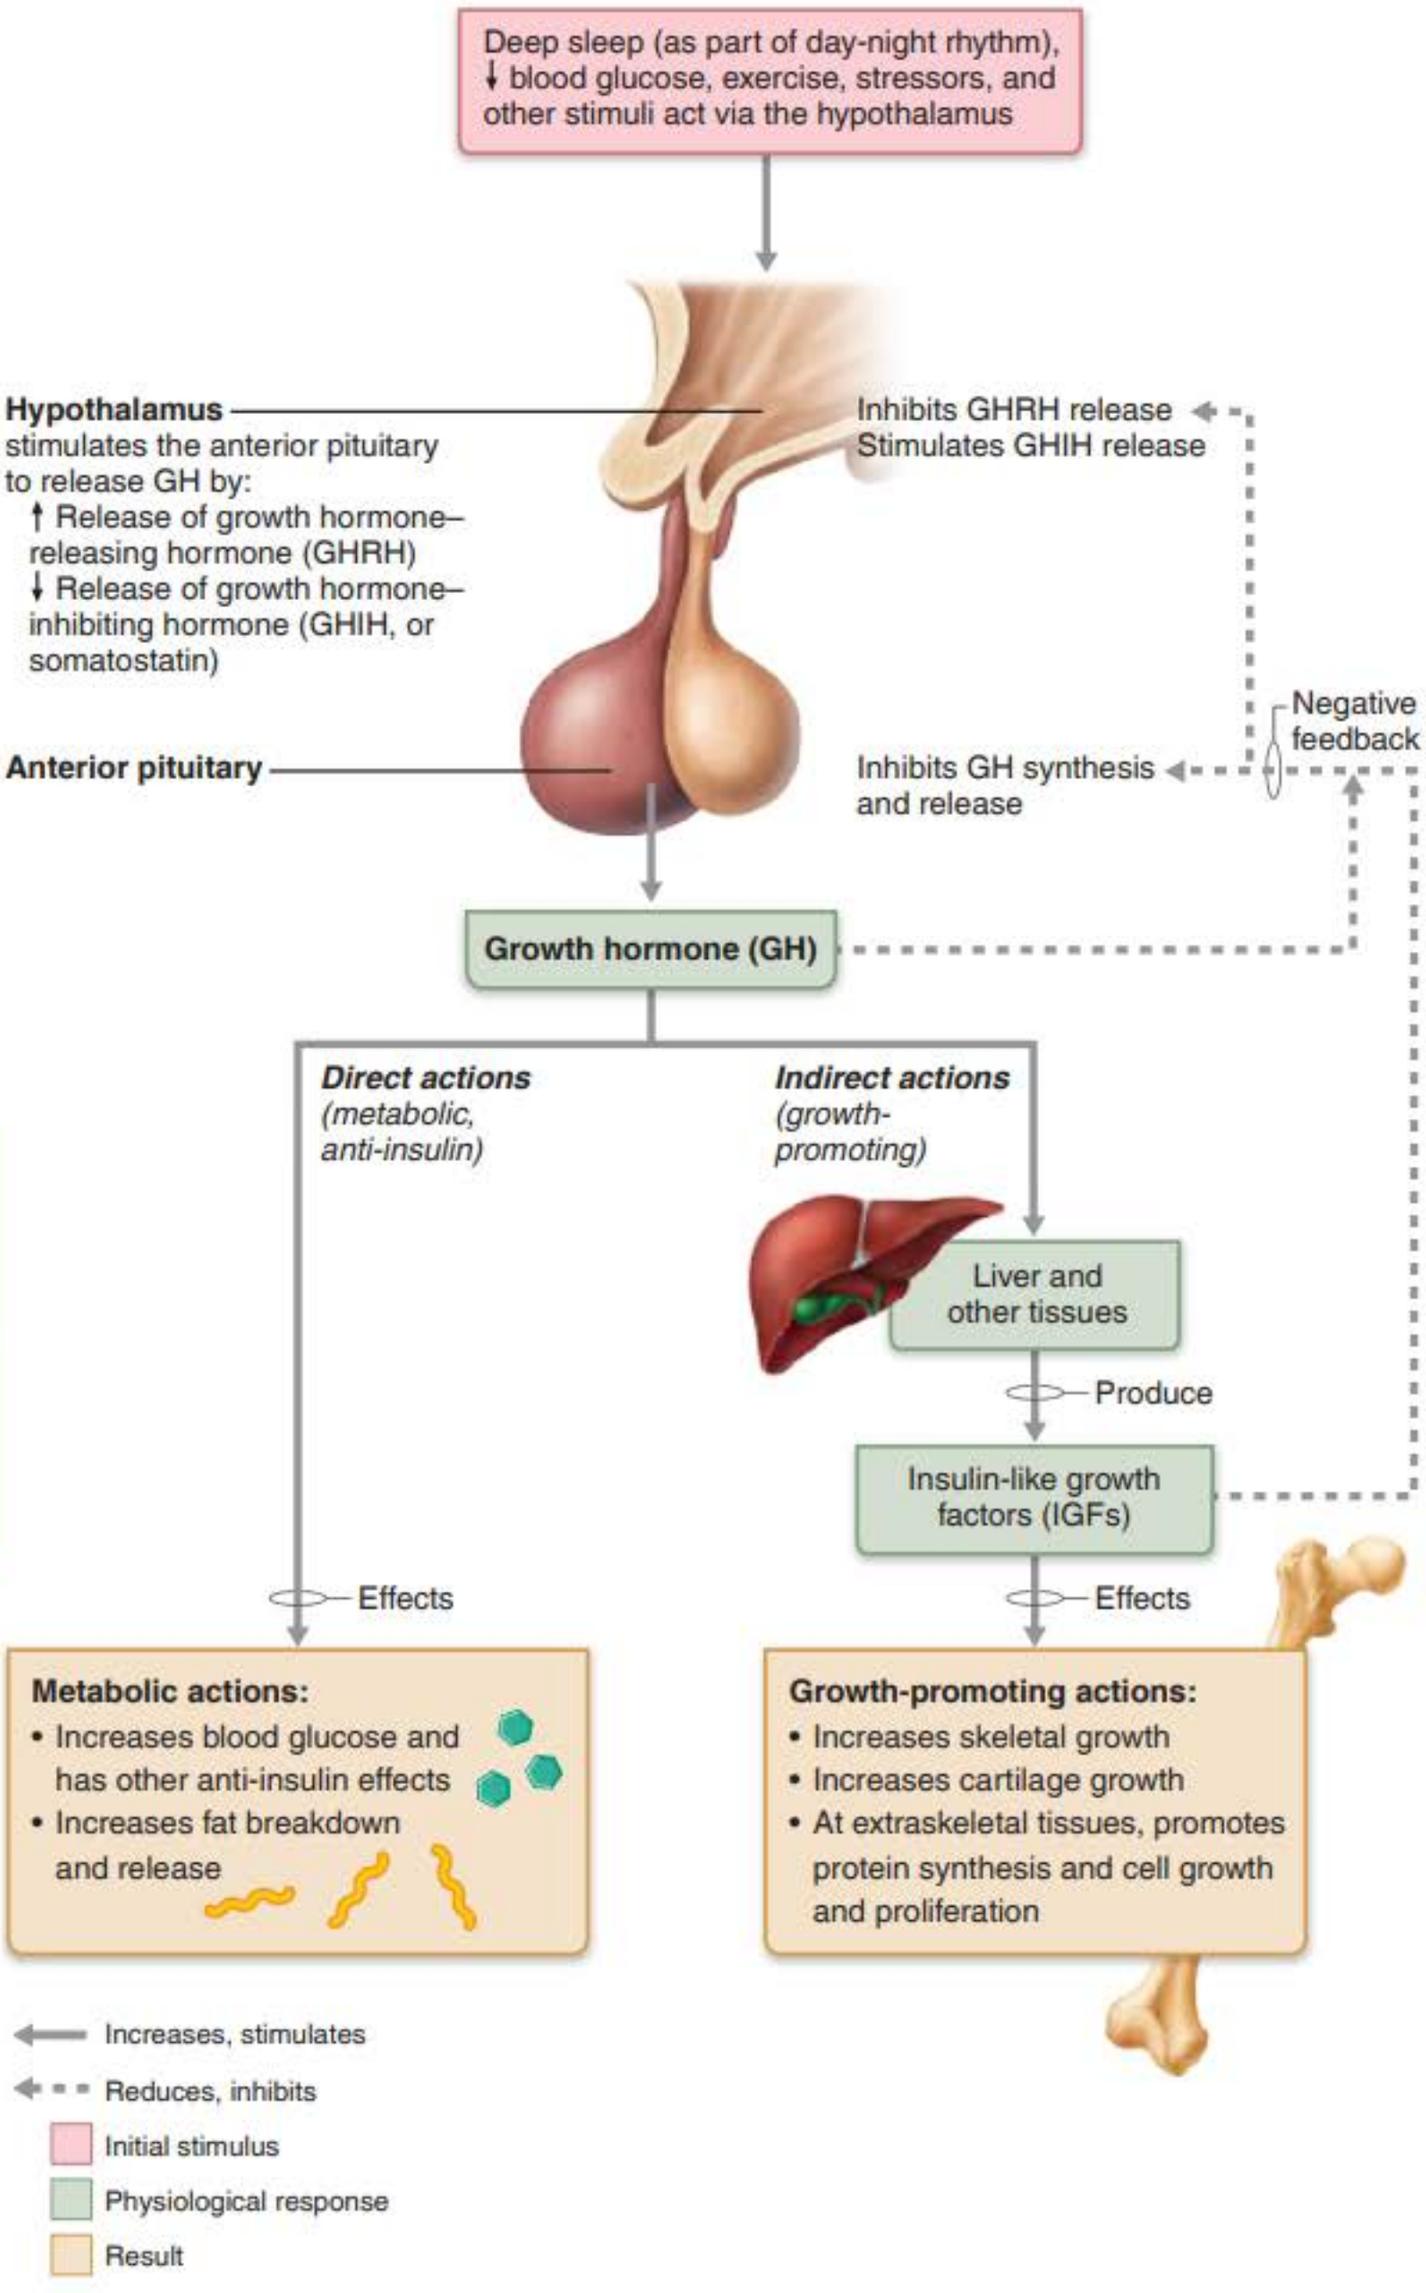


Figure 16.5 Growth-promoting and metabolic actions of growth hormone (GH).

Drinking alcoholic beverages inhibits ADH secretion and causes copious urine output. The dry mouth and intense thirst of a "hangover" reflect this dehydrating effect. Drinking lots of water also inhibits ADH release.

Under certain conditions, such as severe blood loss, exceptionally large amounts of ADH are released, causing vasoconstriction and raising blood pressure. This response targets different ADH receptors found on vascular smooth muscle. For this reason, ADH is also called **vasopressin**.

HOMEOSTATIC IMBALANCE 16.1 CLINICAL

One result of ADH deficiency is **diabetes insipidus**, a syndrome marked by intense thirst and huge urine output. The name of this condition (*diabetes* = overflow; *insipidus* = tasteless) distinguishes it from diabetes mellitus (*mel* = honey), in which insulin deficiency causes large amounts of blood glucose to be lost in the urine. At one time, a clinician would taste the patient's urine to determine the type of diabetes.

Diabetes insipidus can be caused by a pituitary tumor or by a blow to the head that damages the hypothalamus or the posterior pituitary. Though inconvenient, the condition is not serious when the thirst center is operating properly and the person drinks enough water to prevent dehydration. However, it can be life threatening in unconscious or comatose patients, so accident victims with head trauma must be carefully monitored.

The opposite problem, hypersecretion of ADH, can occur in children with meningitis, or in adults who have neurosurgery, hypothalamic injury, or cancer (particularly lung cancer) in which cancer cells are additional sources of ADH. It also may occur after general anesthesia or administration of certain drugs. The resulting condition, *syndrome of inappropriate ADH secretion* (*SIADH*), is marked by retention of fluid, headache and disorientation due to brain edema, weight gain, and decreased solute concentration in the blood. SIADH management requires restricting fluids and carefully monitoring blood sodium levels.

Anterior Pituitary Hormones

The anterior pituitary has traditionally been called the "master endocrine gland" because many of the numerous hormones it produces regulate the activity of other endocrine glands. In

recent years, however, it has been dethroned by the hypothalamus, which is now known to control the activity of the anterior pituitary.

The anterior pituitary releases six hormones, all of them peptides or proteins—growth hormone, thyroid-stimulating hormone, adrenocorticotropic hormone, follicle-stimulating hormone, luteinizing hormone, and prolactin (Table 16.3). When the anterior pituitary receives an appropriate chemical stimulus from the hypothalamus, it releases one or more of its hormones. Although many different hormones pass from the hypothalamus to the anterior lobe, each target cell distinguishes the messages directed to it and responds in kind—secreting the proper hormone in response to specific releasing hormones, and shutting off hormone release in response to specific inhibiting hormones.

Four of the six anterior pituitary hormones—thyroid-stimulating hormone, adrenocorticotropic hormone, follicle-stimulating hormone, and luteinizing hormone—are **tropic hormones** or **tropins** that regulate the secretory action of other endocrine glands (*tropi* = turn on, change). All anterior pituitary hormones except growth hormone affect their target cells via a cyclic AMP second-messenger system.

Growth Hormone (GH)

Somatotropic cells of the anterior lobe produce **growth hormone** (**GH**, also called *somatotropin*). GH is essentially an anabolic (tissue building) hormone that has both metabolic and growth-promoting actions (**Figure 16.5**).

Direct Actions on Metabolism Acting directly, GH exerts metabolic effects. It mobilizes fats from fat depots for transport to cells, increasing blood levels of fatty acids and encouraging their use for fuel. It also decreases the rate of glucose uptake and metabolism, conserving glucose. In the liver, it encourages glycogen breakdown and release of glucose to the blood. This *glucose sparing* action, which raises blood glucose levels, is called the *anti-insulin effect* of GH because its effects oppose those of insulin. In addition, GH increases amino acid uptake into cells and their incorporation into proteins.

Indirect Actions on Growth GH mediates most of its growth-enhancing effects indirectly via a family of growth-promoting proteins called **insulin-like growth factors (IGFs)**. The liver, skeletal muscle, bone, and other tissues produce IGFs in response to GH. IGFs produced by the liver act as hormones, while IGFs made in other tissues act locally within those tissues (as paracrines).

IGFs stimulate actions required for growth:

- Uptake of nutrients from the blood and their incorporation into proteins and DNA, allowing growth by cell division
- Formation of collagen and deposition of bone matrix

Although GH stimulates most body cells to enlarge and divide, its major targets are bone and skeletal muscle. Stimulation of the epiphyseal plate leads to long bone growth, and stimulation of skeletal muscles increases muscle mass.

Regulation of Secretion Secretion of GH is regulated chiefly by two hypothalamic hormones with antagonistic effects.

- **Growth hormone–releasing hormone (GHRH)** stimulates GH release. Typically, GHRH, and therefore GH, secretion has a daily cycle with the highest levels occurring during evening sleep. The total amount secreted daily peaks during adolescence and then declines with age. There are also a number of secondary triggers that cause GHRH secretion (see Table 16.3 on p. 612).
- **Growth hormone–inhibiting hormone (GHIH)**, also called **somatostatin** (so″mah-to-stat′in), inhibits GH release. GHIH release is triggered by the feedback of GH and IGFs. Rising levels of GH also feed back to inhibit its own release. GHIH is also produced in various locations in the gut, where it inhibits the release of virtually all gastrointestinal and pancreatic secretions—both endocrine and exocrine.

HOMEOSTATIC IMBALANCE 16.2 CLINICAL

Both hypersecretion and hyposecretion of GH may result in structural abnormalities. Hypersecretion in children results in **gigantism** because GH targets the still-active epiphyseal (growth) plates. The person becomes abnormally tall, often reaching a height of 2.4 m (8 feet), but has relatively normal body proportions (**Figure 16.6**).

Figure 16.6 Disorders of pituitary growth hormone. An individual exhibiting gigantism (center) is flanked by a pituitary dwarf (left) and a woman of normal height (right).

16

If excessive GH is secreted after the epiphyseal plates have closed, **acromegaly** (ak″ro-meg′ah-le) results. Literally translated as "enlarged extremities," this condition is characterized by overgrowth of bones of the hands, feet, and face. Hypersecretion usually results from an anterior pituitary tumor that churns out excessive GH. The usual treatment is surgical removal of the tumor, but this surgery does not reverse anatomical changes that have already occurred.

Hyposecretion of GH in adults usually causes no problems, but GH deficiency in children slows long bone growth, a condition called **pituitary dwarfism** (Figure 16.6). Such individuals attain a maximum height of 1.2 m (4 feet), but usually have fairly normal body proportions. Lack of GH is often accompanied by deficiencies of other anterior pituitary hormones, and if thyroid-stimulating hormone and gonadotropins are lacking, the individual will be malproportioned and will fail to mature sexually as well. Fortunately, human GH is produced commercially by genetic engineering techniques. When pituitary dwarfism is diagnosed before puberty, growth hormone replacement therapy can promote nearly normal growth.

The availability of synthetic GH also has a downside. Athletes and the elderly have been tempted to use GH for its bodybuilding properties, and some parents seek to give their children the hormone in an attempt to make them taller. However, while muscle mass increases, there is no objective evidence for an increase in muscle strength in either athletes or the elderly, and only minimal increases in stature occur in normal children. Moreover, taking GH can lead to fluid retention, joint and muscle pain, diabetes, and may promote cancer.

Thyroid-Stimulating Hormone (TSH)

Thyroid-stimulating hormone (TSH), or **thyrotropin**, is a tropic hormone that stimulates normal development and secretory activity of the thyroid gland. Its release follows the hypothalamic–pituitary–target endocrine organ feedback loop described earlier and shown specifically for TSH in **Figure 16.7**.

The hypothalamic peptide **thyrotropin-releasing hormone (TRH)** triggers the release of TSH from **thyrotropic cells** of the anterior pituitary. Rising blood levels of thyroid hormones act on both the pituitary and the hypothalamus to inhibit TSH secretion. GHIH also inhibits TSH secretion.

Adrenocorticotropic Hormone (ACTH)

Adrenocorticotropic hormone (ACTH) (ah-dre″no-kor″tĭ-ko-trōp′ik), or **corticotropin**, is secreted by the **corticotropic cells** of the anterior pituitary. It is split from a *prohormone* (a large precursor molecule) with the tongue-twisting name **pro-opiomelanocortin (POMC)** (pro″o″pe-o-mah-lan″o-kor′tin). ACTH stimulates the adrenal cortex to release corticosteroid hormones, most importantly glucocorticoids that help the body resist stressors.

ACTH release, elicited by hypothalamic **corticotropin-releasing hormone (CRH)**, has a daily rhythm, with levels peaking in the morning, shortly before awakening. Rising levels of glucocorticoids feed back and block secretion of CRH and ACTH release. Internal and external factors that alter the normal ACTH rhythm by triggering CRH release include fever, hypoglycemia (low blood glucose levels), and stressors of all types.

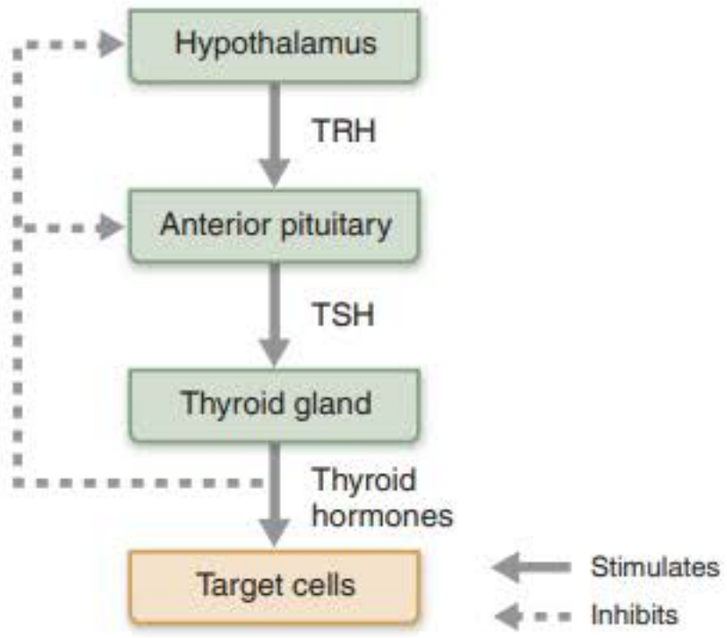

Figure 16.7 Regulation of thyroid hormone secretion. (TRH = thyrotropin-releasing hormone, TSH = thyroid-stimulating hormone)

Gonadotropins (FSH and LH)

Follicle-stimulating hormone (FSH) and **luteinizing hormone (LH)** (lu′te-in-īz″ing) are referred to collectively as **gonadotropins**. They regulate the function of the gonads (ovaries and testes). In both sexes, FSH stimulates production of gametes (sperm or eggs) and LH promotes production of gonadal hormones. In females, LH works with FSH to cause an egg-containing ovarian follicle to mature. LH then triggers ovulation and promotes synthesis and release of ovarian hormones. In males, LH stimulates the interstitial cells of the testes to produce the male hormone testosterone.

Gonadotropins are virtually absent from the blood of prepubertal boys and girls. During puberty, the **gonadotropic cells** of the anterior pituitary are activated and gonadotropin levels rise, causing the gonads to mature. In both sexes, **gonadotropin-releasing hormone (GnRH)** produced by the hypothalamus prompts gonadotropin release. Gonadal hormones, produced in response to the gonadotropins, feed back to suppress FSH and LH release. (Chapter 27 covers these hormones in more detail.)

Prolactin (PRL)

Prolactin (PRL) is a protein hormone structurally similar to GH. Produced by **prolactin cells**, PRL's only well-documented effect in humans is to stimulate milk production by the breasts (*pro* = for; *lact* = milk). The role of prolactin in males is not well understood.

Unlike other anterior pituitary hormones, PRL release is controlled primarily by an inhibitory hormone, **prolactin-inhibiting hormone (PIH)**, now known to be **dopamine**, which prevents prolactin secretion. Decreased PIH secretion leads to a surge in PRL release. There are a number of *prolactin-releasing factors*, including TRH, but their exact roles are not well understood.

In females, prolactin levels rise and fall in rhythm with estrogen blood levels. Estrogens stimulate prolactin release, both directly and indirectly. A brief rise in prolactin levels just before the menstrual period partially accounts for the breast swelling and tenderness some women experience at that time, but because this PRL stimulation is so brief, the breasts do not produce milk. In pregnant women, PRL blood levels rise dramatically toward the end of pregnancy, and milk production becomes possible. After birth, the infant's suckling stimulates release of prolactin-releasing factors in the mother, encouraging continued milk production.

HOMEOSTATIC IMBALANCE 16.3 CLINICAL

Hypersecretion of prolactin is more common than hyposecretion (which is not a problem in anyone except women who choose to nurse). In fact, *hyperprolactinemia* is the most frequent abnormality of anterior pituitary tumors. Clinical signs include inappropriate lactation, lack of menses, infertility in females, and impotence in males.

Check Your Understanding

10. What is the key difference between the way the hypothalamus communicates with the anterior pituitary and the way it communicates with the posterior pituitary?

11. Zoe drank too much alcohol one night and suffered from a headache and nausea the next morning. What caused these "hangover" effects?

12. List the four anterior pituitary hormones that are tropic hormones and name their target glands.

For answers, see Answers Appendix.

16.7 The thyroid gland controls metabolism

Learning Outcomes

- **Describe the effects of the two groups of hormones produced by the thyroid gland.**
- **Follow the process of thyroxine formation and release.**

Location and Structure

The butterfly-shaped **thyroid gland** is located in the anterior neck, on the trachea just inferior to the larynx (Figure 16.1 and **Figure 16.8a**). A median tissue mass called the *isthmus* (is′mus) connects its two lateral *lobes*. The thyroid gland is the largest pure endocrine gland in the body. Its prodigious blood supply (from the *superior* and *inferior thyroid arteries*) makes thyroid surgery a painstaking (and bloody) endeavor.

Internally, the gland is composed of hollow, spherical **follicles** (Figure 16.8b). The walls of each follicle are formed largely by cuboidal or squamous epithelial cells called *follicular cells*, which produce the glycoprotein **thyroglobulin** (thi″ro-glob′u-lin). The central cavity, or lumen, of the follicle stores **colloid**, an amber-colored, sticky material consisting of thyroglobulin molecules with attached iodine atoms. *Thyroid hormone* is derived from this iodinated thyroglobulin.

Practice Histology questions: MasteringA&P® > Study Area > Lab Tools > PAL

Table 16.4 Major Effects of Thyroid Hormone (T_4 and T_3) in the Body

PROCESS OR SYSTEM AFFECTED	NORMAL PHYSIOLOGICAL EFFECTS	EFFECTS OF HYPOSECRETION	EFFECTS OF HYPERSECRETION
Basal metabolic rate (BMR)/ temperature regulation	Promotes normal oxygen use and BMR; calorigenesis; enhances effects of sympathetic nervous system	BMR below normal; decreased body temperature, cold intolerance; decreased appetite; weight gain; reduced sensitivity to catecholamines	BMR above normal; increased body temperature, heat intolerance; increased appetite; weight loss
Carbohydrate/lipid/protein metabolism	Promotes glucose catabolism; mobilizes fats; essential for protein synthesis; enhances liver's synthesis of cholesterol	Decreased glucose metabolism; elevated cholesterol/triglyceride levels in blood; decreased protein synthesis; edema	Enhanced catabolism of glucose, proteins, and fats; weight loss; loss of muscle mass
Nervous system	Promotes normal development of nervous system in fetus and infant; promotes normal adult nervous system function	In infant, slowed/deficient brain development, intellectual disability; in adult, mental dulling, depression, paresthesias, memory impairment, hypoactive reflexes	Irritability, restlessness, insomnia, personality changes, exophthalmos (in Graves' disease)
Cardiovascular system	Promotes normal functioning of the heart	Decreased efficiency of heart's pumping action; low heart rate and blood pressure	Increased sensitivity to catecholamines can lead to rapid heart rate, palpitations, high blood pressure, and ultimately heart failure
Muscular system	Promotes normal muscular development and function	Sluggish muscle action; muscle cramps; myalgia	Muscle atrophy and weakness
Skeletal system	Promotes normal growth and maturation of the skeleton	In child, growth retardation, skeletal stunting and retention of child's body proportions; in adult, joint pain	In child, excessive skeletal growth initially, followed by early epiphyseal closure and short stature; in adult, demineralization of skeleton
Gastrointestinal (GI) system	Promotes normal GI motility and tone; increases secretion of digestive juices	Depressed GI motility, tone, and secretory activity; constipation	Excessive GI motility; diarrhea
Reproductive system	Promotes normal female reproductive ability and lactation	Depressed ovarian function; sterility; depressed lactation	In females, depressed ovarian function; in males, impotence
Integumentary system	Promotes normal hydration and secretory activity of skin	Skin pale, thick, and dry; facial edema; hair coarse and thick	Skin flushed, thin, and moist; hair fine and soft; nails soft and thin

16

The *parafollicular cells*, another population of endocrine cells in the thyroid gland, produce *calcitonin*. The parafollicular cells lie in the follicular epithelium but protrude into the soft connective tissue that separates and surrounds the thyroid follicles.

Thyroid Hormone (TH)

Often referred to as the body's major metabolic hormone, **thyroid hormone (TH)** is actually two iodine-containing amine hormones, **thyroxine** (thi-rok′sin), or **T_4**, and **triiodothyronine** (tri″i-o″do-thi′ro-nēn), or **T_3**. T_4 is the major hormone secreted by the thyroid follicles. Most T_3 is formed at the target tissues by conversion of T_4 to T_3. Both T_4 and T_3 are constructed from two linked tyrosine amino acids, but T_4 has four bound iodine atoms, and T_3 has three (and so the names T_4 and T_3).

TH affects virtually every cell in the body (**Table 16.4**). Like steroids, TH enters a target cell. It binds to intracellular receptors within the cell's nucleus and initiates transcription of mRNA for protein synthesis. Effects of thyroid hormone include:

- Increasing basal metabolic rate and body heat production, by turning on transcription of genes concerned with glucose oxidation. This is the hormone's **calorigenic effect** (*calorigenic* = heat producing).
- Regulating tissue growth and development. TH is critical for normal skeletal and nervous system development and maturation and for reproductive capabilities.
- Maintaining blood pressure by increasing the number of adrenergic receptors in blood vessels.

Synthesis

The thyroid gland is unique among the endocrine glands in its ability to store its hormone extracellularly and in large quantities. A normal thyroid gland stores enough colloid to provide normal levels of hormone for two to three months.

When TSH from the anterior pituitary binds to receptors on follicular cells, their *first* response is to secrete stored thyroid hormone. Their *second* response is to begin synthesizing

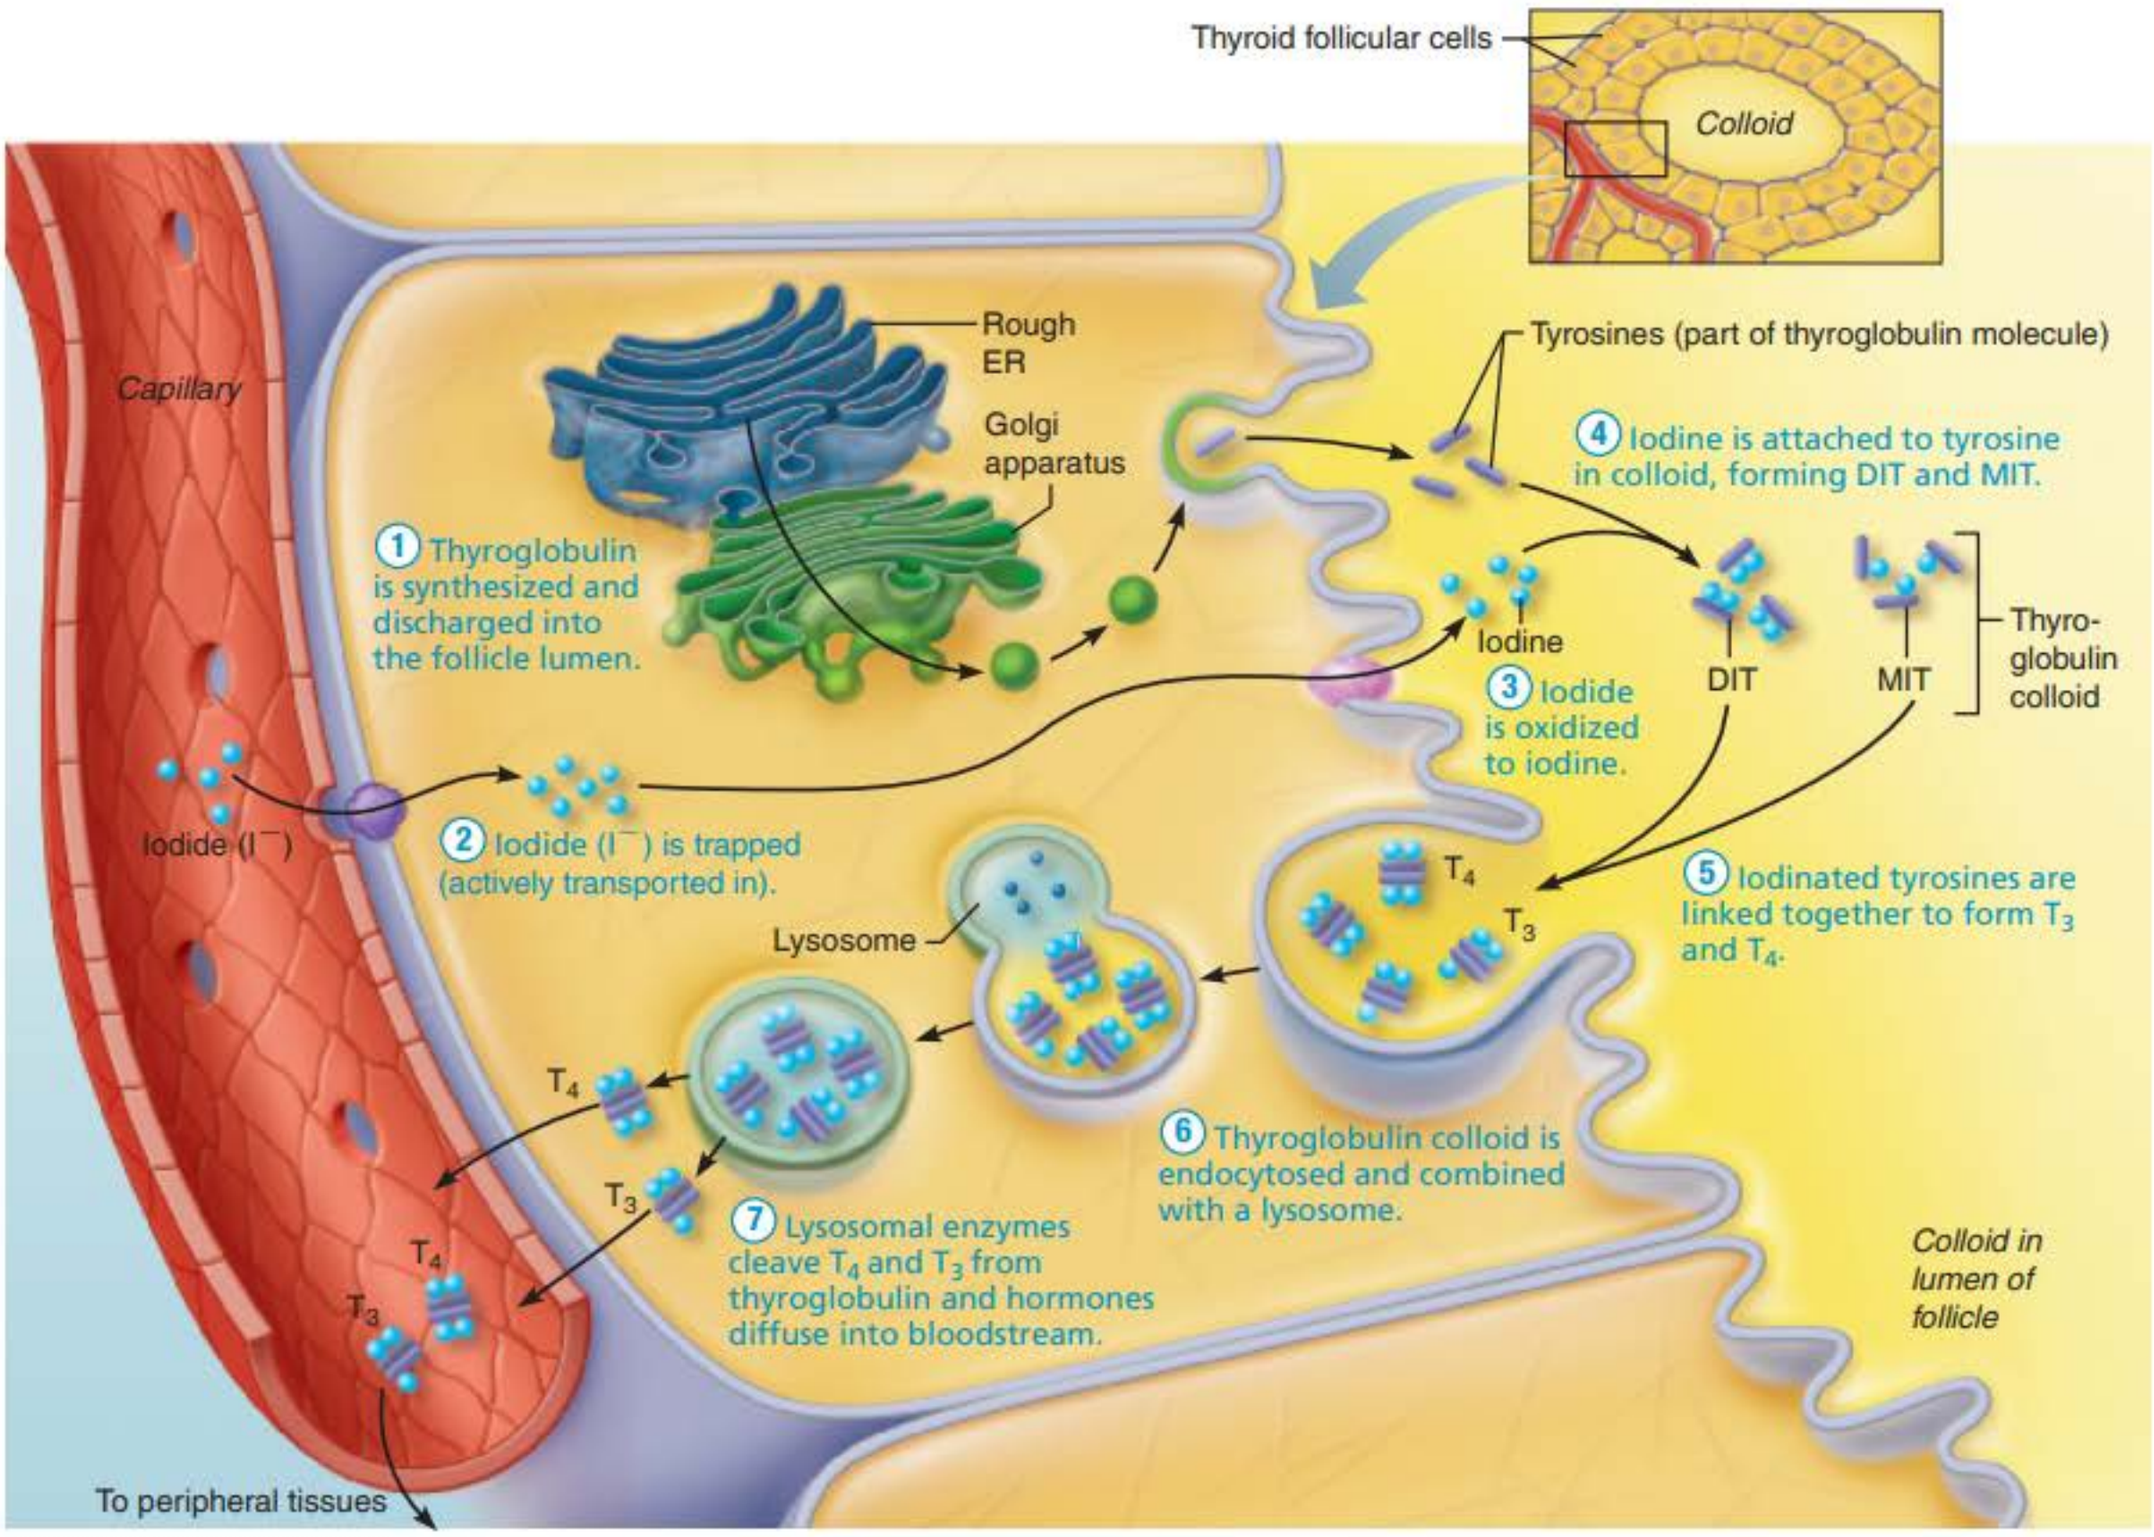

Figure 16.9 Synthesis of thyroid hormone. Only a few tyrosines of the thyroglobulins in the colloid are illustrated. The unstructured yellow substance in the follicle lumen is colloid. (MIT = monoiodotyrosine; DIT = diiodotyrosine)

more colloid to "restock" the follicle lumen. As a general rule, TSH levels are lower during the day, peak just before sleep, and remain high during the night. Consequently, thyroid hormone release and synthesis follows a similar pattern.

Let's examine how follicular cells synthesize thyroid hormone (**Figure 16.9**):

1. **Thyroglobulin is synthesized and discharged into the follicle lumen.** After being synthesized on the ribosomes of the follicular cell's rough endoplasmic reticulum, thyroglobulin is transported to the Golgi apparatus, where sugar molecules are attached and the thyroglobulin is packed into transport vesicles. These vesicles move to the apex of the follicular cell, where they discharge their contents into the follicle lumen to become part of the stored colloid.
2. **Iodide is trapped.** To produce the functional iodinated hormones, the follicular cells must accumulate iodides (anions of iodine, I^-) from the blood. Iodide trapping depends on active transport. (The concentration of I^- is over 30 times higher inside the cell than in blood.) Once trapped inside the follicular cell, iodide then moves into the follicle lumen by facilitated diffusion.
3. **Iodide is oxidized to iodine.** At the border of the follicular cell and colloid, iodides are oxidized (by removal of electrons) and converted to iodine (I_2).
4. **Iodine is attached to tyrosine.** Iodine is attached to tyrosine amino acids that are part of the thyroglobulin molecule. This iodination reaction, mediated by peroxidase enzymes, occurs at the junction of the follicular cell and the colloid. Attachment of one iodine to a tyrosine produces **monoiodotyrosine** (**MIT**), and attachment of two iodines produces **diiodotyrosine** (**DIT**).
5. **Iodinated tyrosines are linked together to form T_3 and T_4.** Enzymes in the colloid link MIT and DIT together. Two linked DITs result in T_4, and coupling of MIT and DIT produces T_3. At this point, the hormones are still part of the thyroglobulin colloid.

⑥ **Thyroglobulin colloid is endocytosed.** To secrete the hormones, the follicular cells must reclaim iodinated thyroglobulin by endocytosis and combine the vesicles with lysosomes.

⑦ **Lysosomal enzymes split T_4 and T_3 from thyroglobulin and the hormones diffuse from the follicular cell into the bloodstream.** The main hormonal product secreted is T_4. Some T_4 is converted to T_3 before secretion, but most T_3 is generated in the peripheral tissues.

Transport and Regulation

Most T_4 and T_3 released into the blood immediately binds to *thyroxine-binding globulins* (*TBGs*) and other transport proteins produced by the liver. Both T_4 and T_3 bind to target tissue receptors, but T_3 binds more tightly and is about 10 times more active. Most peripheral tissues have the enzymes needed to convert T_4 to T_3 by removing one iodine atom.

Figure 16.7 (◀ p. 616) shows the negative feedback loop that regulates blood levels of TH. Falling TH blood levels trigger release of *thyroid-stimulating hormone* (*TSH*), and ultimately of more TH. Rising TH levels feed back to inhibit the hypothalamic–anterior pituitary axis, temporarily shutting off the stimulus for TSH release.

In infants, exposure to cold stimulates the hypothalamus to secrete *thyrotropin-releasing hormone* (*TRH*), which triggers TSH release. The thyroid gland then releases larger amounts of thyroid hormones, enhancing body metabolism and heat production. Factors that inhibit TSH release include GHIH, dopamine, and rising levels of glucocorticoids. Excessively high blood iodide concentrations also inhibit TH release.

16

HOMEOSTATIC IMBALANCE 16.4 — CLINICAL

Both overactivity and underactivity of the thyroid gland can cause severe metabolic disturbances. Hypothyroid disorders may result from some thyroid gland defects or secondarily from inadequate TSH or TRH release. They also occur when the thyroid gland is removed surgically and when dietary iodine is inadequate.

In adults, the full-blown hypothyroid syndrome is called **myxedema** (mik″sĕ-de′mah; "mucous swelling"). Symptoms include a low metabolic rate; feeling chilled; constipation; thick, dry skin and puffy eyes; edema; lethargy; and mental sluggishness. A **goiter** (an enlarged protruding thyroid gland) occurs if myxedema results from lack of iodine (**Figure 16.10a**). The follicular cells produce colloid but cannot iodinate it and make functional hormones. The pituitary gland secretes increasing amounts of TSH in a futile attempt to stimulate the thyroid to produce TH, but the only result is that the follicles accumulate more and more *unusable* colloid. Depending on the cause, iodine supplements or hormone replacement therapy can reverse myxedema.

Before iodized salt became available, the midwestern United States was called the "goiter belt." Goiters were common because this area had iodine-poor soil and no access to iodine-rich seafood. In places where goiters are especially common, these goiters are called *endemic goiters*.

Thyroid hormone is critically important for normal growth and brain development in early childhood, so newborns are routinely screened for hypothyroidism. *Congenital hypothyroidism* is usually caused by poor development of the thyroid gland. Rarely, a pituitary problem or maternal medications may affect the baby's ability to make TH. In the first weeks of life, an infant with congenital hypothyroidism may have no symptoms at all, or may present with a weak cry, poor feeding, constipation, or prolonged jaundice. Early treatment with oral thyroid hormone replacement is crucial and usually allows a normal, healthy life. Most affected children will require lifelong TH replacement.

The most common hyperthyroid pathology is **Graves' disease**. In this autoimmune condition, a person makes abnormal antibodies directed against thyroid follicular cells. Rather than marking these cells for destruction as antibodies normally do, these antibodies paradoxically mimic TSH and continuously stimulate TH release.

Typical symptoms of Graves' disease include elevated metabolic rate; sweating; rapid, irregular heartbeat; nervousness; and weight loss despite adequate food. Eyeballs may protrude

(a) An enlarged thyroid (goiter); due to iodine deficiency

(b) Bulging eyes (exophthalmos) of Graves' disease

Figure 16.10 Thyroid disorders.

(*exophthalmos*) if the tissue behind the eyes becomes edematous and fibrous (Figure 16.10b). Treatments include surgically removing the thyroid gland or ingesting radioactive iodine (^{131}I), which destroys the most active thyroid cells.

Calcitonin

Calcitonin, a polypeptide hormone released by the **parafollicular**, or **C, cells** of the thyroid gland in response to a rise in blood Ca^{2+} levels, does not have a known physiological role in humans. In fact, calcitonin does not need to be replaced in patients whose thyroid gland has been removed.

However, at pharmacological doses (doses higher than normally found in the body), calcitonin has a bone-sparing effect and is given therapeutically to patients to treat Paget's disease and sometimes osteoporosis (bone diseases; ◀ pp. 193–194). At these high concentrations, calcitonin targets the skeleton, where it (1) inhibits osteoclast activity, inhibiting bone resorption and release of Ca^{2+} from the bony matrix, and (2) stimulates Ca^{2+} uptake and incorporation into bone matrix.

Check Your Understanding

13. What is the difference between T_3 and T_4? Which one of these is referred to as thyroxine?

14. Why does TH require plasma proteins in order to move through blood? Where are the receptors for TSH located?

For answers, see Answers Appendix.

16.8 The parathyroid glands are primary regulators of blood calcium levels

Learning Outcome

▶ **Indicate the general functions of parathyroid hormone.**

The tiny, yellow-brown **parathyroid glands** are nearly hidden from view in the posterior aspect of the thyroid gland (**Figure 16.11a**). There are usually four of these glands, but the number varies—as many as eight have been reported in some individuals, and some may be located in other regions of the neck or even in the thorax.

The parathyroid's glandular cells are arranged in thick, branching cords containing scattered *oxyphil cells* and large numbers of smaller **parathyroid cells** (Figure 16.11b). The

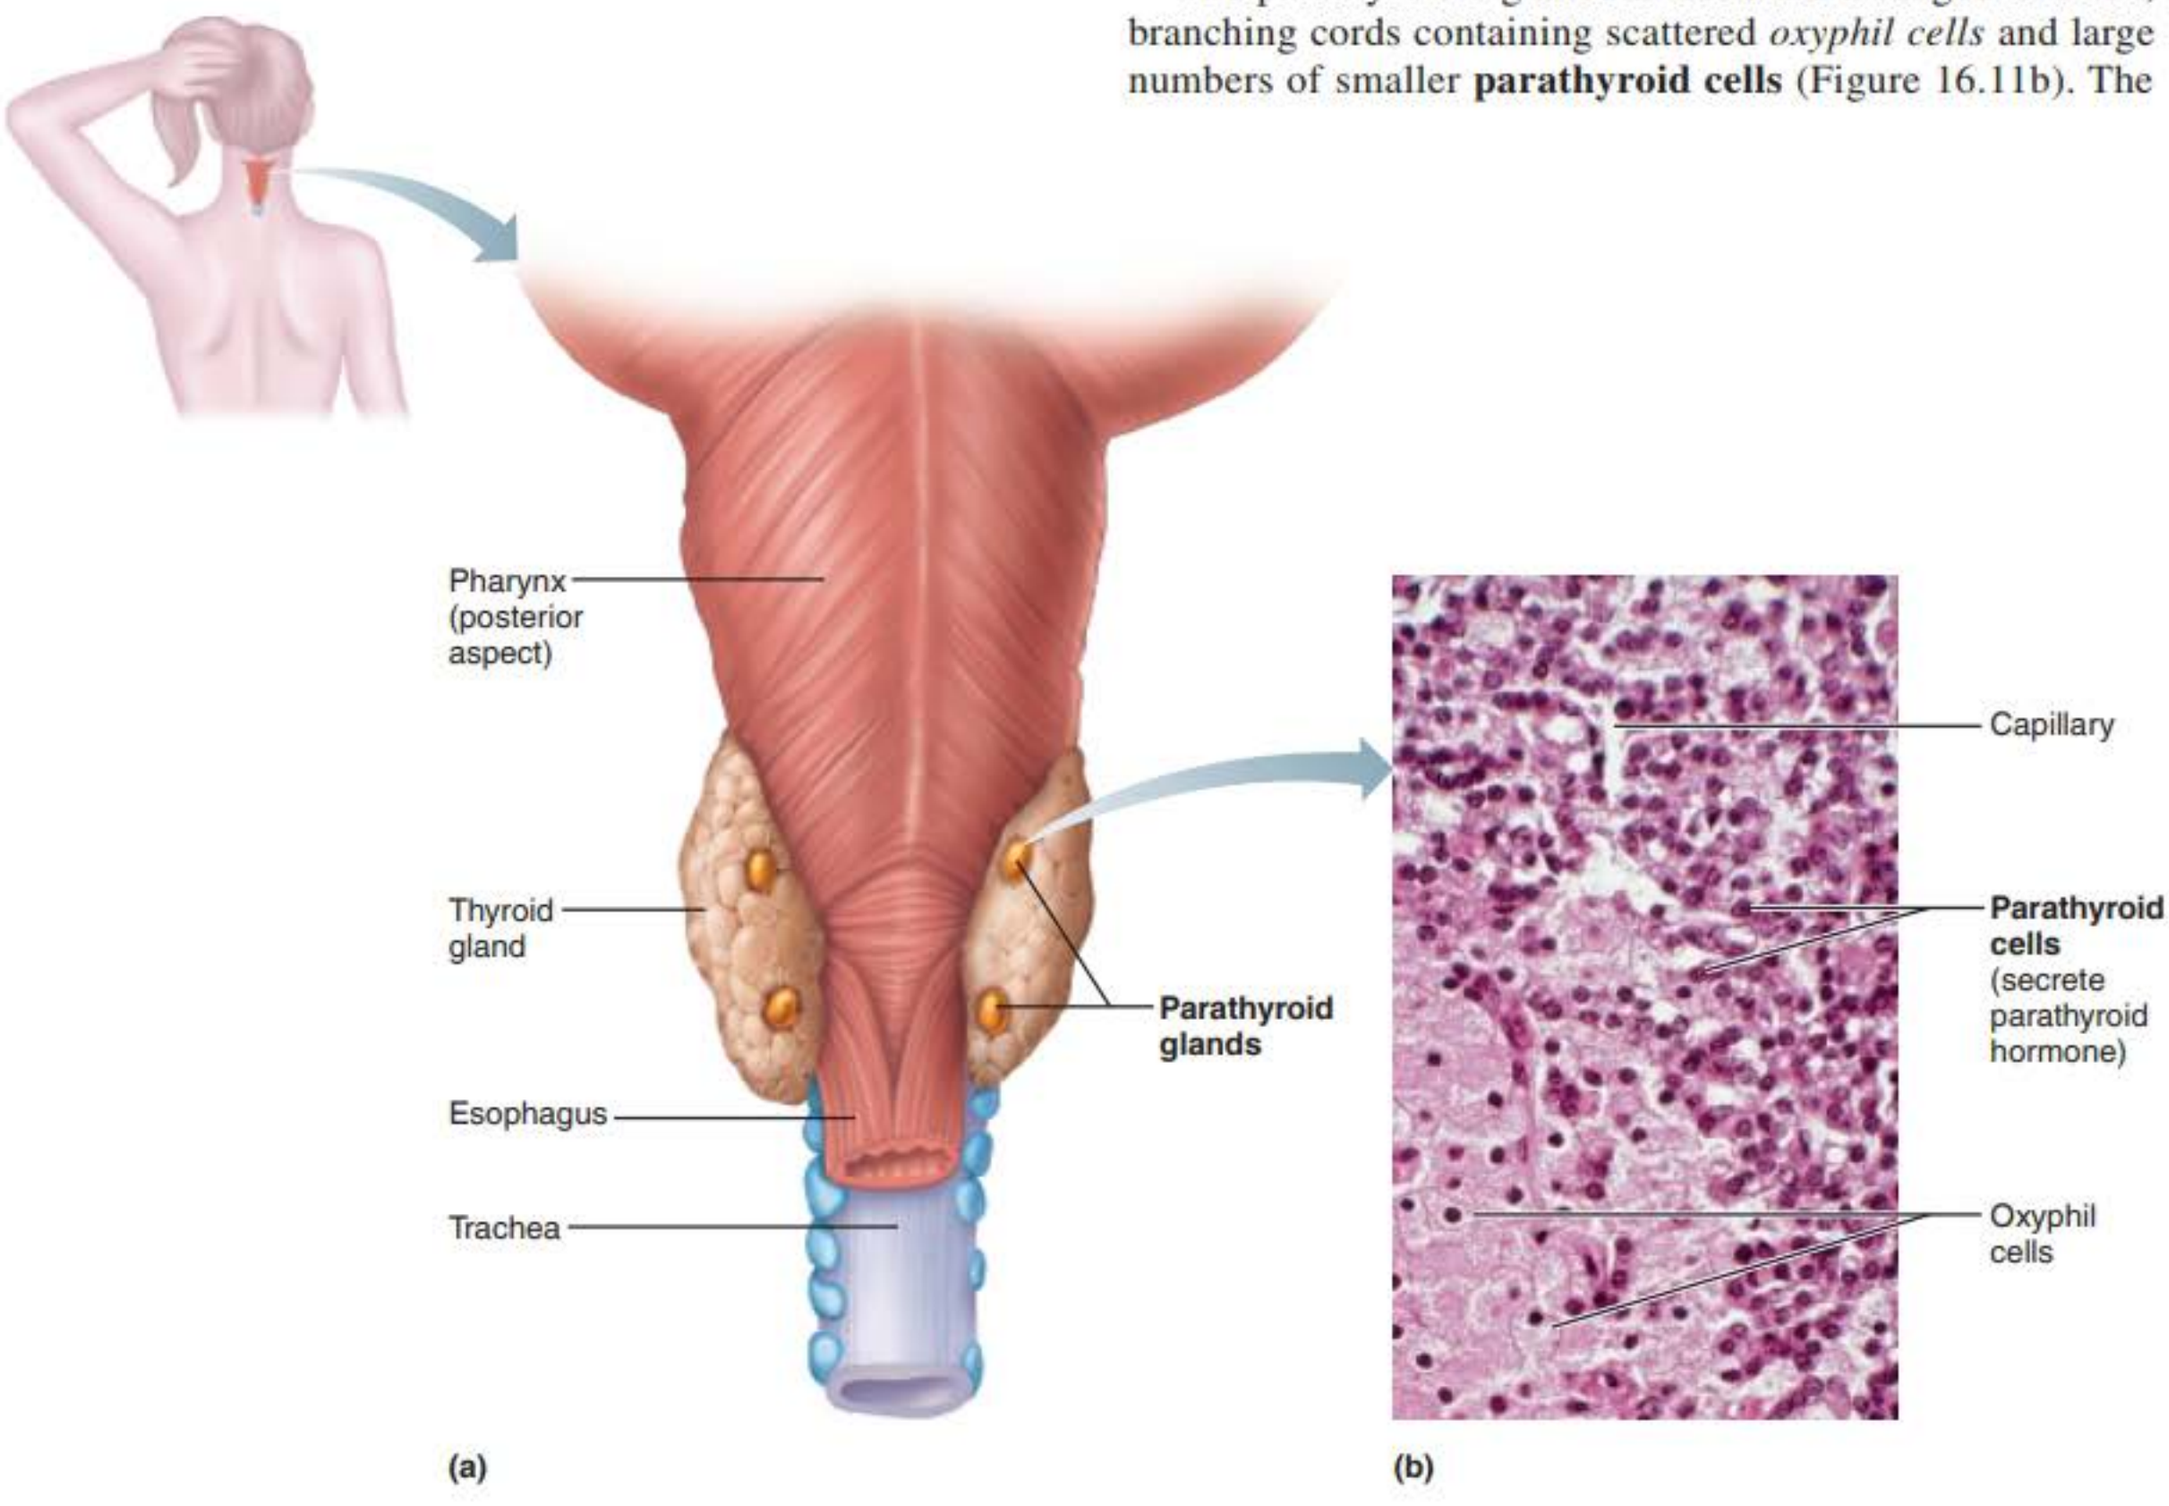

Figure 16.11 The parathyroid glands. (a) The parathyroid glands are located on the posterior aspect of the thyroid gland and are more inconspicuous than depicted. **(b)** Photomicrograph of parathyroid gland tissue (160×).

Practice Histology questions: MasteringA&P® > Study Area > Lab Tools > PAL

parathyroid cells secrete parathyroid hormone. The function of the oxyphil cells is unclear.

Parathyroid hormone (PTH), or *parathormone*, the protein hormone of these glands, is the single most important hormone controlling calcium balance in the blood. Precise control of calcium levels is critical because Ca^{2+} homeostasis is essential for so many functions, including transmission of nerve impulses, muscle contraction, and blood clotting.

Falling blood Ca^{2+} levels trigger PTH release, and rising blood Ca^{2+} levels inhibit its release. PTH increases Ca^{2+} levels in blood by stimulating three target organs: the skeleton, the kidneys, and the intestine (**Figure 16.12**). PTH release:

- Stimulates osteoclasts (bone-resorbing cells) to digest some of the calcium-rich bony matrix and release ionic calcium and phosphates to the blood (◀ Figure 6.14, p. 189).
- Enhances the kidney's reabsorption of Ca^{2+} from the forming urine into the blood [and excretion of phosphate (PO_4^{3-})].
- Promotes activation of vitamin D, thereby increasing absorption of Ca^{2+} by intestinal mucosal cells. Vitamin D is required for absorption of Ca^{2+} from food, but first the kidneys must convert it to its active vitamin D_3 form, *calcitriol* (1,25-dihydroxycholecalciferol). PTH stimulates this transformation.

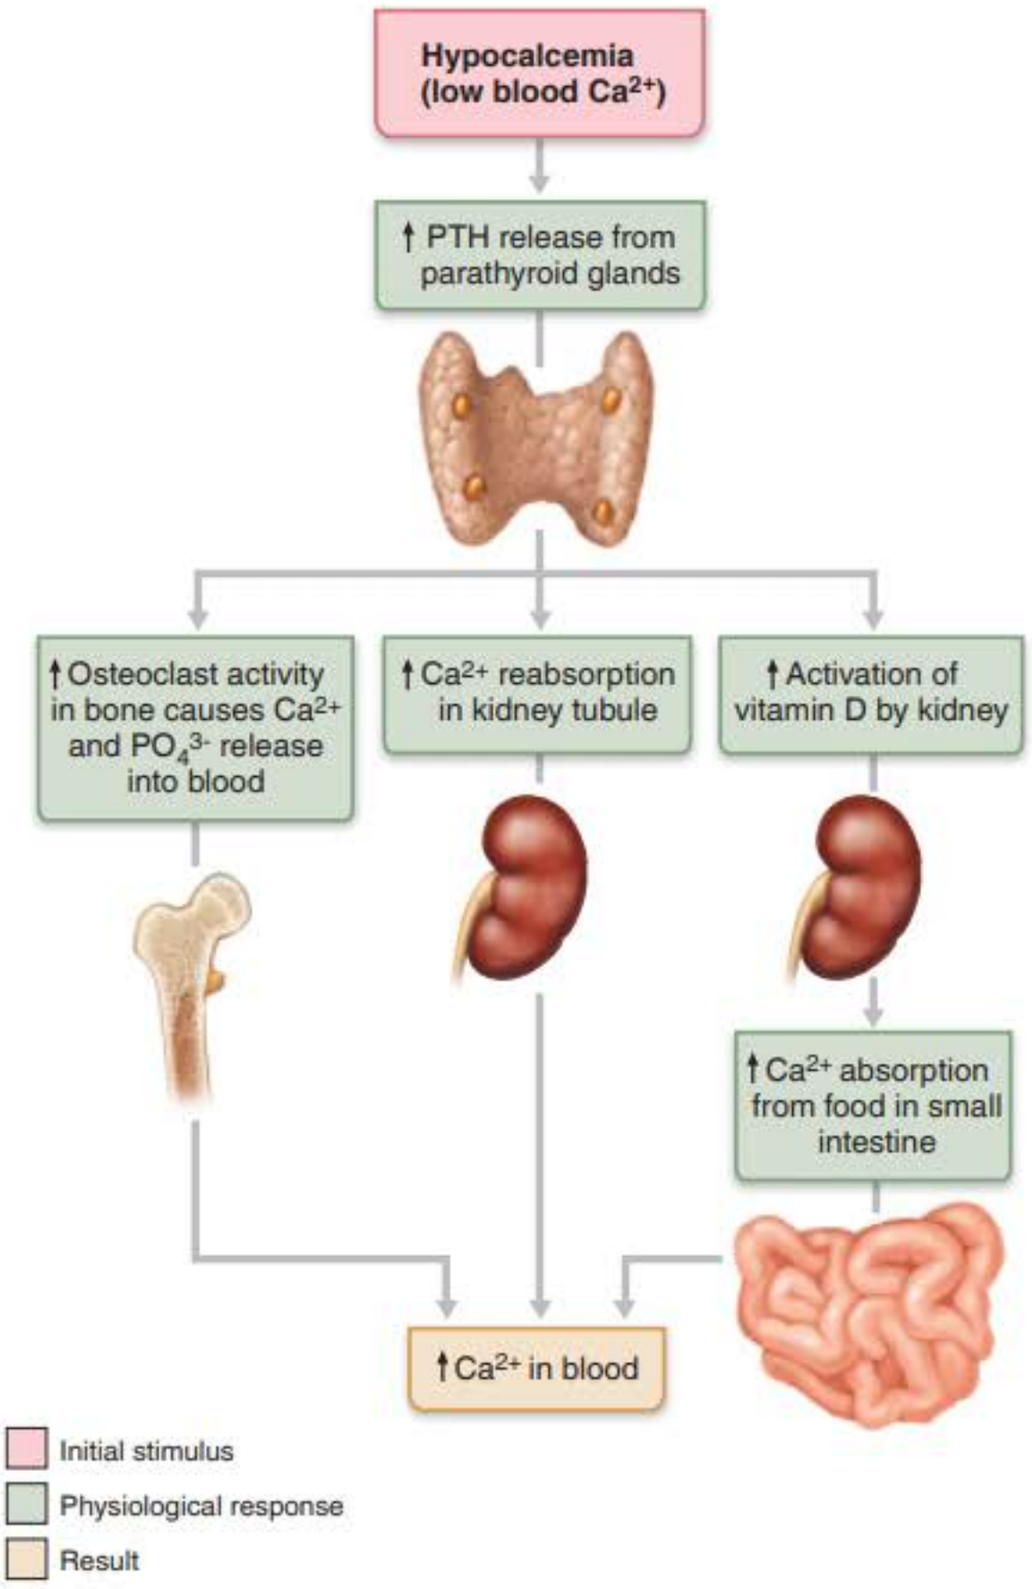

Figure 16.12 Effects of parathyroid hormone on bone, the kidneys, and the intestine.

HOMEOSTATIC IMBALANCE 16.5 — CLINICAL

Hyperparathyroidism (excess PTH) is the third most common endocrine disorder. It is often caused by a parathyroid gland tumor. Calcium leaches from the bones, which soften and deform as fibrous connective tissue replaces their mineral salts. In *osteitis fibrosa cystica*, a severe form of this disorder, the bones have a moth-eaten appearance on X rays and tend to fracture spontaneously. The resulting hypercalcemia (abnormally elevated blood Ca^{2+} level) has many outcomes, but the two most notable are (1) it depresses the nervous system, which leads to abnormal reflexes and weak skeletal muscles, and (2) excess calcium salts precipitate in the kidney tubules, forming kidney stones. Calcium deposits may also form in soft tissues throughout the body and severely impair vital organ functioning.

Hypoparathyroidism (PTH deficiency) most often follows parathyroid gland trauma or removal during thyroid surgery. The resulting hypocalcemia (low blood Ca^{2+}) makes neurons more excitable and accounts for the classic signs and symptoms of tingling sensations, *tetany* (twitching muscle), and convulsions. Untreated, the symptoms progress to respiratory paralysis and death.

15. What is the major effect of thyroid hormone? Parathyroid hormone? Calcitonin?

16. Name the cells that release each of the three hormones listed above.

For answers, see Answers Appendix.

16.9 The adrenal glands produce hormones involved in electrolyte balance and the stress response

Learning Outcome

▶ **List hormones produced by the adrenal gland, and cite their physiological effects.**

The paired **adrenal glands** are pyramid-shaped organs perched atop the kidneys (*ad* = near; *renal* = kidney), where they are enclosed in a fibrous capsule and a cushion of fat (see Figure 16.1 and **Figure 16.13**). They are also called the **suprarenal glands** (*supra* = above).

Each adrenal gland is structurally and functionally two endocrine glands. The inner **adrenal medulla**, more like a knot of nervous tissue than a gland, is part of the sympathetic nervous system (◀ p. 542). The outer **adrenal cortex**, encapsulating the medulla and forming the bulk of the gland, is glandular tissue derived from embryonic mesoderm. Each region produces its own set of hormones summarized in **Table 16.5** (p. 626), but all adrenal hormones help us cope with stressful situations.

Practice Histology questions: MasteringA&P® > Study Area > Lab Tools > PAL

16

The Adrenal Cortex

The adrenal cortex synthesizes well over two dozen steroid hormones, collectively called **corticosteroids**. The multistep steroid synthesis pathway begins with cholesterol, and involves varying intermediates depending on the hormone being formed. Unlike the amino acid–based hormones, steroid hormones are not stored in cells. Consequently, their rate of release depends on their rate of synthesis.

The large, lipid-laden cortical cells are arranged in three layers or zones (Figure 16.13). From the outside in, they are:

- **Zona glomerulosa** (zo′nah glo-mer″u-lo′sah). The cell clusters forming this superficial layer produce *mineralocorticoids*, hormones (such as aldosterone) that help control the balance of minerals and water in the blood.
- **Zona fasciculata** (fah-sik″u-la′tah). The cells of this middle layer, arranged in more or less linear cords, mainly produce the metabolic hormones called *glucocorticoids* (such as cortisol).
- **Zona reticularis** (rĕ-tik″u-lar′is). The cells of this innermost layer, next to the adrenal medulla, have a netlike arrangement. They mainly produce small amounts of adrenal sex hormones, or *gonadocorticoids*.

Note, however, that the two innermost layers of the adrenal cortex share production of glucocorticoids and gonadocorticoids, although each layer predominantly produces one type.

Mineralocorticoids

The essential function of **mineralocorticoids** is to regulate the electrolyte (mineral salt) concentrations in extracellular fluids, particularly of Na^+ and K^+. The single most abundant cation in extracellular fluid is Na^+, and the amount of Na^+ in the body largely determines the volume of the extracellular fluid—where Na^+ goes, water follows. Changes in Na^+ concentration lead to changes in blood volume and blood pressure. Moreover, the regulation of Na^+ is coupled to the regulation of many other ions, including K^+, H^+, HCO_3^- (bicarbonate), and Cl^- (chloride).

The extracellular concentration of K^+ is also critical—it sets the resting membrane potential of all cells and determines how easily action potentials are generated in nerve and muscle. Not surprisingly, Na^+ and K^+ regulation are crucial to overall body homeostasis. Their regulation is the primary job of **aldosterone** (al-dos′ter-ōn), the most potent mineralocorticoid. Aldosterone accounts for more than 95% of the mineralocorticoids produced and is essential for life.

Aldosterone reduces excretion of Na^+ from the body. Its primary target is the kidney tubules, where it:

- Stimulates Na^+ reabsorption (causing increased blood volume and blood pressure because water follows Na^+)
- Causes K^+ secretion into the tubules for elimination from the body

In some instances, aldosterone can alter the acid-base balance of the blood (by increasing H^+ excretion). Aldosterone also

enhances Na^+ reabsorption from perspiration, saliva, and gastric juice.

Aldosterone's regulatory effects are brief (approximately 20 minutes), allowing plasma electrolyte balance to be precisely controlled and continuously modified. The mechanism of aldosterone activity involves the synthesis and activation of proteins required for Na^+ transport such as Na^+-K^+ ATPase, the pump that exchanges Na^+ for K^+ across plasma membranes.

Decreasing blood volume and blood pressure, and rising blood levels of K^+, stimulate aldosterone secretion. The reverse conditions inhibit its secretion. Four mechanisms regulate aldosterone secretion, but two of them—the renin-angiotensin-aldosterone mechanism and plasma concentrations of potassium—are by far the most important (**Figure 16.14**).

① The renin-angiotensin-aldosterone mechanism. The renin-angiotensin-aldosterone mechanism (re′nin an″je-o-ten′sin) influences both blood volume and blood pressure by regulating the release of aldosterone and therefore Na^+ and water reabsorption by the kidneys.

1. When blood pressure (or blood volume) falls, specialized cells of the *juxtaglomerular complex* in the kidneys are excited.
2. These cells respond by releasing **renin** into the blood.
3. Renin splits off part of the plasma protein **angiotensinogen** (an″je-o-ten′sin-o-jen), triggering an enzymatic cascade that forms **angiotensin II**, which stimulates the glomerulosa cells to release aldosterone.

However, the renin-angiotensin-aldosterone mechanism does much more than trigger aldosterone release, and all of its effects ultimately raise blood pressure. We describe these additional effects in Chapters 19 and 26.

② Plasma concentration of potassium. Fluctuating blood levels of K^+ directly influence the zona glomerulosa cells in the adrenal cortex. Increased K^+ stimulates aldosterone release, whereas decreased K^+ inhibits it.

③ ACTH. Under normal circumstances, ACTH released by the anterior pituitary has little or no effect on aldosterone release. However, when a person is severely stressed, the hypothalamus secretes more corticotropin-releasing hormone (CRH), and the resulting rise in ACTH blood levels steps up the rate of aldosterone secretion to a small extent. The resulting increase in blood volume and blood pressure helps deliver nutrients and respiratory gases during the stressful period.

④ Atrial natriuretic peptide (ANP). Atrial natriuretic peptide, a hormone secreted by the heart when blood pressure rises, fine-tunes blood pressure and sodium-water balance of the body. One of its major effects is to inhibit the renin-angiotensin-aldosterone mechanism. It blocks renin and aldosterone secretion and inhibits other angiotensin-induced mechanisms that enhance water and Na^+ reabsorption. Consequently, ANP's overall influence is to decrease blood pressure by allowing Na^+ (and water) to flow out of the body in urine (*natriuretic* = producing salty urine).

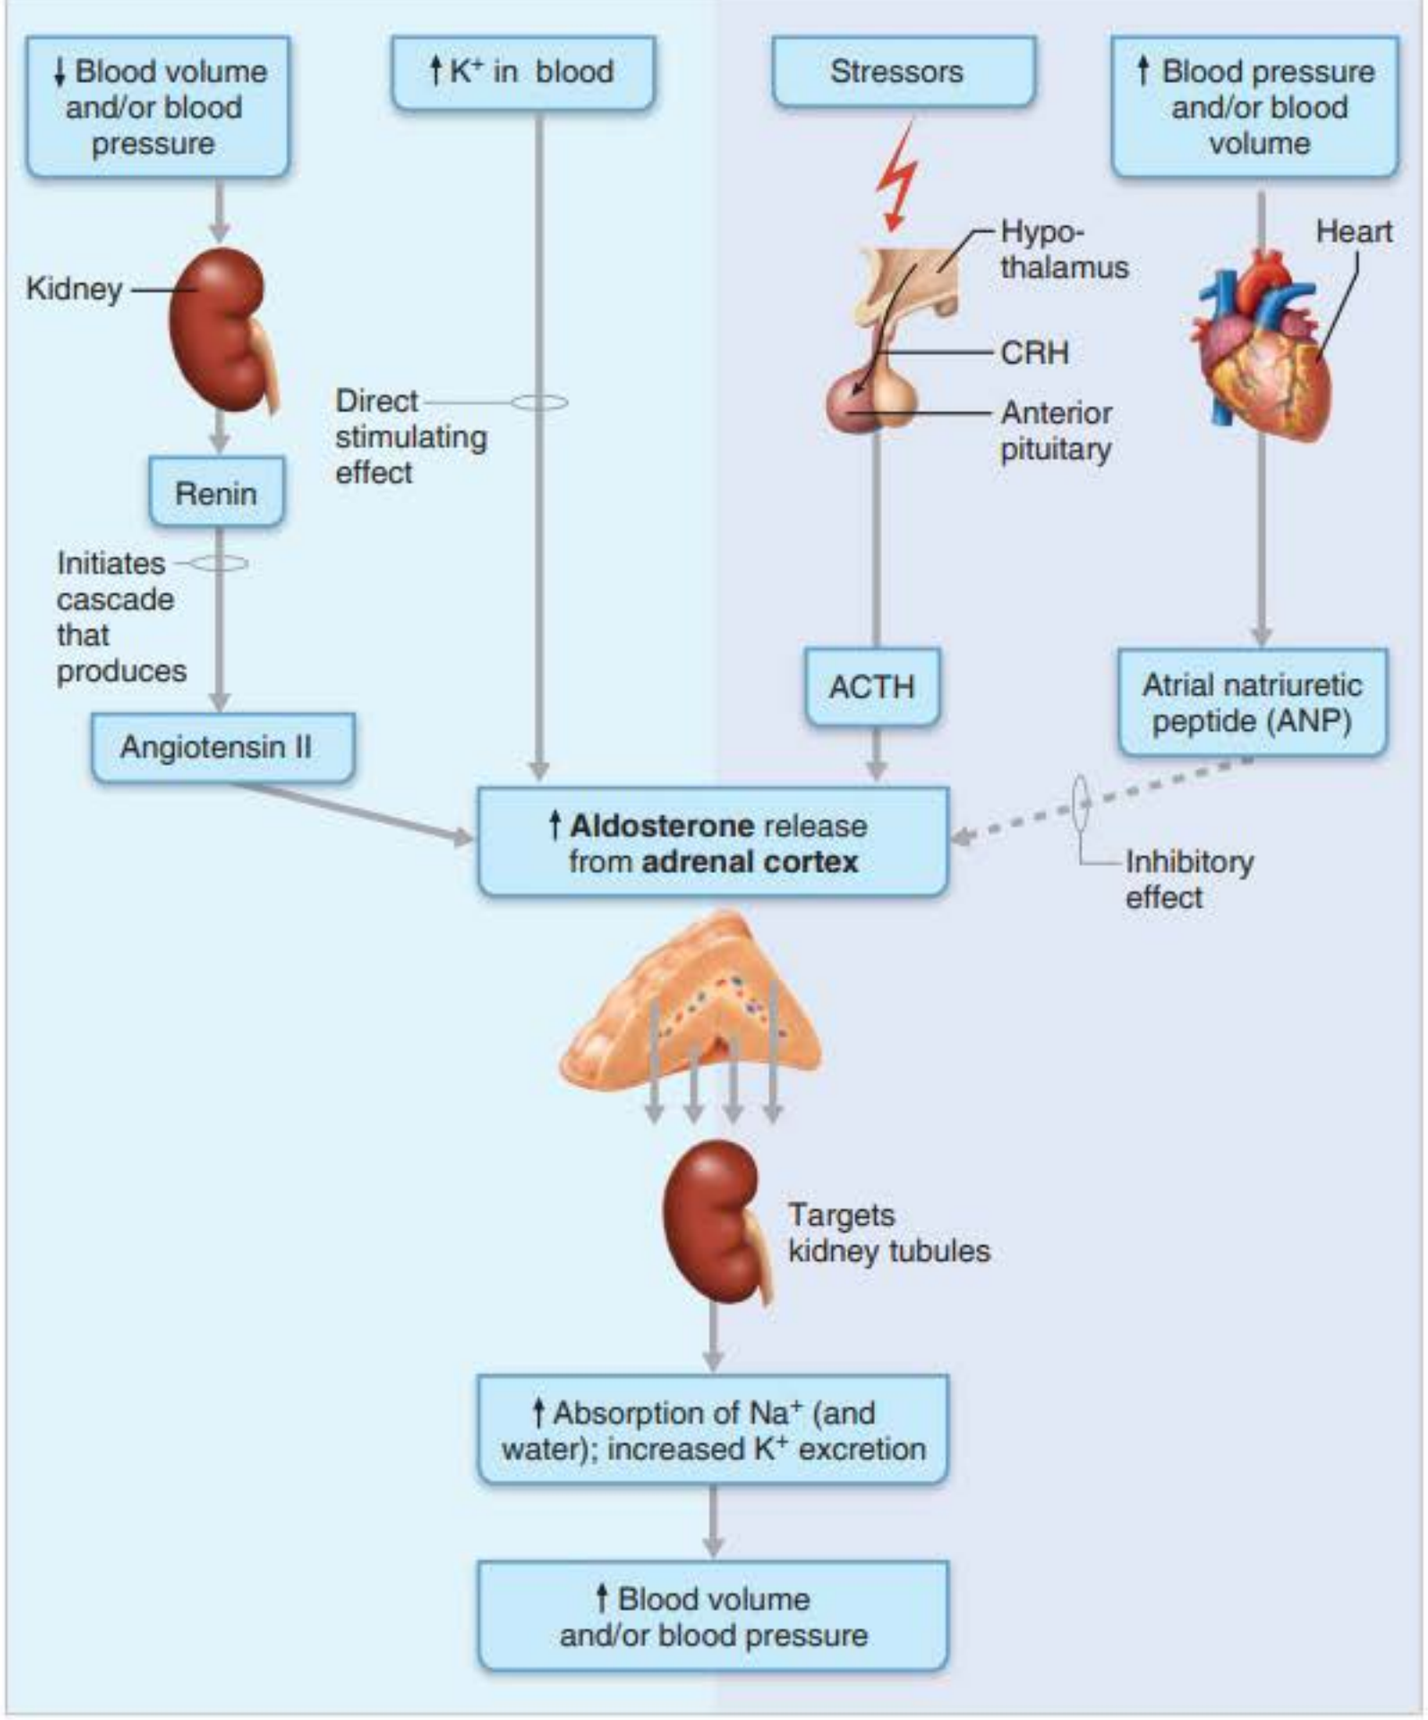

Figure 16.14 Major mechanisms controlling aldosterone release.

HOMEOSTATIC IMBALANCE 16.6 CLINICAL

Hypersecretion of aldosterone, a condition called *aldosteronism*, typically results from adrenal tumors. Two major sets of problems result: (1) hypertension and edema due to excessive Na^+ and water retention, and (2) accelerated excretion of potassium ions. If K^+ loss is extreme, neurons become nonresponsive, leading to muscle weakness and eventually paralysis.

Glucocorticoids

The **glucocorticoids** influence the energy metabolism of most body cells and help us resist stressors. Under normal circumstances, they help the body adapt to intermittent food intake by keeping blood glucose levels fairly constant, and help maintain blood pressure.

Glucocorticoid hormones include **cortisol (hydrocortisone)**, **cortisone**, and **corticosterone**, but only cortisol is secreted in significant amounts in humans. As with all steroid hormones, glucocorticoids act on target cells by modifying gene activity.

Regulation of Secretion Negative feedback regulates glucocorticoid secretion. Cortisol release is promoted by ACTH. ACTH release is triggered in turn by the hypothalamic releasing hormone CRH. Rising cortisol levels feed back to act on both the hypothalamus and the anterior pituitary, preventing CRH release and shutting off ACTH and cortisol secretion.

Cortisol secretory bursts, driven by patterns of eating and activity, occur in a definite pattern throughout the day and night. Cortisol blood levels peak shortly before we rise in the morning. The lowest levels occur in the evening just before and shortly after we fall asleep.

Various stressors (for example, hemorrhage, infection, or physical or emotional trauma) interrupt the normal cortisol rhythm. Higher CNS centers override the inhibitory effects of elevated cortisol levels and trigger CRH release. The resulting increase in ACTH blood levels causes an outpouring of cortisol from the adrenal cortex.

Actions The dramatically higher output of glucocorticoids during stress is essential for negotiating the crisis. Cortisol provokes a marked rise in blood levels of glucose, fatty acids, and amino acids. Cortisol's prime metabolic effect is to provoke *gluconeogenesis*, that is, the formation of glucose from fats and proteins. In order to "save" glucose for the brain, cortisol mobilizes fatty acids from adipose tissue and encourages their increased use for energy. Under cortisol's influence, proteins are broken down to provide building blocks for repair or to make enzymes for metabolic processes. Cortisol's second critical function is to enhance the sympathetic nervous system's vasoconstrictive effects, helping to maintain blood pressure.

Note that *ideal amounts of glucocorticoids promote normal function*, but too much cortisol exerts significant anti-inflammatory and anti-immune effects. Excessive levels of glucocorticoids:

- Depress cartilage and bone formation
- Inhibit inflammation by decreasing the release of inflammatory chemicals
- Depress the immune system
- Disrupt normal cardiovascular, neural, and gastrointestinal function

Glucocorticoid drugs can control symptoms of many chronic inflammatory disorders, such as rheumatoid arthritis and allergic responses. However, these potent drugs are a double-edged sword because they also cause the undesirable effects of excessive levels of these hormones.

HOMEOSTATIC IMBALANCE 16.7 CLINICAL

The pathology of glucocorticoid excess, **Cushing's syndrome**, may be caused by an ACTH-releasing pituitary tumor (in which case it is called **Cushing's disease**); by an ACTH-releasing malignancy of the lungs, pancreas, or kidneys; or by a tumor of the adrenal cortex. However, it most often results from the clinical administration of glucocorticoid drugs.

The syndrome is characterized by persistent elevated blood glucose levels (*steroid diabetes*), dramatic losses in muscle and bone protein, and water and salt retention, leading to hypertension and edema. The so-called *cushingoid signs* (**Figure 16.15**) include a swollen "moon" face, redistribution of fat to the abdomen and the posterior neck (causing a "buffalo hump"), easy bruising, and poor wound healing. Because of enhanced anti-inflammatory effects, infections may become overwhelmingly severe before producing recognizable symptoms. Eventually, muscles weaken and spontaneous fractures force the person to become bedridden. The only treatment is to remove the cause—be it surgically removing the tumor or discontinuing the drug.

Addison's disease, the major hyposecretory disorder of the adrenal cortex, usually involves deficits in both glucocorticoids and mineralocorticoids. Affected individuals tend to lose

Table 16.5 Adrenal Gland Hormones: Summary of Regulation and Effects

HORMONE	REGULATION OF RELEASE	TARGET ORGAN AND EFFECTS	EFFECTS OF HYPERSECRETION ↑ AND HYPOSECRETION ↓
Adrenocortical Hormones			
Mineralocorticoids (chiefly aldosterone)	**Stimulated** by renin-angiotensin-aldosterone mechanism (activated by decreasing blood volume or blood pressure), elevated blood K^+ levels, and ACTH (minor influence) **Inhibited** by increased blood volume and pressure, and decreased blood K^+ levels	Kidneys: increase blood levels of Na^+ and decrease blood levels of K^+; since water reabsorption usually accompanies sodium retention, blood volume and blood pressure rise	↑: Aldosteronism ↓: Addison's disease
Glucocorticoids (chiefly cortisol)	**Stimulated** by ACTH **Inhibited** by feedback inhibition exerted by cortisol	Body cells: promote gluconeogenesis and hyperglycemia; mobilize fats for energy metabolism; stimulate protein catabolism; assist body to resist stressors; depress inflammatory and immune responses	↑: Cushing's syndrome ↓: Addison's disease
Gonadocorticoids (chiefly androgens, converted to testosterone or estrogens after release)	**Stimulated** by ACTH; mechanism of inhibition incompletely understood, but feedback inhibition not seen	Insignificant effects in males; contributes to female libido; development of pubic and axillary hair in females; source of estrogens after menopause	↑: Masculinization of females (adrenogenital syndrome) ↓: No effects known
Adrenal Medullary Hormones			
Catecholamines (epinephrine and norepinephrine)	**Stimulated** by preganglionic fibers of the sympathetic nervous system	Sympathetic nervous system target organs: effects mimic sympathetic nervous system activation; increase heart rate and metabolic rate; increase blood pressure by promoting vasoconstriction	↑: Prolonged fight-or-flight response; hypertension ↓: Unimportant

weight; plasma glucose and sodium levels drop, and potassium levels rise. Severe dehydration and hypotension are common. Corticosteroid replacement therapy is the usual treatment.

A common early sign of Addison's disease is a characteristic bronzing of the skin. This occurs because the lack of negative feedback by corticosteroids increases ACTH release by the anterior pituitary. At high levels, ACTH triggers melanin production in melanocytes.

Gonadocorticoids (Adrenal Sex Hormones)

Most **gonadocorticoids** secreted by the adrenal cortex are weak **androgens**, or male sex hormones, such as *androstenedione* and *dehydroepiandrosterone* (*DHEA*). Most are converted in tissue cells to more potent male hormones, such as *testosterone*, and some are converted to estrogens. The amount of gonadocorticoids produced by the adrenal cortex is insignificant compared with the amounts made by the gonads during late puberty and adulthood.

The exact role of the adrenal sex hormones is still in question, but we know that they contribute to axillary and pubic hair development. In adult women, adrenal androgens are thought to contribute to the sex drive, and they largely account for the estrogens produced after menopause when ovarian estrogens are no longer produced. Control of gonadocorticoid secretion is not completely understood. ACTH stimulates their release, but the gonadocorticoids do not appear to exert feedback inhibition on ACTH release.

HOMEOSTATIC IMBALANCE 16.8 CLINICAL

Since androgens predominate, hypersecretion of gonadocorticoids causes *adrenogenital syndrome* (masculinization). In adult males, elevated gonadocorticoid levels may not be noticeable since testicular testosterone has already produced masculinization, but in prepubertal males and in females, the results can be dramatic. In boys, the reproductive organs mature and secondary sex characteristics appear early, and the sex drive emerges with a vengeance. Females develop a beard and a masculine distribution of body hair, and the clitoris grows to resemble a small penis.

The Adrenal Medulla

We discussed the adrenal medulla in Chapter 14 as part of the autonomic nervous system (◀ p. 542), so our coverage here is brief. The spherical **medullary chromaffin cells** (kro′mah-fin), which crowd around porous blood-filled capillaries, are modified postganglionic sympathetic neurons. The cells synthesize the *catecholamines* **epinephrine** and **norepinephrine (NE)** via a molecular sequence from tyrosine to dopamine to NE to epinephrine.

When a short-term stressor activates the body to fight-or-flight status, the sympathetic nervous system is mobilized. Blood vessels constrict and the heart beats faster (together raising the blood pressure), and blood is diverted from temporarily nonessential organs to the heart and skeletal muscles. Blood glucose levels rise, and preganglionic sympathetic nerve endings weaving through the adrenal medulla signal for release of catecholamines, which reinforce and prolong the fight-or-flight response.

Unequal amounts of the two hormones are stored and released. Approximately 80% is epinephrine and 20% norepinephrine. With a few exceptions, the two hormones exert the same effects (◀ Table 14.3, p. 544). Epinephrine is the more potent stimulator of metabolic activities and dilator of small airways (bronchioles), but norepinephrine has a greater influence on peripheral vasoconstriction and blood pressure. Epinephrine is used clinically as a heart stimulant and to dilate the bronchioles during acute asthmatic attacks and severe allergic reactions.

Unlike hormones from the adrenal cortex, which promote long-lasting body responses to stressors, catecholamines cause fairly brief responses. *Focus on Stress and the Adrenal Gland* (**Focus Figure 16.2** on pp. 628–629) illustrates how our bodies respond to stressors in the short and long term.

HOMEOSTATIC IMBALANCE 16.9 CLINICAL

A deficiency in adrenal medulla hormones is not a problem because these hormones merely intensify activities set into motion by the sympathetic nervous system neurons. Unlike glucocorticoids and mineralocorticoids, adrenal catecholamines are not essential for life.

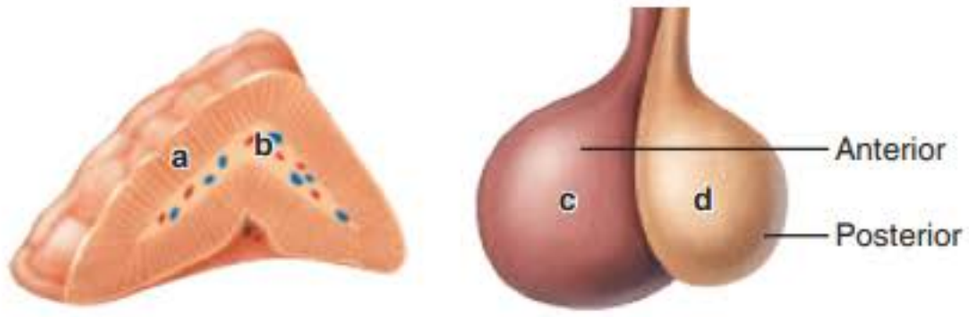
On the other hand, hypersecretion of catecholamines, sometimes arising from a medullary chromaffin cell tumor called a *pheochromocytoma* (fe-o-kro″mo-si-to′mah), produces symptoms of uncontrolled sympathetic nervous system activity—increased metabolic rate, rapid heartbeat and palpitations, hypertension, intense nervousness, and sweating.

Check Your Understanding

17. List the three classes of hormones released from the adrenal cortex and briefly state the major effect(s) of each.

18. What are the two major stimuli for aldosterone release? What is the major stimulus for cortisol release?

19. Which part of the gland(s) below releases steroid hormones? Amino acid–based hormones? Name the hormone released from (c) that acts on (a). Histologically, what do (b) and (d) have in common that differentiates them from other glands?



For answers, see Answers Appendix.

16.10 The pineal gland secretes melatonin

Learning Outcome

▶ **Briefly describe the importance of melatonin.**

The tiny, pinecone-shaped **pineal gland** hangs from the roof of the third ventricle in the diencephalon (see Figure 16.1 and ◀ Figure 12.11, p. 447). Its secretory cells, called **pinealocytes**, are arranged in compact cords and clusters. Lying between pinealocytes in adults are dense particles containing calcium salts. These salts are radiopaque, making the pineal gland a handy landmark for determining brain orientation in X rays.

Although many peptides and amines have been isolated from this minute gland, its only major secretory product is **melatonin** (mel″ah-to′nin), an amine hormone derived from serotonin. Melatonin concentrations in the blood rise and fall in a diurnal (daily) cycle. Peak levels occur during the night and make us drowsy, and lowest levels occur around noon. Recent evidence suggests that melatonin also controls the production of protective antioxidant and detoxification molecules within cells.

The pineal gland indirectly receives input from the visual pathways (retina → suprachiasmatic nucleus of hypothalamus → superior cervical ganglion → pineal gland) concerning the intensity and duration of daylight. In some animals, mating behavior and gonadal size vary with relative lengths of light and dark periods, and melatonin mediates these effects.

In children, melatonin may have an antigonadotropic effect. In other words, it may affect the timing of puberty and inhibit precocious (too early) sexual maturation.

The *suprachiasmatic nucleus* of the hypothalamus, an area referred to as our "biological clock," is richly supplied with melatonin receptors, and exposure to bright light (known to suppress melatonin secretion) can reset the clock timing. As a result, changing melatonin levels may influence rhythmic variations in physiological processes such as body temperature, sleep, and appetite.

Check Your Understanding

20. APPLY Synthetic melatonin supplements are available, although their efficacy and long-term safety have not been proved. What do you think they might be used for?

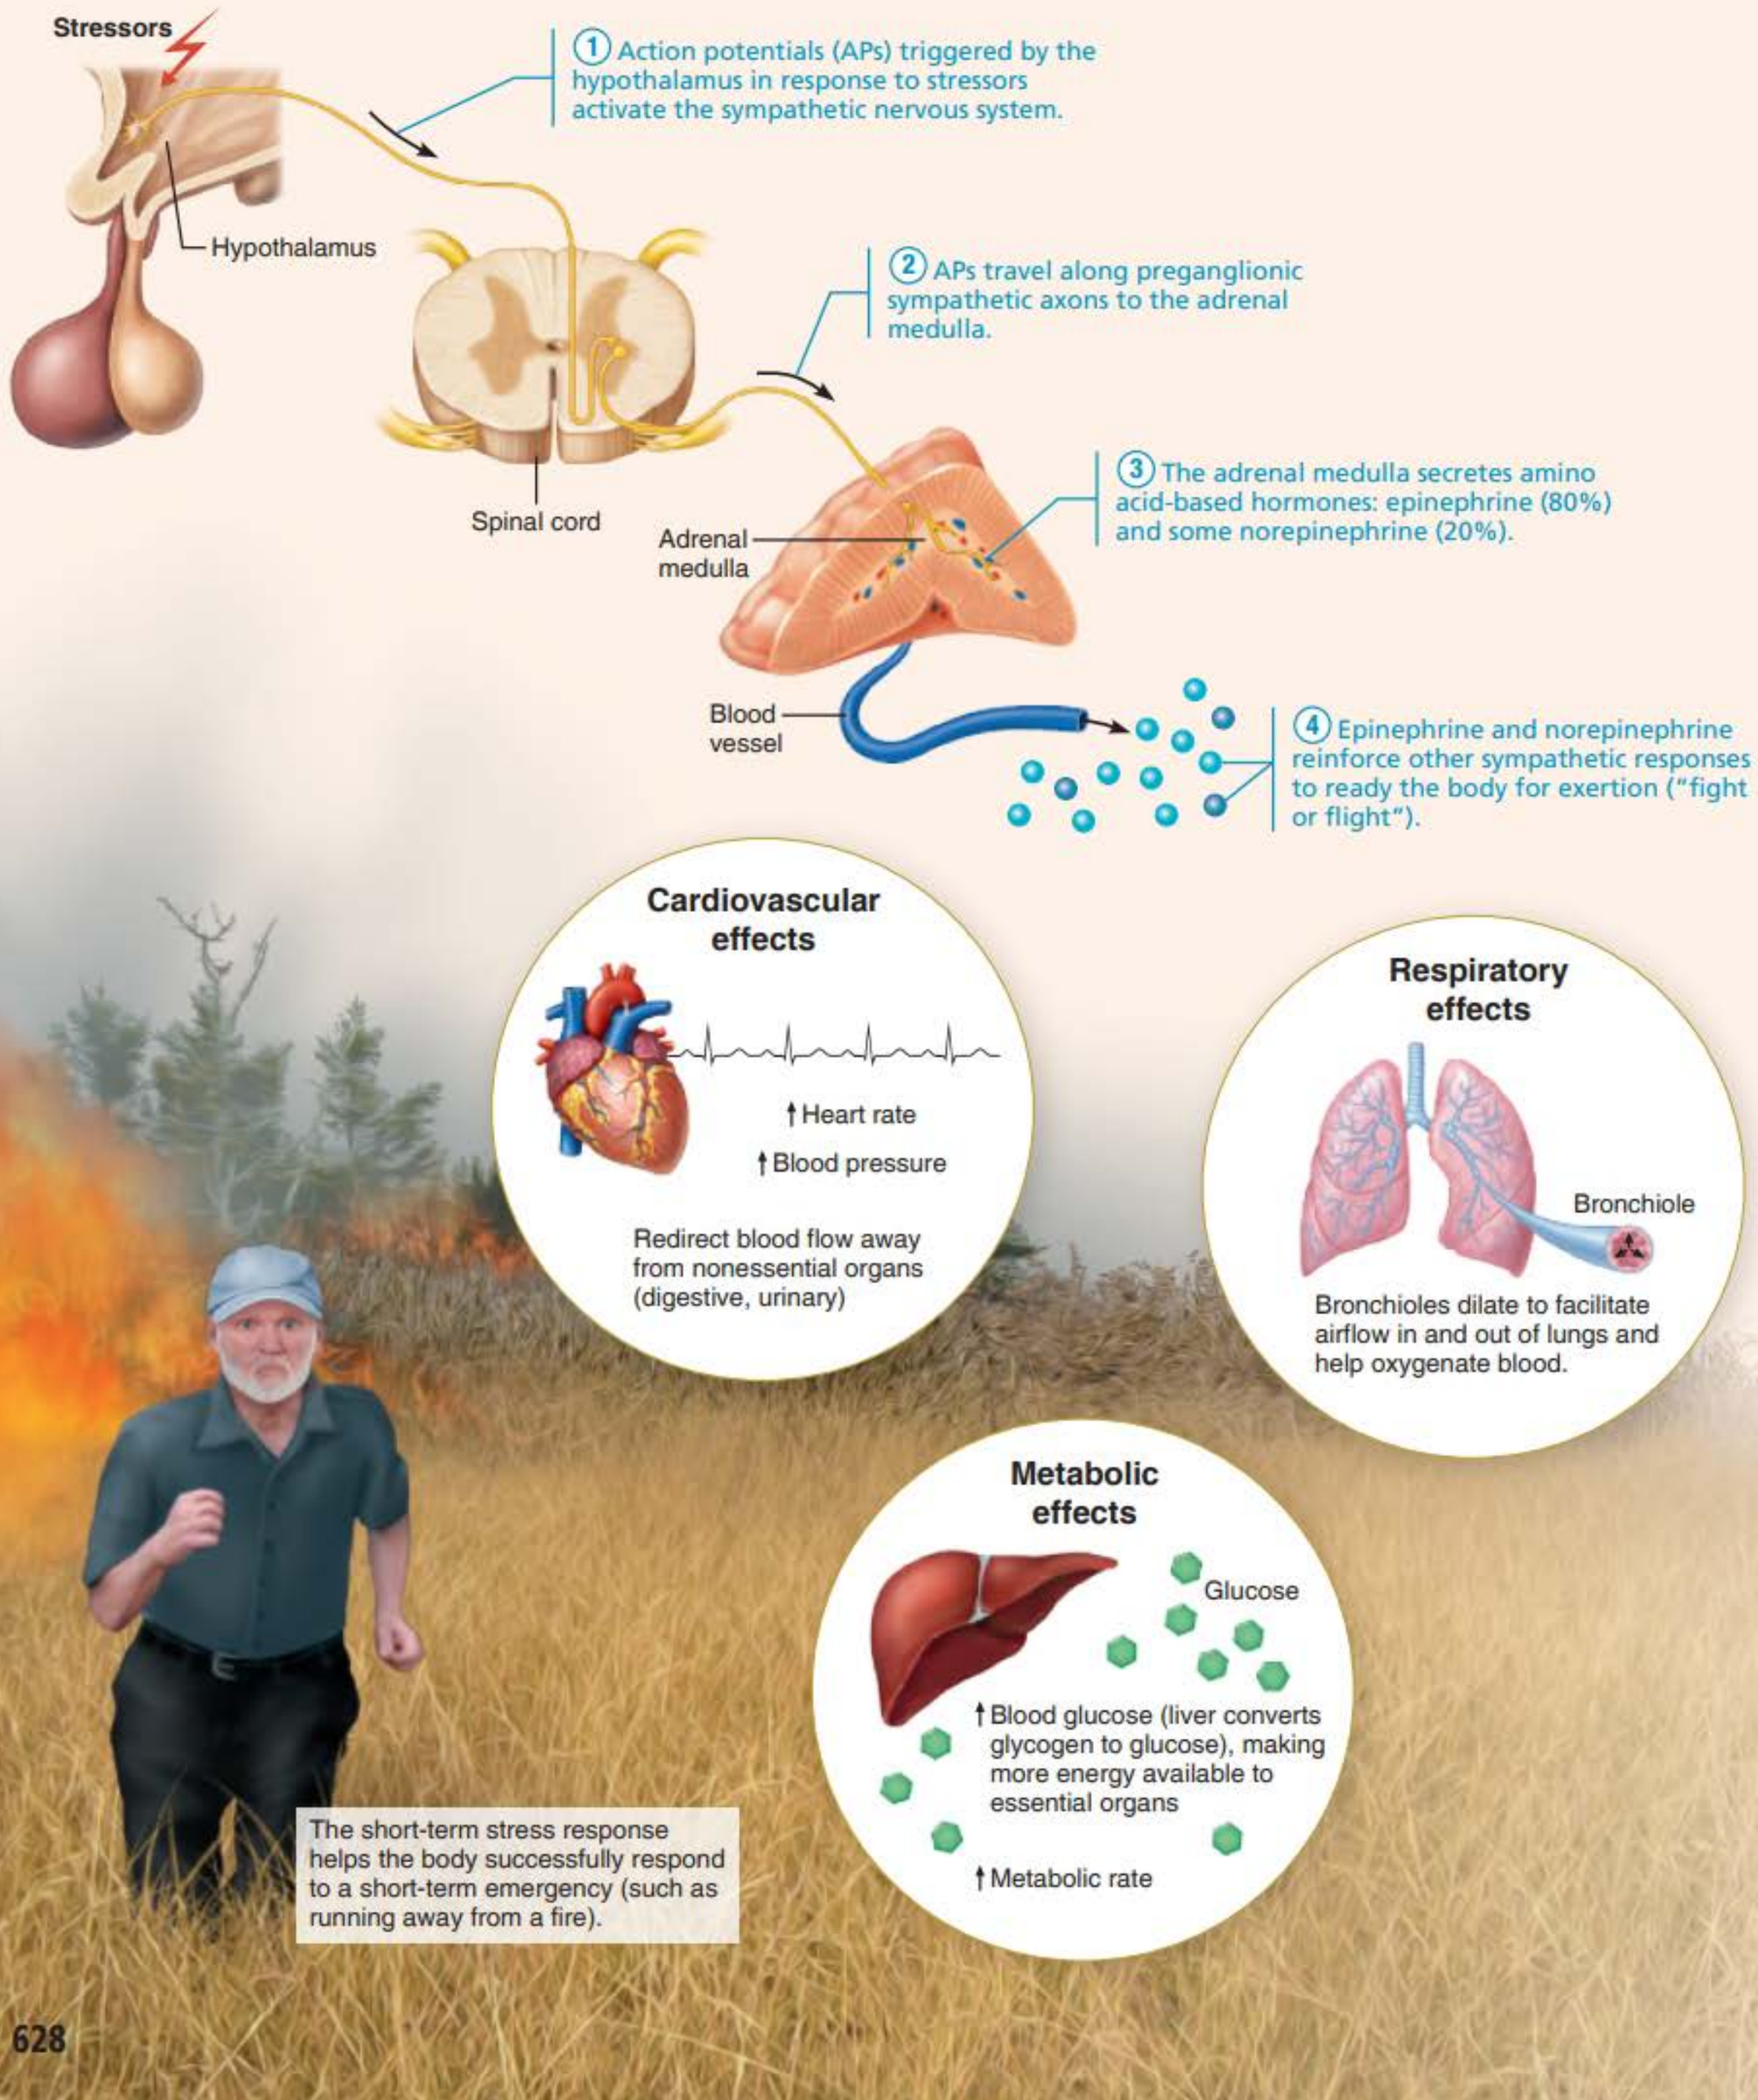
For answers, see Answers Appendix.

16

FOCUS FIGURE 16.2 Stress and the Adrenal Gland

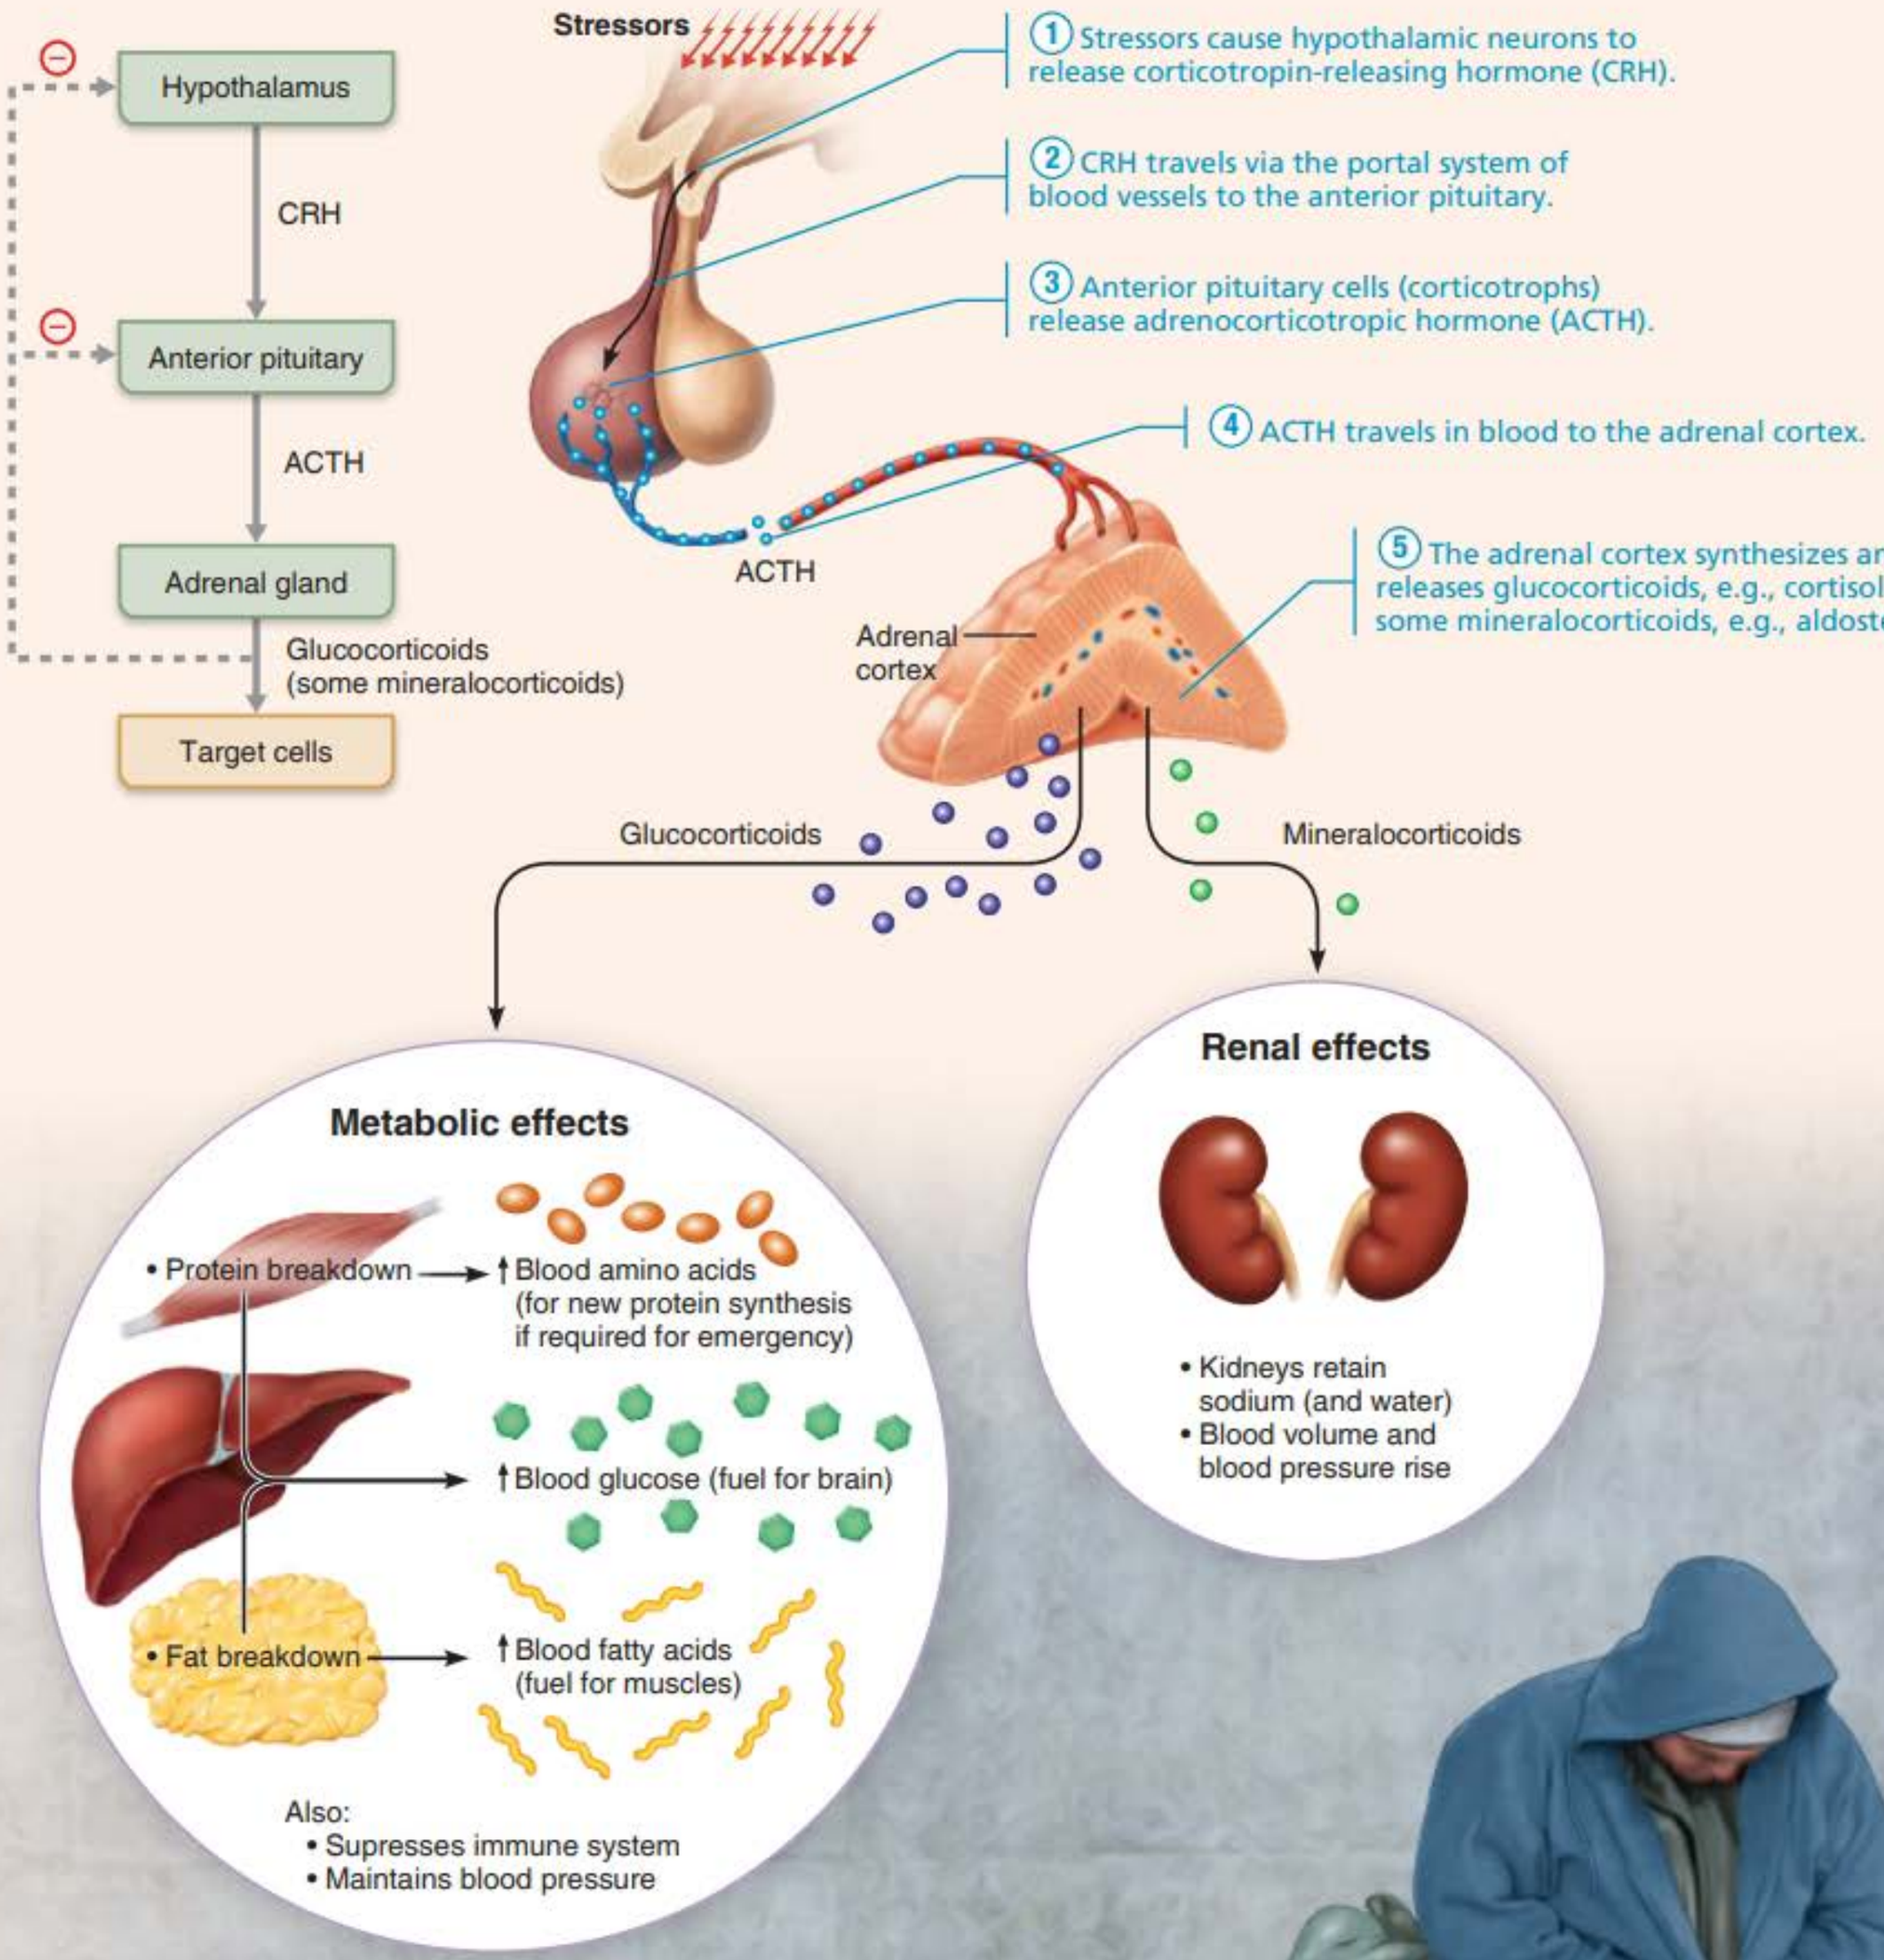
Stress is a bodywide nonspecific response to stressors—actual or potential threats to homeostasis. The hypothalamus coordinates this response in the short and long term.

Short-Term Stress: The hypothalamus activates the *adrenal medulla* via *neural stimuli*.



The short-term stress response helps the body successfully respond to a short-term emergency (such as running away from a fire).

Long-Term Stress: The hypothalamus activates the *adrenal cortex* via *hormonal stimuli*. This greatly reinforces the continuing short-term stress response.



The long-term stress response helps the body successfully deal with some long-term stressors (such as starvation). However, if the stress response is prolonged, it can become detrimental. It may lead to high blood pressure, muscle loss, altered immune function, and other problems.

16.11 The pancreas, gonads, and most other organs secrete hormones

Learning Outcomes

- **Compare and contrast the effects of the two major pancreatic hormones.**
- **Describe the functional roles of hormones of the testes, ovaries, and placenta.**
- **State the location of enteroendocrine cells.**
- **Briefly explain the hormonal functions of the heart, kidney, skin, adipose tissue, bone, and thymus.**

So far, we've examined the endocrine role of the hypothalamus and of glands dedicated solely to endocrine function. We will now consider a set of organs that contain endocrine tissue but also have other major functions. These include the pancreas, gonads, and placenta.

The Pancreas

Located partially behind the stomach in the abdomen, the soft, tadpole-shaped **pancreas** is a mixed gland composed of both endocrine and exocrine gland cells (see Figure 16.1). Along with the thyroid and parathyroids, it develops as an outpocketing of the epithelial lining of the gastrointestinal tract. *Acinar cells*, forming the bulk of the gland, produce an enzyme-rich juice that is carried by ducts to the small intestine during digestion.

Scattered among the acinar cells are approximately a million **pancreatic islets** (also called *islets of Langerhans*), tiny cell clusters that produce pancreatic hormones (**Figure 16.16**). The islets contain two major populations of hormone-producing cells:

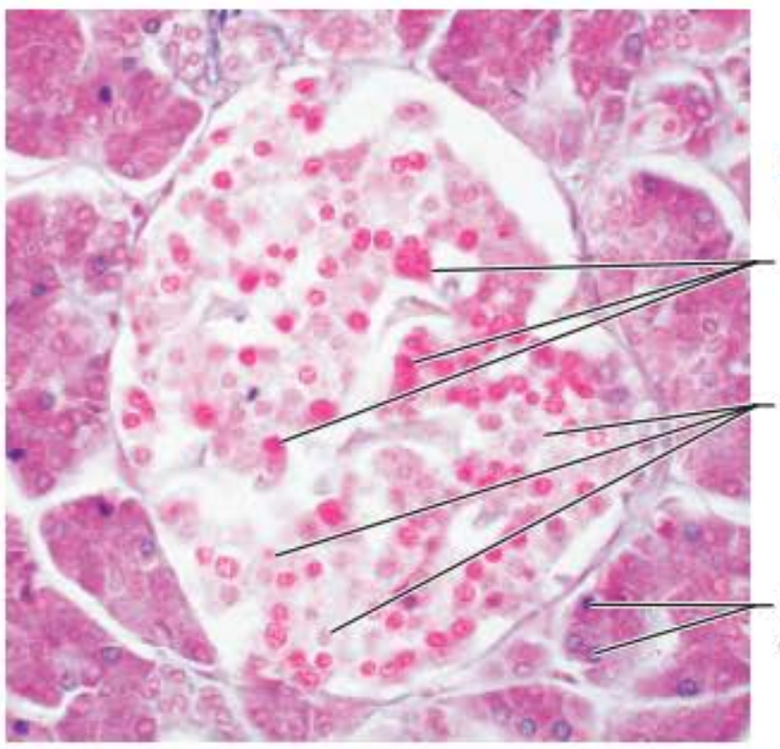


Figure 16.16 Photomicrograph of differentially stained pancreatic tissue. A pancreatic islet is surrounded by acinar cells, which produce the exocrine product (enzyme-rich pancreatic juice) (190×).

Practice Histology questions: MasteringA&P® > Study Area > Lab Tools > PAL

- **Alpha (α) cells** release glucagon and are fewer in number
- **Beta (β) cells** release insulin and are more numerous.

These cells act as tiny fuel sensors, secreting glucagon and insulin appropriately during the fasting and fed states.

Insulin and glucagon are intimately but independently involved in regulating blood glucose levels. Their effects are antagonistic: Glucagon is a *hyperglycemic* hormone (increases blood glucose), whereas insulin is a *hypoglycemic* hormone (decreases blood glucose) (**Figure 16.17**). Some islet cells also synthesize other peptides in small amounts, including *somatostatin, pancreatic polypeptide* (*PP*), and others. However, here we will focus on glucagon and insulin.

Glucagon

Glucagon (gloo′kah-gon), a 29-amino-acid polypeptide, is an extremely potent hyperglycemic agent: One molecule can cause the release of 100 million glucose molecules into the blood! The major target of glucagon is the liver, where it promotes the following actions:

- Breakdown of glycogen to glucose (*glycogenolysis*) (Figure 16.17)
- Synthesis of glucose from lactic acid and from noncarbohydrate molecules (*gluconeogenesis*)
- Release of glucose to the blood by liver cells, causing blood glucose levels to rise

A secondary effect is to lower blood levels of amino acids as the liver cells sequester these molecules to make new glucose molecules.

Humoral stimuli, mainly falling blood glucose levels, prompt the alpha cells to secrete glucagon. However, sympathetic nervous system stimulation and rising amino acid levels (as might follow a protein-rich meal) are also stimulatory. Glucagon release is suppressed by rising blood glucose levels, insulin, and somatostatin.

Insulin

Insulin is a small (51-amino-acid) protein consisting of two amino acid chains linked by disulfide (–S–S–) bonds. It is synthesized as part of a larger polypeptide chain called **proinsulin**. Enzymes then excise the middle portion of this chain, releasing functional insulin. This "clipping" process occurs in the secretory vesicles just before the beta cell releases insulin.

Insulin's effects are most obvious when we have just eaten. Its main effect is to lower blood glucose levels (Figure 16.17), but it also promotes protein synthesis and fat storage. Circulating insulin lowers blood glucose levels in three ways.

- It enhances membrane transport of glucose (and other simple sugars) into most body cells, especially muscle and fat cells.
- It inhibits the breakdown of glycogen to glucose.
- It inhibits the conversion of amino acids or fats to glucose. These inhibiting effects counter any metabolic activity that would increase plasma levels of glucose.

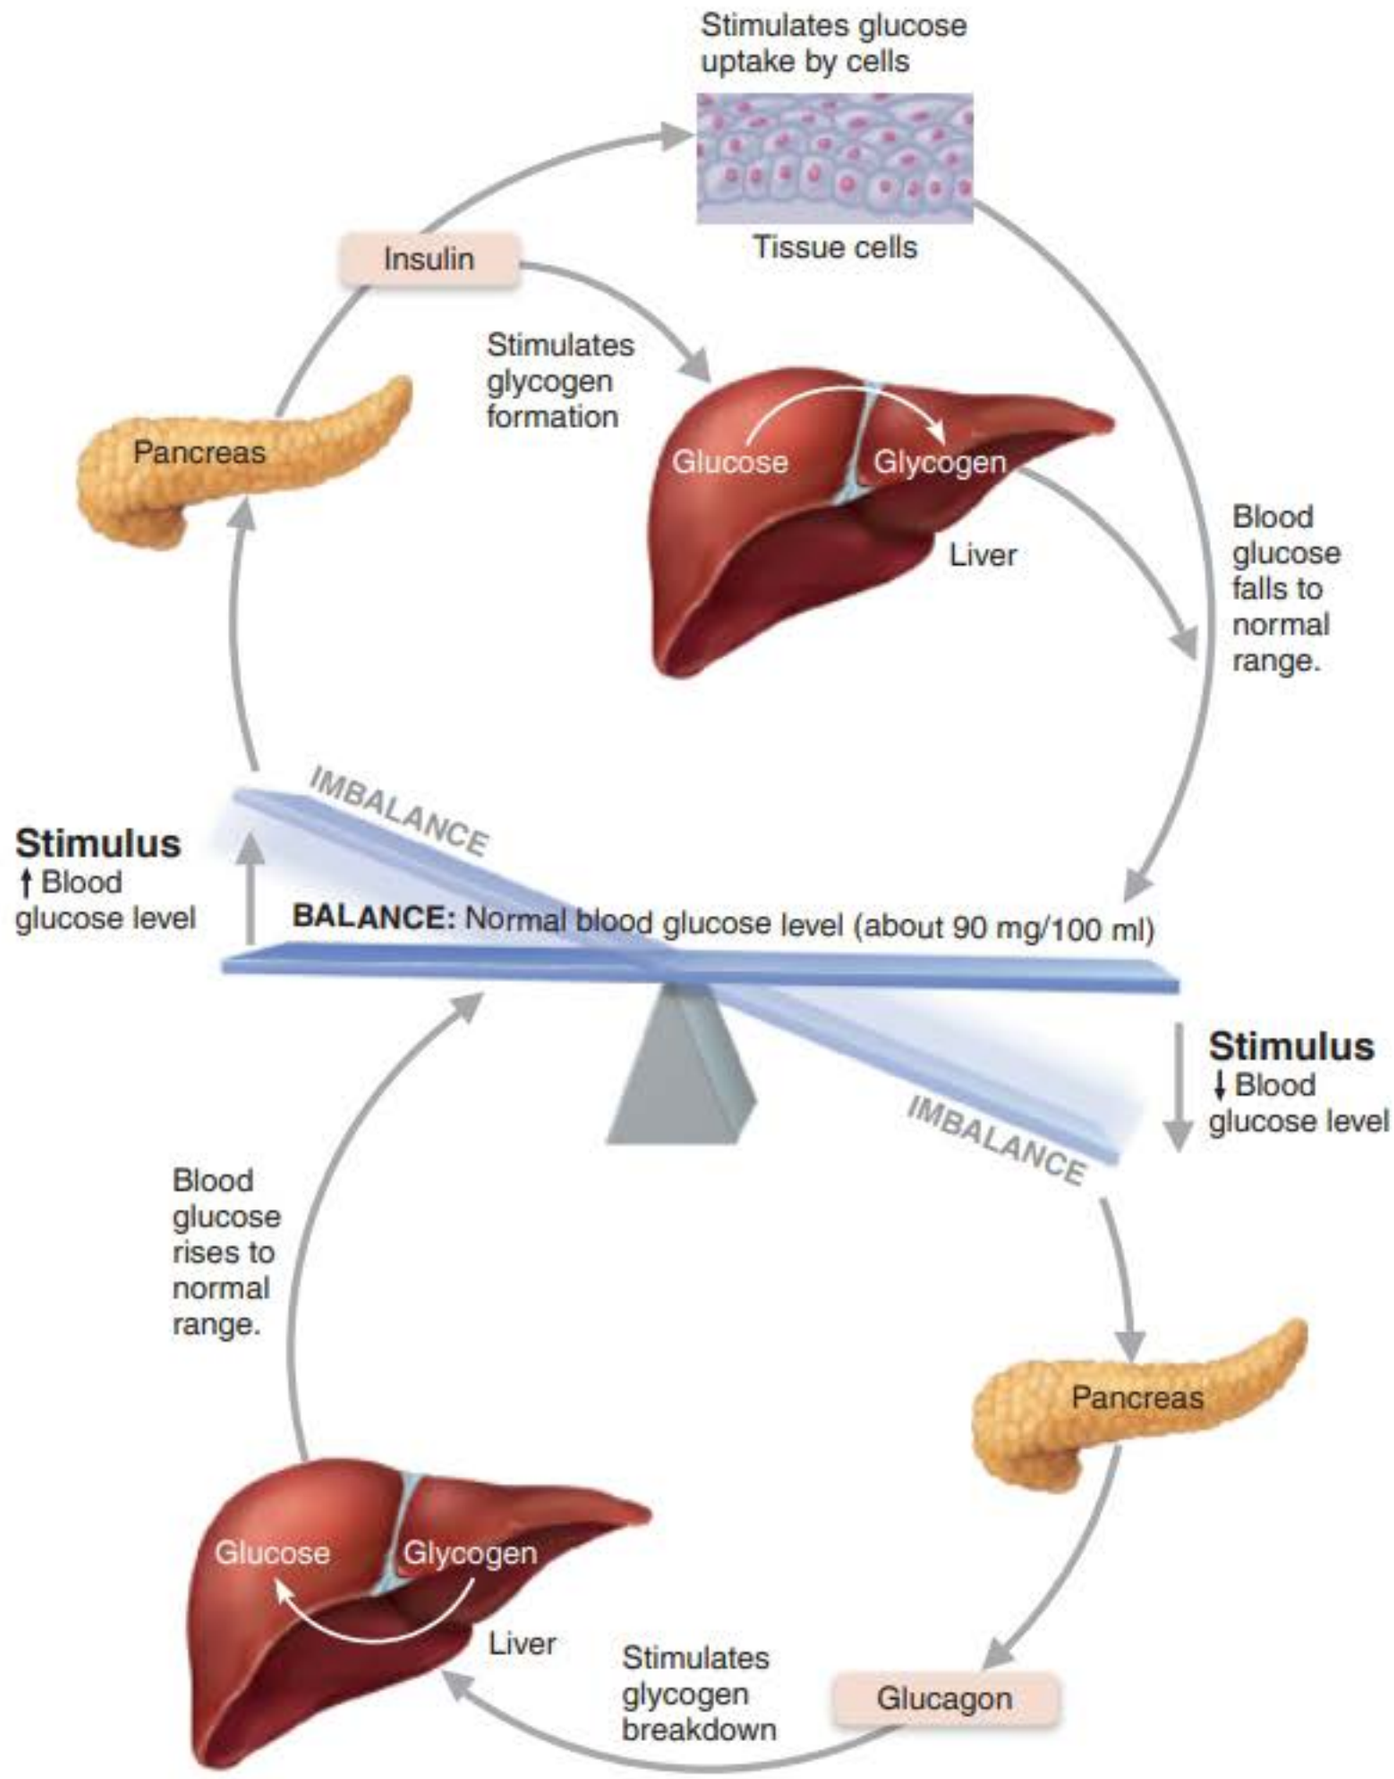

Figure 16.17 Insulin and glucagon from the pancreas regulate blood glucose levels.

Insulin is *not* needed for glucose entry into liver, kidney, and brain tissue, all of which have easy access to blood glucose regardless of insulin levels. However, insulin does have important roles in the brain—it participates in neuronal development, feeding behavior, and learning and memory.

Insulin activates its receptor (a tyrosine kinase enzyme), which phosphorylates specific proteins, beginning the cascade that promotes glucose uptake and insulin's other effects. After glucose enters a target cell, insulin binding triggers enzymatic activities that:

- Catalyze the oxidation of glucose for ATP production
- Join glucose molecules together to form glycogen
- Convert glucose to fat (particularly in adipose tissue)

As a rule, energy needs are met first, followed by glycogen formation. Finally, if excess glucose is still available, it is converted to fat. Insulin also stimulates amino acid uptake and protein synthesis in muscle tissue.

Factors That Influence Insulin Release Pancreatic beta cells secrete insulin when stimulated by:

- Elevated blood glucose levels. This is the chief controlling factor.
- Rising blood levels of amino acids and fatty acids.
- Acetylcholine released by parasympathetic nerve fibers.
- Hyperglycemic hormones (such as glucagon, epinephrine, growth hormone, thyroxine, or glucocorticoids). This effect is indirect and occurs because all of these hormones increase blood glucose levels.

Somatostatin and sympathetic nervous system activation depress insulin release.

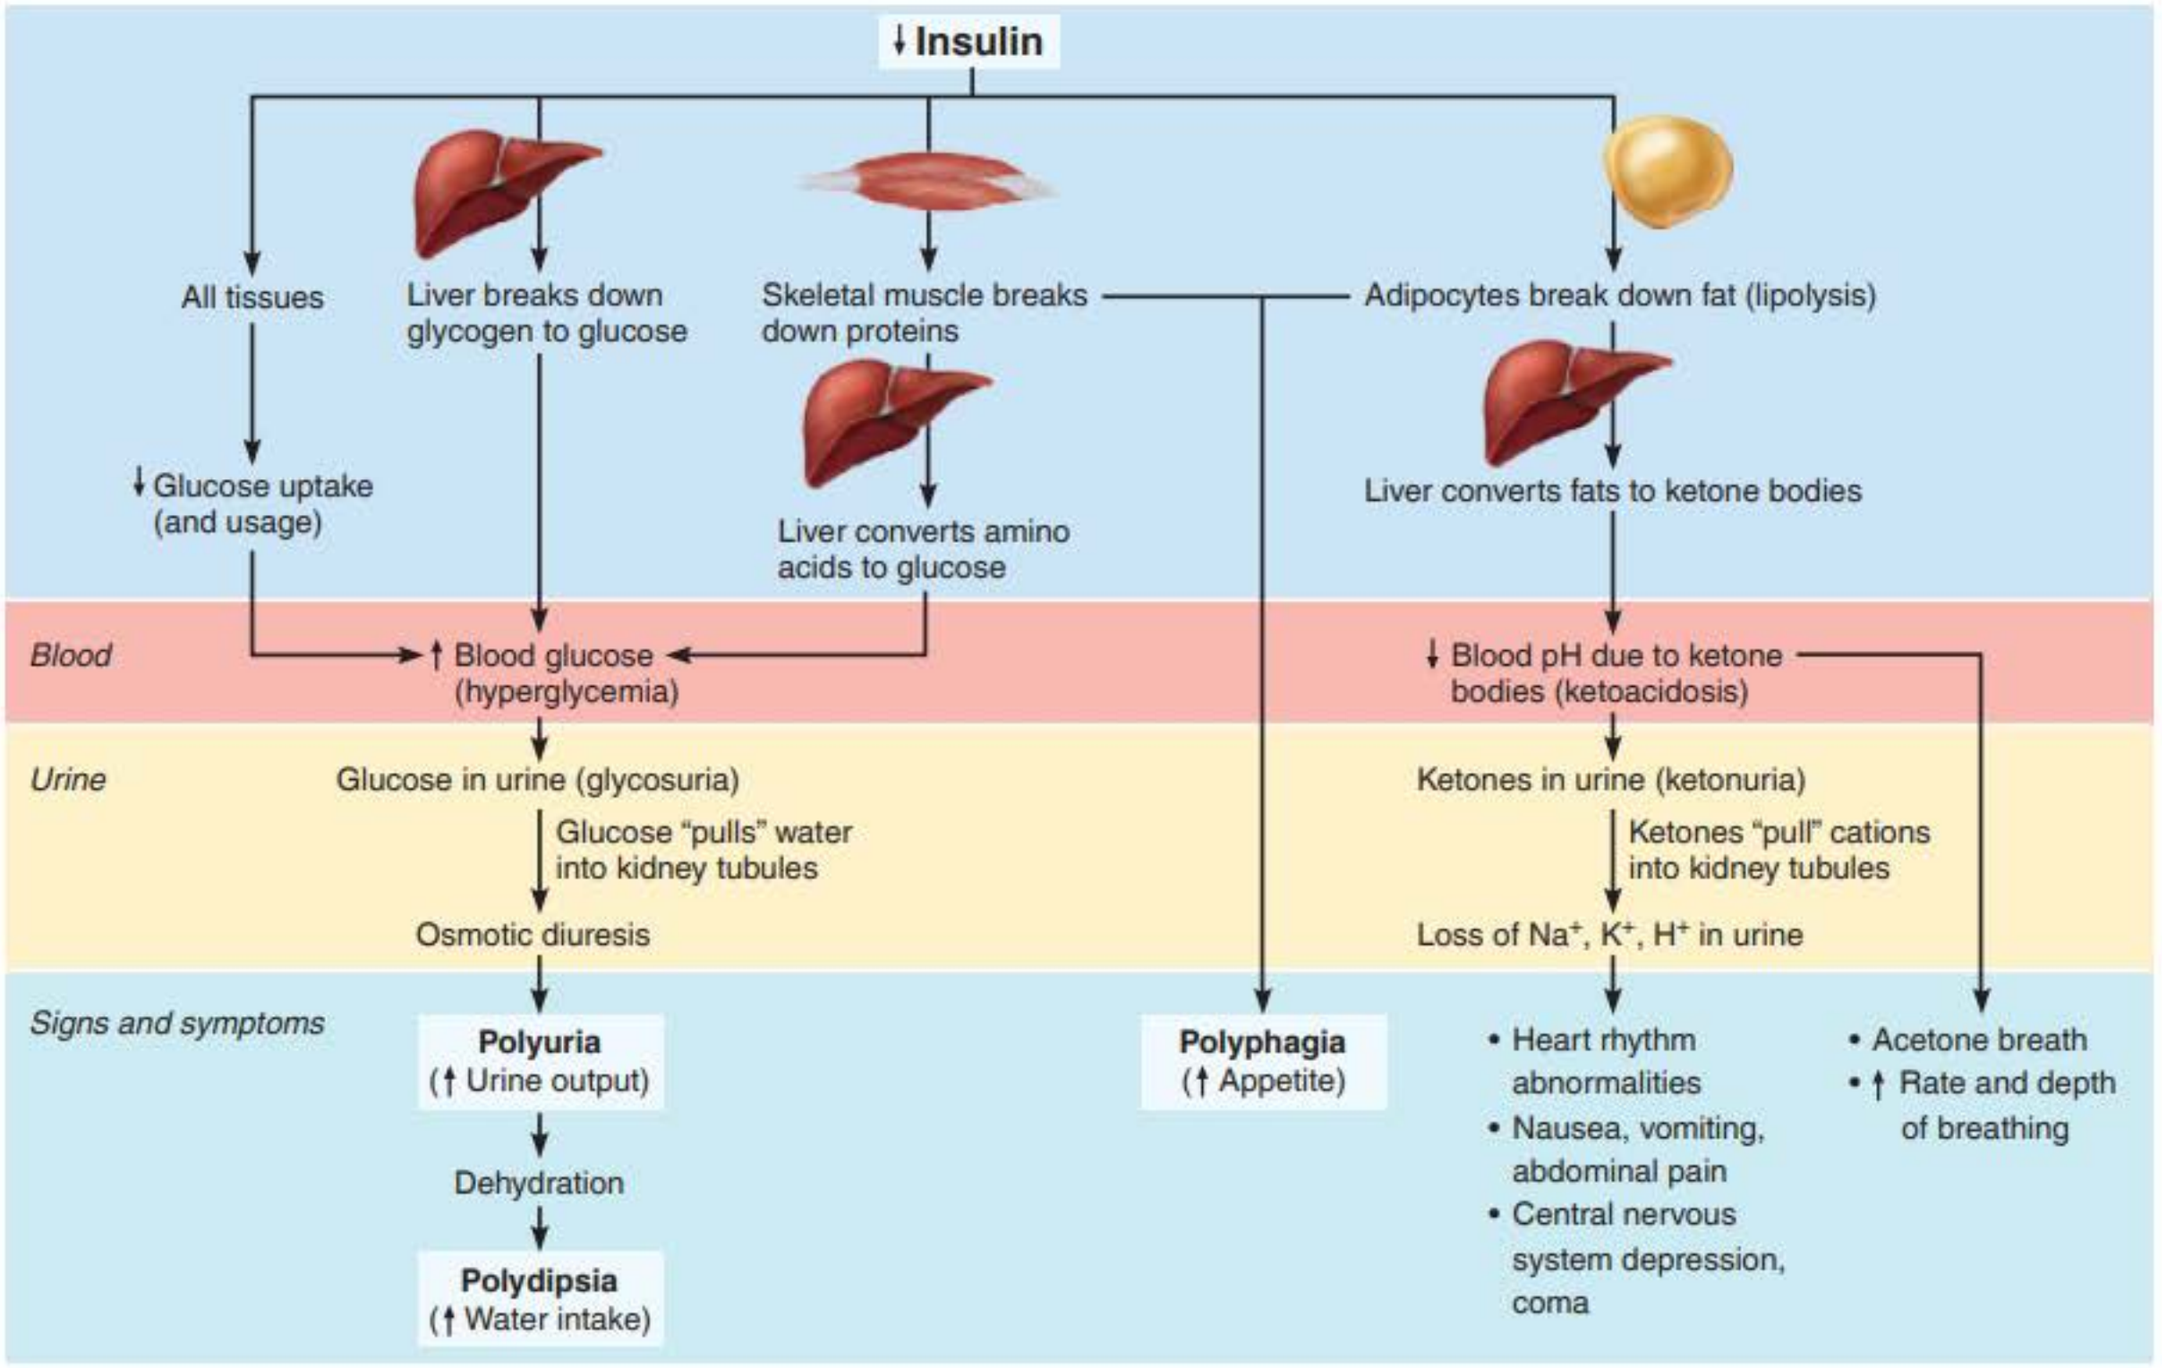

Figure 16.18 Consequences of insulin deficit (diabetes mellitus).

As you can see, blood glucose levels represent a balance of humoral, neural, and hormonal influences. Insulin is the major hypoglycemic factor that counterbalances the many hyperglycemic hormones.

HOMEOSTATIC IMBALANCE 16.10 — CLINICAL

Diabetes mellitus (DM) results from either hyposecretion or hypoactivity of insulin. When insulin is absent, the result is *type 1 diabetes mellitus*. If insulin is present, but its effects are deficient, the result is *type 2 diabetes mellitus*. In either case, blood glucose levels remain high after a meal because glucose is unable to enter most tissue cells.

Diabetes is so common that you will encounter many patients with this disease in your career. It is described in more detail in **A Closer Look**. The three cardinal signs of diabetes mellitus (outlined in **Figure 16.18**) are:

- **Polyuria.** Excessive glucose in the blood leads to excessive glucose in the kidney filtrate where it acts as an osmotic diuretic (that is, it inhibits water reabsorption by the kidney tubules). The end result is **polyuria**, a huge urine output that decreases blood volume and causes dehydration.
- **Polydipsia.** Dehydration stimulates hypothalamic thirst centers, causing **polydipsia**, or excessive thirst.
- **Polyphagia. Polyphagia** refers to excessive hunger and food consumption, a sign that the person is "starving in the land of plenty." Although plenty of glucose is available, the body cannot use it. Instead, the body breaks down protein and fat to supply energy, and this is thought to stimulate appetite.

When sugars cannot be used as cellular fuel, more fats are mobilized, resulting in high fatty acid levels in the blood, a condition called lipidemia. In severe cases of diabetes mellitus, blood levels of fatty acids and their metabolites (acetoacetic acid, acetone, and others) rise dramatically. The fatty acid metabolites, collectively called **ketones** (ke′tōnz) or **ketone bodies**, are organic acids. When they accumulate in the blood, the blood pH drops, resulting in **ketoacidosis**, and ketone bodies begin to spill into the urine (*ketonuria*).

Severe ketoacidosis is life threatening. The nervous system responds by initiating rapid deep breathing (hyperpnea) to blow off carbon dioxide from the blood and increase blood pH. (We will explain the physiological basis of this mechanism in Chapter 22.) Serious electrolyte losses also occur as the body rids itself of excess ketone bodies. Ketone bodies are negatively charged and carry positive ions out with them, so sodium and

Sweet Revenge: Taming the Diabetes Monster?

Few medical breakthroughs have been as electrifying as the discovery of insulin in 1921, an event that changed diabetes mellitus (DM) from a death sentence to a survivable disease. Nonetheless, DM is still a huge health problem: Determining blood glucose levels accurately and maintaining desirable levels sorely challenge our present biotechnology. Let's take a closer look at the characteristics and challenges of type 1 and type 2, the major forms of diabetes mellitus.

More than 1 million Americans have **type 1 diabetes mellitus**, formerly called *insulin-dependent diabetes mellitus*. Symptoms appear suddenly, usually before age 15, following a long asymptomatic period during which the immune system destroys the pancreas's beta cells. Consequently, type 1 diabetics effectively lack insulin.

Type 1 diabetes susceptibility genes have been localized on several chromosomes, indicating that type 1 diabetes is an example of a multigene autoimmune response. However, some investigators believe that *molecular mimicry* is at least part of the problem: Some foreign substance (for example, a virus) has entered the body and is so similar to certain self (beta cell) proteins that the immune system attacks the beta cells as well as the invader. Sadly, once beta cells are destroyed, they're gone for good.

The goal of several lines of current research is to halt the destruction of beta cells. While broad-spectrum immunosuppressants have been used, these have serious side effects, and more targeted approaches are being pursued. Unfortunately, beta cell destruction is rapid and virtually complete by the time of diagnosis.

Type 1 diabetes patients typically develop long-term vascular and neural problems. The lipidemia and high blood cholesterol levels typical of the disease can lead to severe vascular complications including atherosclerosis, strokes, heart attacks, kidney shutdown, gangrene, and blindness. Nerve damage leads to loss of sensation, impaired bladder function, and impotence. Female type 1 diabetics also tend to have lumpy breasts and to undergo premature menopause, which increases their risk for cardiac problems.

Hyperglycemia is the culprit behind these complications, and the closer to normal blood glucose levels are held, the less likely complications are. Continuous glucose monitors make this much easier than relying on finger pricks. Currently, frequent insulin injections (up to four times daily, or better yet, by a continuous infusion pump) are recommended to reduce vascular and renal complications. Nevertheless, coupling glucose sensors to an insulin pump to make a true artificial pancreas has been surprisingly difficult. It was only in 2016 that the first such device was approved in the United States.

Pancreatic islet cell transplants have become increasingly successful in helping type 1 diabetics. Still, only about 50% of patients need no injected insulin after two years. The need for long-term immunosuppression limits this treatment to only those diabetics who cannot control their blood glucose by any other means.

Over 90% of DM cases are **type 2 diabetes mellitus**, formerly called *non-insulin-dependent diabetes mellitus*. Type 2 diabetics produce insulin, but their insulin receptors are unable to respond to it, a phenomenon called **insulin resistance**. Type 2 DM grows increasingly common with age and with the increasing size of our waistlines. About 12 million people in the U.S. have been diagnosed with type 2 diabetes, and roughly half as many are believed to be undiagnosed. Type 2 diabetics are at risk for the same complications as type 1 diabetics—heart disease, amputations, kidney failure, and blindness.

A hereditary predisposition is particularly striking in this diabetic group. Mutations in any one of several genes could lead to insulin resistance. About 25–30% of Americans carry a gene that predisposes them to type 2 diabetes, with nonwhites affected to a much greater extent. If an identical twin has type 2 diabetes mellitus, the probability that the other twin will have the disease is virtually 100%.

Lifestyle factors also play a key role: Type 2 diabetics are almost always overweight and sedentary. Adipose tissue of obese people overproduces a number of signaling chemicals including *tumor necrosis factor alpha* and *resistin*, which may alter the enzymatic cascade triggered by insulin binding. It is now well established that weight loss and regular exercise can lower the risk of type 2 diabetes dramatically, even for people at high risk.

In many cases type 2 diabetes can be managed solely by exercise, weight loss, and a healthy diet. Some type 2 diabetics also benefit from oral medications that lower blood glucose or reduce insulin resistance. However, many type 2 diabetics must eventually inject insulin.

While we cannot yet cure diabetes, biotechnology promises to continue to improve control of blood glucose levels and thereby tame the monster that is diabetes.

potassium ions are also lost. The electrolyte imbalance leads to abdominal pain and possibly vomiting. If untreated, ketoacidosis disrupts heart activity and oxygen transport, and severe depression of the nervous system leads to coma and death.

The opposite condition to diabetes mellitus is *hyperinsulinism*, or excessive insulin secretion. It causes low blood glucose levels, or **hypoglycemia**. This condition triggers the release of hyperglycemic hormones, which cause anxiety, nervousness, tremors, and weakness. Insufficient glucose delivery to the brain causes disorientation, progressing to convulsions, unconsciousness, and even death. In rare cases, hyperinsulinism results from an islet cell tumor. More commonly, it is caused by an overdose of insulin and is easily treated by ingesting sugar.

The Gonads and Placenta

The male and female **gonads** (testes and ovaries) produce steroid sex hormones identical to those produced by adrenal cortical cells (see Figure 16.1). The major distinction is the source and relative amounts produced. As described earlier, gonadotropins regulate the release of gonadal hormones.

The paired *ovaries* are small, oval organs located in the female's abdominopelvic cavity. Besides producing ova, or eggs, the ovaries produce several hormones, most importantly **estrogens** and **progesterone** (pro-jes′tĕ-rōn). Estrogens are responsible for maturation of the reproductive organs and the appearance of the secondary sex characteristics of females at puberty. Acting with progesterone, estrogens promote breast development and cyclic changes in the uterine mucosa (the menstrual cycle).

The male *testes*, located in an extra-abdominal skin pouch called the scrotum, produce sperm and male sex hormones, primarily **testosterone** (tes-tos′tĕ-rōn). During puberty, testosterone initiates the maturation of the male reproductive organs and the appearance of secondary sex characteristics and sex drive. In addition, testosterone is necessary for normal sperm production and maintains the reproductive organs in their mature functional state in adult males.

The *placenta* is a temporary endocrine organ. Besides sustaining the fetus during pregnancy, it secretes several steroid and protein hormones that influence the course of pregnancy. Placental hormones include estrogens, progesterone, and human chorionic gonadotropin (hCG).

We will discuss the roles of the gonadal, placental, and gonadotropic hormones in Chapters 27 and 28, where we consider the reproductive system and pregnancy.

Hormone Secretion by Other Organs

Other hormone-producing cells occur in various organs including the heart, gastrointestinal tract, kidneys, skin, adipose tissue, skeleton, and thymus (**Table 16.6**).

Adipose Tissue

Adipose cells release **leptin**, which serves to tell your body how much stored energy (as fat) you have. The more fat you have, the more leptin there will be in your blood. As we describe in Chapter 24, leptin binds to CNS neurons concerned with appetite control, producing a sensation of satiety. It also appears to stimulate increased energy expenditure.

Two other hormones released by adipose cells affect the sensitivity of cells to insulin. *Resistin* is an insulin antagonist, while *adiponectin* enhances sensitivity to insulin.

Gastrointestinal Tract

Enteroendocrine cells are hormone-secreting cells sprinkled in the mucosa of the gastrointestinal tract. These scattered cells release several peptide hormones that help regulate a wide variety of digestive functions, as we will see in Chapter 23. Enteroendocrine cells also release amines such as serotonin, which act as paracrines, diffusing to and influencing nearby target cells without first entering the bloodstream. Enteroendocrine cells have been referred to as *paraneurons* because they are similar in certain ways to neurons and many of their hormones and paracrines are chemically identical to neurotransmitters.

Heart

Chambers of the heart called *atria* contain specialized cardiac muscle cells that secrete **atrial natriuretic peptide (ANP)**. As noted on p. 624, ANP decreases the amount of sodium in the extracellular fluid, thereby reducing blood volume and blood pressure.

Kidneys

Interstitial cells in the kidneys secrete **erythropoietin** (ĕ-rith″ro-poi′ĕ-tin; "red-maker"), a glycoprotein hormone that signals the bone marrow to increase production of red blood cells. The kidneys also release **renin**, which acts as an enzyme to initiate the renin-angiotensin-aldosterone mechanism of aldosterone release described earlier.

Skeleton

Osteoblasts in bone secrete *osteocalcin*, a hormone that prods pancreatic beta cells to divide and secrete more insulin. It also restricts fat storage by adipocytes, and triggers the release of adiponectin. This improves glucose handling and reduces body fat.

Interestingly, insulin promotes the conversion of inactive osteocalcin to active osteocalcin in bone, forming a two-way conversation between bone and the pancreas. Osteocalcin levels are low in type 2 diabetes, and increasing its level may offer a new treatment approach.

Skin

The skin produces **cholecalciferol**, an inactive form of vitamin D_3, when modified cholesterol molecules in epidermal cells are exposed to ultraviolet radiation. This compound then enters the blood via the dermal capillaries, is modified in the liver, and becomes fully activated in the kidneys. The active form of vitamin D_3, **calcitriol**, is an essential regulator of the carrier system that intestinal cells use to absorb Ca^{2+} from food. Without

Table 16.6 Selected Examples of Hormones Produced by Organs Other than the Major Endocrine Organs

SOURCE	HORMONE	CHEMICAL COMPOSITION	TRIGGER	TARGET ORGAN AND EFFECTS
Adipose tissue	Leptin	Peptide	Secretion proportional to fat stores; increased by nutrient uptake	Brain: suppresses appetite; increases energy expenditure
Adipose tissue	Resistin, adiponectin	Peptides	Secretion proportional to fat stores for resistin, inversely proportional for adiponectin	Fat, muscle, liver: resistin antagonizes insulin's action and adiponectin enhances it
Gastrointestinal (GI) tract mucosa				
• Stomach	Gastrin, ghrelin	Peptides	See Table 23.1 on p. 888; Figure 24.25 on p. 961	
• Duodenum (of small intestine)	Secretin, cholecystokinin (CCK), glucose-dependent insulinotropic peptide (GIP)	Peptides	See Table 23.1 on p. 888	
Heart (atria)	Atrial natriuretic peptide (ANP)	Peptide	Secreted in response to stretching of atria (by rising blood pressure)	Kidney: inhibits sodium ion reabsorption and renin release Adrenal cortex: inhibits secretion of aldosterone; decreases blood pressure
Kidney	Erythropoietin (EPO)	Glycoprotein	Secreted in response to hypoxia	Red bone marrow: stimulates production of red blood cells
Skeleton	Osteocalcin	Peptide	Unknown; insulin promotes its activation	Increases insulin production and insulin sensitivity
Skin (epidermal cells)	Cholecalciferol (provitamin D_3)	Steroid	Activated by the kidneys to active vitamin D_3 (calcitriol) in response to parathyroid hormone	Intestine: stimulates active transport of dietary calcium across cell membranes of small intestine
Thymus	Thymulin, thymopoietins, thymosins	Peptides	Unknown	Mostly act locally as paracrines; involved in T lymphocyte development and in immune responses

this vitamin, bones become soft and weak. In addition, most cells throughout the body have vitamin D receptors. Vitamin D modulates immune functions, decreases inflammation, and may act as an anticancer agent.

Thymus

Located deep to the sternum in the thorax is the **thymus** (see Figure 16.1). Large and conspicuous in infants and children, the thymus shrinks throughout adulthood. By old age, it is composed largely of adipose and fibrous connective tissues.

Thymic epithelial cells secrete several different families of peptide hormones, including *thymosins* (thi′mo-sinz), *thymulin*, and *thymopoietins*. These hormones are thought to be involved in the normal development of *T lymphocytes* and the immune response, but their roles are not well understood. Although called hormones, they mainly act locally as paracrines. We describe the thymus in Chapter 20 in our discussion of lymphoid organs and tissues.

Check Your Understanding

21. Which hormone does the heart produce and what is its function?

22. What is the main function of the hormone produced by the skin?

23. MAKE CONNECTIONS Diabetes mellitus and diabetes insipidus are both due to lack of a hormone. Which hormone causes which? What symptom do they have in common? What would you find in the urine of a patient with one but not the other?

24. MAKE CONNECTIONS Which of the two chemical classes of hormones introduced at the beginning of this chapter do the gonadal hormones belong to? Which major endocrine gland secretes hormones of this same chemical class?

For answers, see Answers Appendix.

Developmental Aspects of the Endocrine System

Hormone-producing glands arise from all three embryonic germ layers. Endocrine glands derived from mesoderm produce steroid hormones. All others produce amines, peptides, or protein hormones.

Effects of Environmental Pollutants

Exposure to environmental pollutants—many pesticides, industrial chemicals, arsenic, dioxin, and other soil and water pollutants—can disrupt endocrine function. So far, sex hormones, thyroid hormone, and glucocorticoids have proved vulnerable to the effects of such pollutants. Interference with glucocorticoids, which turn on many genes that may suppress cancer, may help to explain high cancer rates in populations exposed to various types of toxins.

Endocrine Function throughout Life

Barring exposure to environmental pollutants, and hypersecretory and hyposecretory disorders, most endocrine organs operate smoothly until old age. Aging may alter the rates of hormone secretion, breakdown, and excretion, or the sensitivity of target cell receptors.

Structural changes in the anterior pituitary occur with age. The amount of connective tissue increases, vascularization decreases, and the number of hormone-secreting cells declines. These changes may or may not affect hormone production. In women, for example, blood levels and the release rhythm of ACTH remain constant, but levels of gonadotropins increase with age. GH levels decline in both sexes, which partially explains muscle atrophy in old age.

The adrenal glands also show structural changes with age, but normal controls of cortisol persist as long as a person is healthy and not stressed. Chronic stress, on the other hand, drives up blood levels of cortisol and appears to contribute to hippocampal (and memory) deterioration. Plasma levels of aldosterone fall by half in old age, but this change may reflect a decline in renin release by the kidneys, which become less responsive to renin-evoking stimuli. No age-related differences have been found in the release of catecholamines by the adrenal medulla.

The gonads, particularly the ovaries, undergo significant changes with age. In late middle age, the ovaries become smaller and unresponsive to gonadotropins. As female hormone production declines dramatically, the ability to bear children ends, and problems associated with estrogen deficiency appear, such as atherosclerosis and osteoporosis. Testosterone production by the testes also wanes with age, but this effect usually is not seen until very old age.

Glucose tolerance (the ability to dispose of a glucose load effectively) begins to deteriorate as early as the fourth decade of life. Blood glucose levels rise higher and return to resting levels more slowly in the elderly than in young adults. The fact that the islet cells continue to secrete near-normal amounts of insulin leads researchers to conclude that decreasing glucose tolerance with age may reflect declining receptor sensitivity to insulin (pre–type 2 diabetes).

Thyroid hormone synthesis and release diminish somewhat with age. Typically, the follicles are loaded with colloid in the elderly, and the gland becomes fibrosed. Basal metabolic rate declines with age. Mild hypothyroidism is only one cause of this decline. The increase in body fat relative to muscle is equally important, because muscle tissue is more active metabolically than fat.

The parathyroid glands change little with age, and PTH levels remain fairly normal throughout life. Estrogens protect women against the demineralizing effects of PTH, but estrogen production wanes after menopause, leaving older women vulnerable to the bone-demineralizing effects of PTH and to osteoporosis.

16

RELATED CLINICAL TERMS

Galactorrhea Inappropriate lactation (discharge of milk from the nipple). May occur in women who are not breastfeeding, and in men. Usually due to excess prolactin.

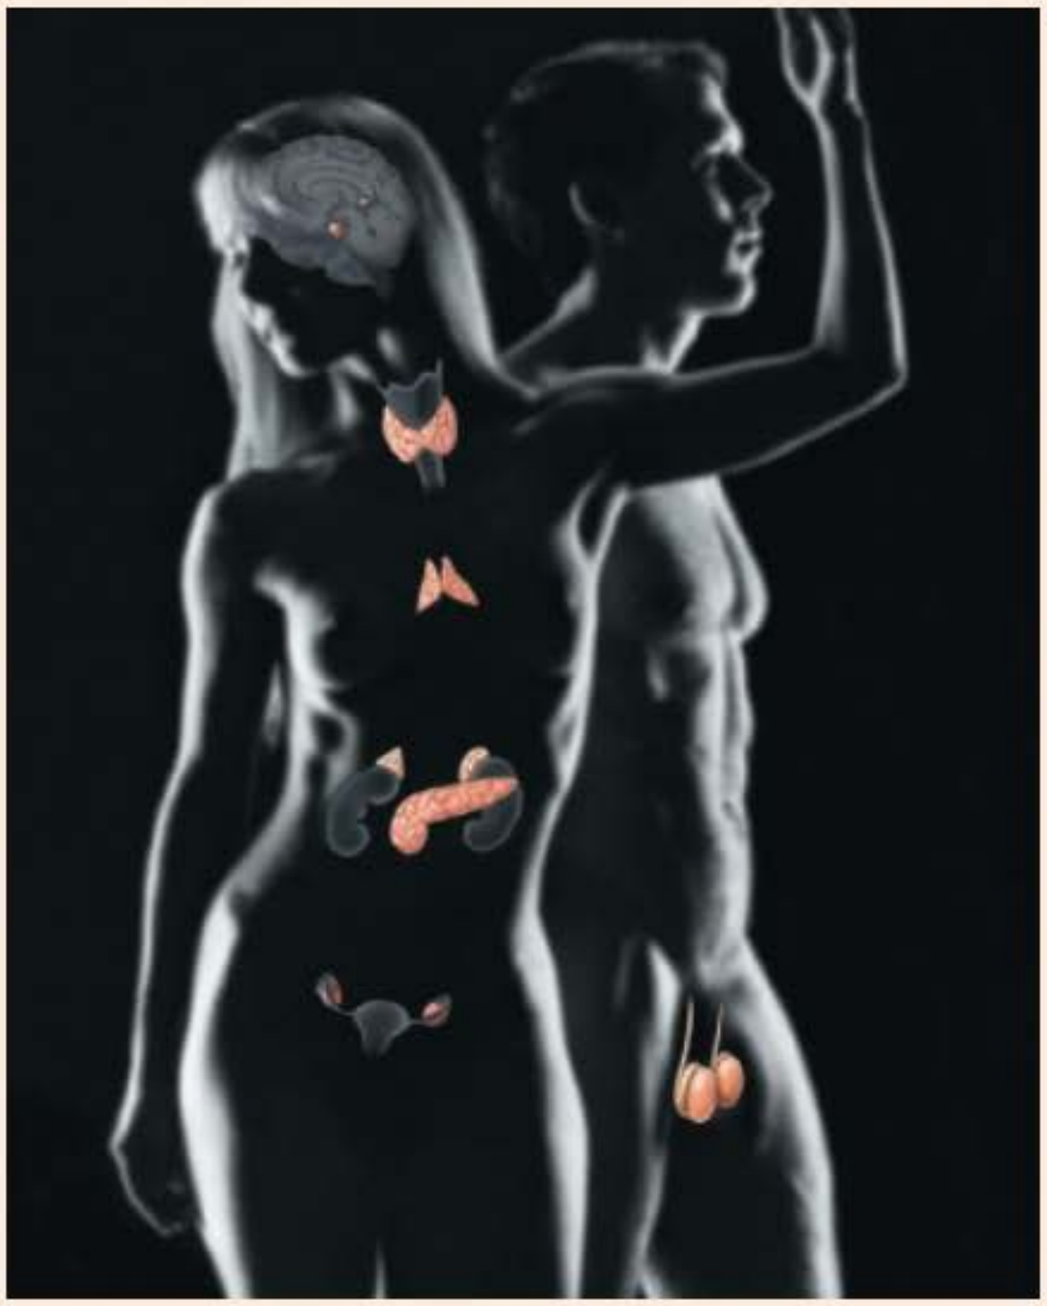
Hirsutism (her′soot-izm; *hirsut* = hairy, rough) Excessive hair growth; usually refers to this phenomenon in women and reflects excessive androgen production.

Hypophysectomy (hi-pof″ĭ-sek′to-me) Surgical removal of the pituitary gland.

Prolactinoma (pro-lak″tĭ-no′mah; *oma* = tumor) The most common type (30–40% or more) of pituitary gland tumor; evidenced by hypersecretion of prolactin and menstrual disturbances in women.

Thyroid storm (thyroid crisis) A sudden and dangerous increase in all of the manifestations of hyperthyroidism due to excessive amounts of circulating TH. Signs include fever, rapid heart rate, high blood pressure, dehydration, nervousness, and tremors. Precipitating factors include severe infection, excessive intake of TH supplements, or trauma.

Homeostatic Interrelationships between the Endocrine System and Other Body Systems



Integumentary System Chapter 5

- Androgens cause activation of sebaceous glands; estrogens increase skin hydration
- Skin produces cholecalciferol (provitamin D)

Skeletal System Chapters 6–8

- PTH regulates calcium blood levels; growth hormone, T_3, T_4, and sex hormones are necessary for normal skeletal development
- The skeleton provides some protection to endocrine organs, especially to those in the brain, chest, and pelvis

Muscular System Chapters 9–10

- Growth hormone is essential for normal muscular development; other hormones (thyroxine and catecholamines) influence muscle metabolism
- Muscular system mechanically protects some endocrine glands; muscular activity elicits catecholamine release

Nervous System Chapters 11–15

- Many hormones (growth hormone, thyroxine, sex hormones) influence normal maturation and function of the nervous system
- Hypothalamus controls anterior pituitary function and produces two hormones released from the posterior pituitary

Cardiovascular System Chapters 17–19

- Several hormones influence blood volume, blood pressure, and heart contractility; erythropoietin stimulates red blood cell production
- Blood is the main transport medium of hormones; heart produces atrial natriuretic peptide

Lymphatic System/Immunity Chapters 20–21

- Lymphocytes "programmed" by thymic hormones seed the lymph nodes; glucocorticoids depress the immune response and inflammation
- Chemical messengers of the immune system stimulate the release of cortisol and ACTH; lymph provides a route for transport of hormones

Respiratory System Chapter 22

- Epinephrine influences ventilation (dilates bronchioles)
- Respiratory system provides oxygen; disposes of carbon dioxide; converting enzyme in lungs converts angiotensin I to angiotensin II

Digestive System Chapter 23

- GI hormones and paracrines influence GI function; activated vitamin D necessary for absorption of calcium from diet; catecholamines influence digestive motility and secretory activity
- Digestive system provides nutrients to endocrine organs

Urinary System Chapters 25–26

- Aldosterone and ADH influence renal function
- Kidneys activate vitamin D (considered a hormone); erythropoietin released by kidneys influences red blood cell formation

Reproductive System Chapters 27–28

- Hypothalamic, anterior pituitary, and gonadal hormones direct reproductive system development and function; oxytocin and prolactin involved in birth and breast-feeding
- Gonadal hormones feed back to influence endocrine system function

CHAPTER SUMMARY

16.1 The endocrine system is one of the body's two major control systems (pp. 602–603)

1. The nervous and endocrine systems are the major controlling systems of the body. The nervous system exerts rapid controls via nerve impulses; the endocrine system exerts more prolonged effects via hormones.
2. Hormonally regulated processes include reproduction; growth and development; maintaining electrolyte, water, and nutrient balance; regulating cellular metabolism and energy balance; and mobilizing body defenses.
3. Endocrine organs are ductless, well-vascularized glands that release hormones directly into the blood or lymph. They are small and widely separated in the body.
4. The purely endocrine organs are the pituitary, thyroid, parathyroid, adrenal, and pineal glands. The hypothalamus is a neuroendocrine organ. The pancreas, gonads, and placenta also have endocrine tissue.
5. Local chemical messengers, not generally considered part of the endocrine system, include autocrines, which act on the cells that secrete them, and paracrines, which act on a different cell type nearby.

16.2 The chemical structure of a hormone determines how it acts (p. 603)

1. Most hormones are steroids or amino acid based. Steroids are lipid soluble. All amino acid–based hormones are water soluble, except for thyroid hormone.

16

16.3 Hormones act through second messengers or by activating specific genes (pp. 603–606)

1. Hormones alter cell activity by stimulating or inhibiting characteristic cellular processes of their target cells.
2. Cell responses to hormone stimulation may involve changes in membrane permeability; enzyme synthesis, activation, or inhibition; secretory activity; and mitosis.
3. Second-messenger mechanisms employing G proteins and intracellular second messengers are a common means by which amino acid–based hormones interact with their target cells. In the cyclic AMP system, the hormone binds to a plasma membrane receptor that couples to a G protein. When the G protein is activated, it couples to adenylate cyclase, which catalyzes the synthesis of cyclic AMP from ATP. Cyclic AMP initiates reactions that activate protein kinases and other enzymes, leading to cellular responses. The PIP_2-calcium signaling mechanism is another important second-messenger system. Other second messengers are cyclic GMP and calcium.
4. Steroid hormones (and thyroid hormone) enter their target cells and effect responses by activating DNA, which initiates messenger RNA formation leading to protein synthesis.

16.4 Three types of stimuli cause hormone release (pp. 607–608)

1. Humoral, neural, or hormonal stimuli activate endocrine organs to release their hormones. Negative feedback is important in regulating hormone levels in the blood.
2. The nervous system, acting through hypothalamic controls, can in certain cases override or modulate hormonal effects.

16.5 Cells respond to a hormone if they have a receptor for that hormone (pp. 608–609)

1. The ability of a target cell to respond to a hormone depends on the presence of receptors, on its plasma membrane or within the cell, to which the hormone can bind.
2. Hormone receptors are dynamic structures. High or low levels of stimulating hormones can change the number and/or sensitivity of hormone receptors.

Half-Life, Onset, and Duration of Hormone Activity (pp. 608–609)

3. Blood levels of hormones reflect a balance between secretion and degradation/excretion. The liver and kidneys are the major organs that degrade hormones; breakdown products are excreted in urine and feces.
4. Hormone half-life and duration of activity are limited and vary from hormone to hormone.

Interaction of Hormones at Target Cells (p. 609)

5. Permissiveness is the situation in which one hormone must be present in order for another hormone to exert its full effects.
6. Synergism occurs when two or more hormones produce the same effects in a target cell and their results together are amplified.
7. Antagonism occurs when a hormone opposes or reverses the effect of another hormone.

16.6 The hypothalamus controls release of hormones from the pituitary gland in two different ways (pp. 609–617)

Pituitary-Hypothalamic Relationships (pp. 610–611)

1. The pituitary gland hangs from the base of the brain and is enclosed by bone. It consists of a hormone-producing glandular portion (anterior pituitary or adenohypophysis) and a neural portion (posterior pituitary or neurohypophysis), which is an extension of the hypothalamus. The neurohypophysis includes the infundibulum (stalk) and the posterior pituitary.
2. The hypothalamus (a) synthesizes two hormones that it exports to the posterior pituitary for storage and later release and (b) regulates the hormonal output of the anterior pituitary via releasing and inhibiting hormones.

The Posterior Pituitary and Hypothalamic Hormones (pp. 611–614)

3. The posterior pituitary stores and releases two hypothalamic hormones, oxytocin and antidiuretic hormone (ADH).
4. Oxytocin stimulates powerful uterine contractions, which trigger labor and delivery of an infant, and milk ejection in nursing women. Its release is mediated reflexively by the hypothalamus and represents a positive feedback mechanism.
5. Antidiuretic hormone stimulates the kidney tubules to reabsorb and conserve water, resulting in small volumes of highly concentrated urine and decreased plasma solute concentration. ADH is released in response to high solute concentrations in the blood and inhibited by low solute concentrations in the blood. Hyposecretion results in diabetes insipidus.

Anterior Pituitary Hormones (pp. 614–617)

6. Four of the six anterior pituitary hormones are tropic hormones that regulate the function of other endocrine organs. Most

anterior pituitary hormones exhibit a diurnal rhythm of release, which is subject to modification by stimuli influencing the hypothalamus.

7. Growth hormone (GH) is an anabolic hormone that stimulates growth of all body tissues but especially skeletal muscle and bone. It may act directly, or indirectly, via insulin-like growth factors (IGFs). GH mobilizes fats, stimulates protein synthesis, and inhibits glucose uptake and metabolism. Its secretion is regulated by growth hormone–releasing hormone (GHRH) and growth hormone–inhibiting hormone (GHIH), or somatostatin. GH hypersecretion causes gigantism in children and acromegaly in adults; hyposecretion in children causes pituitary dwarfism.
8. Thyroid-stimulating hormone (TSH) promotes normal development and activity of the thyroid gland. Thyrotropin-releasing hormone (TRH) stimulates release of TSH; negative feedback of thyroid hormone inhibits it.
9. Adrenocorticotropic hormone (ACTH) stimulates the adrenal cortex to release corticosteroids. Corticotropin-releasing hormone (CRH) triggers ACTH release; rising glucocorticoid levels inhibit it.
10. The gonadotropins—follicle-stimulating hormone (FSH) and luteinizing hormone (LH)—regulate the functions of the gonads in both sexes. FSH stimulates sex cell production; LH stimulates gonadal hormone production. Gonadotropin levels rise in response to gonadotropin-releasing hormone (GnRH). Negative feedback of gonadal hormones inhibits gonadotropin release.
11. Prolactin (PRL) promotes milk production in humans. Its secretion is inhibited by prolactin-inhibiting hormone (PIH).

16.7 The thyroid gland controls metabolism (pp. 617–621)

1. The thyroid gland is located in the anterior neck. Thyroid follicles store colloid containing thyroglobulin, a glycoprotein from which thyroid hormone is derived.
2. Thyroid hormone (TH) includes thyroxine (T_4) and triiodothyronine (T_3), which increase the rate of cellular metabolism. Consequently, oxygen use and heat production rise.
3. Secretion of thyroid hormone, prompted by TSH, requires the follicular cells to take up the stored colloid and split the hormones from the colloid for release. Rising levels of thyroid hormone feed back to inhibit the anterior pituitary and hypothalamus.
4. Most T_4 is converted to T_3 (the more active form) in the target tissues. These hormones act by turning on gene transcription and protein synthesis.
5. Graves' disease is the most common cause of hyperthyroidism. Hyposecretion can be congenital in infants and can cause myxedema in adults.
6. The parafollicular (C) cells of the thyroid gland produce calcitonin. It is not normally important in calcium homeostasis. At pharmacological levels, it inhibits bone matrix resorption and enhances calcium deposit in bone.

16.8 The parathyroid glands are primary regulators of blood calcium levels (pp. 621–622)

1. The parathyroid glands, located on the dorsal aspect of the thyroid gland, secrete parathyroid hormone (PTH), which increases blood calcium levels. It targets bone, the kidneys, and the small intestine (indirectly via vitamin D activation). PTH is the key hormone for calcium homeostasis.
2. Falling blood calcium levels trigger PTH release; rising blood calcium levels inhibit its release.
3. Hyperparathyroidism results in hypercalcemia and extreme bone wasting. Hypoparathyroidism leads to hypocalcemia, evidenced by tetany and respiratory paralysis.

16.9 The adrenal glands produce hormones involved in electrolyte balance and the stress response (pp. 622–627)

1. The paired adrenal (suprarenal) glands sit atop the kidneys. Each adrenal gland has two functional portions, the cortex and the medulla.

The Adrenal Cortex (pp. 623–626)

2. The cortex produces three groups of steroid hormones from cholesterol.
3. Mineralocorticoids (primarily aldosterone) regulate sodium ion reabsorption and potassium ion excretion by the kidneys. Sodium ion reabsorption usually leads to water reabsorption, and raises blood volume and blood pressure. Release of aldosterone is stimulated by the renin-angiotensin-aldosterone mechanism, rising potassium ion levels in the blood, and ACTH. Atrial natriuretic peptide inhibits aldosterone release.
4. Glucocorticoids (primarily cortisol) are important metabolic hormones that help the body resist stressors by increasing blood glucose, fatty acid and amino acid levels, and blood pressure. High levels of glucocorticoids depress the immune system and the inflammatory response. ACTH is the major stimulus for glucocorticoid release.
5. Gonadocorticoids (mainly androgens) are produced in small amounts throughout life.
6. Hypoactivity of the adrenal cortex results in Addison's disease. Hypersecretion can result in aldosteronism, Cushing's syndrome, and adrenogenital syndrome.

The Adrenal Medulla (p. 627)

7. The adrenal medulla produces catecholamines (epinephrine and norepinephrine) in response to sympathetic nervous system stimulation. Catecholamines enhance and prolong the fight-or-flight response to short-term stressors. Hypersecretion leads to symptoms typical of sympathetic nervous system overactivity.

16.10 The pineal gland secretes melatonin (p. 627)

1. The pineal gland is located in the diencephalon. Its primary hormone is melatonin, which influences daily rhythms in body temperature, sleep, and appetite and may have an antigonadotropic effect in children.

16.11 The pancreas, gonads, and most other organs secrete hormones (pp. 630–635)

The Pancreas (pp. 630–634)

1. The pancreas, located in the abdomen close to the stomach, is both an exocrine and an endocrine gland. The endocrine portion (pancreatic islets) releases insulin and glucagon and smaller amounts of other hormones to the blood.
2. Glucagon, released by alpha (α) cells when blood levels of glucose are low, stimulates the liver to release glucose to the blood.
3. Insulin is released by beta (β) cells when blood levels of glucose (and amino acids) are rising. It increases the rate of glucose uptake and metabolism by most body cells. Hyposecretion or hypoactivity of insulin results in diabetes mellitus; cardinal signs are polyuria, polydipsia, and polyphagia.

The Gonads and Placenta (p. 634)

4. The ovaries of the female, located in the pelvic cavity, release two main hormones. The ovarian follicles begin to secrete estrogens at puberty under the influence of FSH. Estrogens stimulate maturation of the female reproductive system and development

of the secondary sex characteristics. Progesterone is released in response to high blood levels of LH. It works with estrogens in establishing the menstrual cycle.

5. The testes of the male begin to produce testosterone at puberty in response to LH. Testosterone promotes maturation of the male reproductive organs, development of secondary sex characteristics, and production of sperm by the testes.
6. The placenta produces hormones of pregnancy—estrogens, progesterone, and others.

Hormone Secretion by Other Organs (pp. 634–635)

7. Many body organs not normally considered endocrine organs contain cells that secrete hormones. Examples include the heart (atrial natriuretic peptide); gastrointestinal tract organs (gastrin, secretin, and others); the kidneys (erythropoietin); skin (cholecalciferol); adipose tissue (leptin, resistin, and adiponectin); bone (osteocalcin); and thymus (thymic hormones).
8. The thymus, located in the upper thorax, declines in size and function with age. It releases the paracrines thymulin, thymosins, and thymopoietins, which are important to the normal development of the immune response.

Developmental Aspects of the Endocrine System (p. 636)

1. Endocrine glands derive from all three germ layers. Those derived from mesoderm produce steroid hormones; the others produce the amino acid–based hormones.
2. The natural decrease in function of the female's ovaries during late middle age results in menopause.
3. All endocrine glands gradually become less efficient as aging occurs. This change leads to a generalized increase in the incidence of diabetes mellitus and a lower metabolic rate.

REVIEW QUESTIONS

To access additional practice questions using your smartphone, tablet, or computer: MasteringA&P® > Study Area > Practice Tests & Quizzes

Level 1 Remember/Understand

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. The major stimulus for release of parathyroid hormone is **(a)** hormonal, **(b)** humoral, **(c)** neural.
2. The anterior pituitary secretes all but **(a)** antidiuretic hormone, **(b)** growth hormone, **(c)** gonadotropins, **(d)** TSH.
3. A hormone not involved in glucose metabolism is **(a)** glucagon, **(b)** cortisone, **(c)** aldosterone, **(d)** insulin.
4. Parathyroid hormone **(a)** increases bone formation and lowers blood calcium levels, **(b)** increases calcium excretion from the body, **(c)** decreases calcium absorption from the gut, **(d)** demineralizes bone and raises blood calcium levels.
5. Choose from the following key to identify the hormones described.

Key: **(a)** aldosterone; **(b)** antidiuretic hormone; **(c)** growth hormone; **(d)** luteinizing hormone; **(e)** oxytocin; **(f)** prolactin; **(g)** T_4 and T_3; **(h)** TSH

____ **(1)** important anabolic hormone; many of its effects mediated by IGFs
____ **(2)** cause the kidneys to conserve water and/or salt (two choices)
____ **(3)** stimulates milk production
____ **(4)** tropic hormone that stimulates the gonads to secrete sex hormones
____ **(5)** increases uterine contractions during birth
____ **(6)** major metabolic hormone(s) of the body
____ **(7)** causes reabsorption of sodium ions by the kidneys
____ **(8)** tropic hormone that stimulates the thyroid gland to secrete thyroid hormone
____ **(9)** secreted by the posterior pituitary (two choices)
____ **(10)** the only steroid hormone in the list

6. A hypodermic injection of epinephrine would **(a)** increase heart rate, increase blood pressure, dilate the bronchioles of the lungs, and increase digestive activity, **(b)** decrease heart rate, decrease blood pressure, constrict the bronchioles, and increase digestive activity, **(c)** decrease heart rate, increase blood pressure, constrict the bronchioles, and decrease digestive activituy, **(d)** increase heart rate, increase blood pressure, dilate the bronchioles, and decrease digestive activity.
7. Testosterone is to the male as which hormone is to the female? **(a)** luteinizing hormone, **(b)** progesterone, **(c)** estrogen, **(d)** prolactin.
8. If anterior pituitary secretion is deficient in a growing child, the child will **(a)** develop acromegaly, **(b)** become a dwarf but have fairly normal body proportions, **(c)** mature sexually at an earlier than normal age, **(d)** be in constant danger of becoming dehydrated.
9. If there is adequate carbohydrate intake, secretion of insulin results in **(a)** lower blood glucose levels, **(b)** increased cell utilization of glucose, **(c)** storage of glycogen, **(d)** all of these.
10. Hormones **(a)** are produced by exocrine glands, **(b)** are carried to all parts of the body in blood, **(c)** remain at constant concentration in the blood, **(d)** affect only non-hormone-producing organs.
11. Some hormones act by **(a)** increasing the synthesis of enzymes, **(b)** converting an inactive enzyme into an active enzyme, **(c)** affecting only specific target organs, **(d)** all of these.
12. Absence of thyroid hormone would result in **(a)** increased heart rate and increased force of heart contraction, **(b)** depression of the CNS and lethargy, **(c)** exophthalmos, **(d)** high metabolic rate.
13. Define hormone.
14. Name a hormone secreted by a muscle cell and two hormones secreted by neurons.

Level 2 Apply/Analyze

15. **(a)** Describe the body location of each of the following endocrine organs: anterior pituitary, pineal gland, pancreas, ovaries, testes, and adrenal glands. **(b)** List the hormones produced by each organ.
16. The anterior pituitary is often referred to as the master endocrine organ, but it, too, has a "master." What controls the release of anterior pituitary hormones?
17. The posterior pituitary is not really an endocrine gland. Why not? What is it?
18. Endemic goiter is not really the result of a malfunctioning thyroid gland. What does cause it?
19. Roger Proulx has severe arthritis and has been taking prednisone (a glucocorticoid) for two months. He isn't feeling

well, complains of repeated "colds," and is extremely "puffy" (edematous). Explain the reason for these symptoms.

Level 3 Evaluate/Synthesize

20. Which type of hormone receptor—plasma membrane bound or intracellular—would be expected to provide the most long-lived response to hormone binding and why?

21. Name two endocrine glands (or regions) that are important in the stress response, and explain why they are important.

22. How are the hyperglycemia and lipidemia of insulin deficiency linked?

23. List some problems that elderly people might have as a result of decreasing hormone production.

24. Mary Morgan has just been brought into the emergency room of City General Hospital. She is perspiring profusely and is breathing rapidly and irregularly. Her breath smells like acetone (sweet and fruity), and her blood glucose tests out at 650 mg/100 ml of blood. She is in acidosis. Which hormone drug should be administered, and why?

25. Kyle, a 5-year-old boy, has been growing by leaps and bounds; his height is 100% above normal for his age. He has been complaining of headaches and vision problems. A CT scan reveals a large pituitary tumor. **(a)** Which hormone is being secreted in excess? **(b)** What condition will Kyle exhibit if corrective measures are not taken? **(c)** What is the probable cause of his headaches and visual problems?

26. Aaron, a 42-year-old single father, goes to his physician complaining of nausea and chronic fatigue. He reports having felt fatigued and listless for about half a year, but he had attributed this to stress. He has lost considerable weight and, strangely, his skin looks tanned, even though he spends long hours at work and rarely ventures outside. His doctor finds very low blood pressure and a rapid, weak pulse. Blood tests show that Aaron does not have anemia, but his plasma glucose, cortisol, and Na^+ are low, and his plasma K^+ is high. His doctor orders an ACTH stimulation test, in which Aaron's secretion of cortisol is measured after he is given a synthetic form of ACTH. **(a)** What would account for Aaron's low plasma Na^+ and high plasma K^+? **(b)** What is the reason for doing an ACTH stimulation test? **(c)** Which gland is primarily affected if ACTH does not cause a normal elevation of cortisol secretion? What is this abnormality called? **(d)** Which gland is primarily affected if ACTH does cause an elevation of cortisol secretion?

CLINICAL CASE STUDY

70-Year-Old Male with Polyuria

Mr. Gutteman, a 70-year-old male, was brought into the ER. He had been sick several days with the flu, and was found confused and barely conscious by his daughter.

Mr. Gutteman is breathing rapidly and has a fever of 39°C (102°F). His skin is dry and flaccid, his mucous membranes are dry, and his eyes are sunken. The physician ordered:

- IV (intravenous) fluid and electrolyte replacement
- Blood and urine tests for presence of glucose and ketones
- Strict I&O [careful measurement of fluid intake (e.g., IV, drinking) and output (e.g., urine)]

1. NCLEX-STYLE You would expect high levels of blood glucose and the presence of glucose and ketones in Mr. Gutteman's urine if:
   a. His pancreas is secreting too much insulin
   b. His liver is secreting too little insulin
   c. His pancreas is secreting too little insulin
   d. His liver is secreting too much glucagon

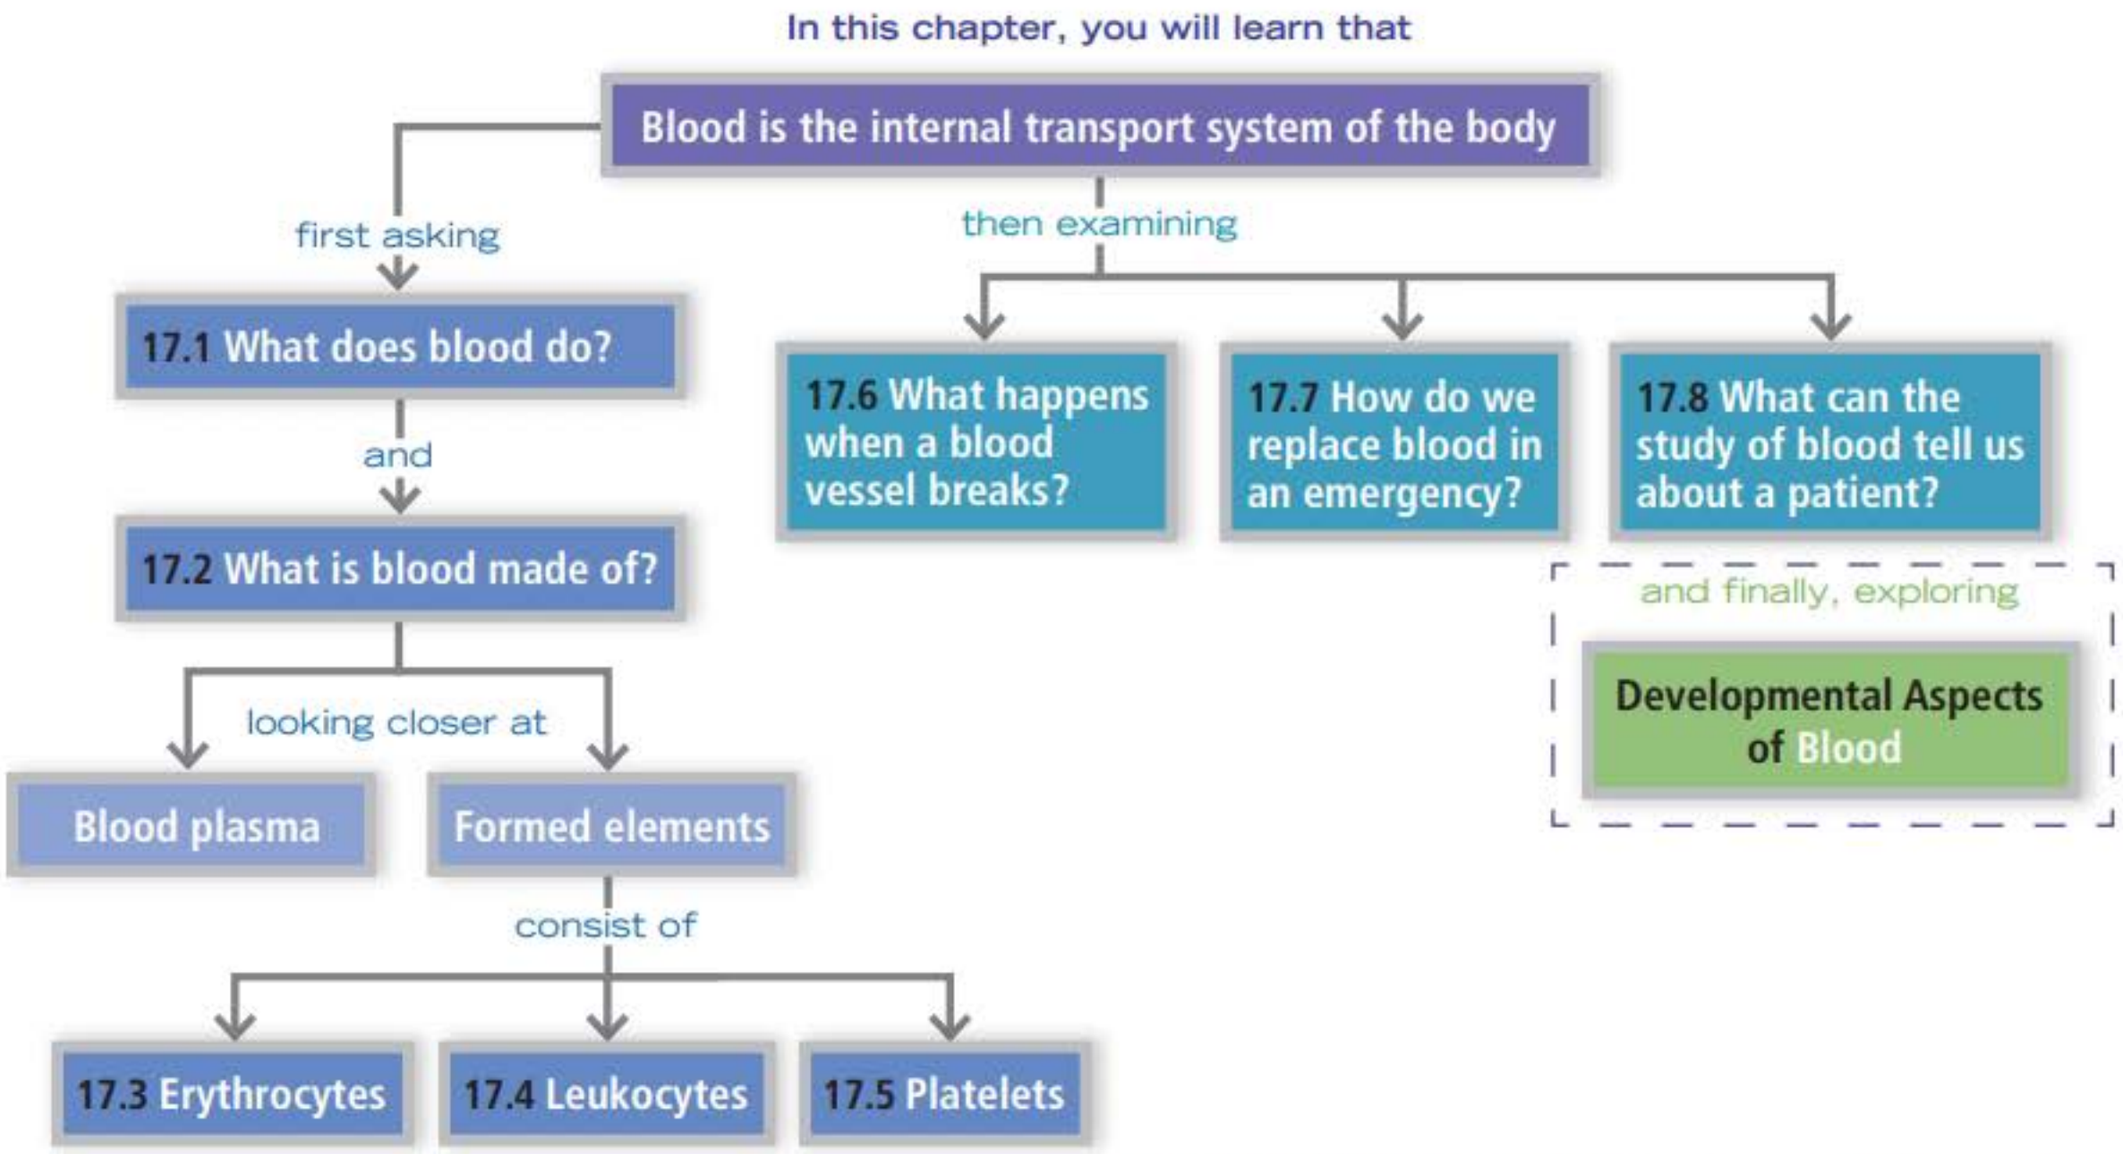
Mr. Gutteman's blood and urine tests are negative for glucose and ketones. However, Mr. Gutteman is losing large amounts of water in urine, and the volume lost is being replaced (via IV).

2. NCLEX-STYLE Given this new information, Mr. Gutteman's excessive fluid loss in his urine most likely indicates:
   a. An increased blood level of aldosterone
   b. A decreased blood level of antidiuretic hormone
   c. An increased blood level of antidiuretic hormone
   d. A decreased blood level of insulin

3. Mr. Gutteman's diagnosis is diabetes insipidus. His daughter is concerned about this, because she knows diabetes is a dangerous disease. She asks whether he will have to follow a diabetic diet. What's your answer?

4. Is diabetes insipidus life threatening? Explain your answer.

17 Blood



Blood is the river of life that surges within us, transporting nearly everything that must be carried from one place to another. Long before modern medicine, blood was viewed as magical—an elixir that held the mystical force of life—because when it drained from the body, life departed as well. Today, blood still has enormous importance in the practice of medicine. Clinicians examine it more often than any other tissue when trying to determine the cause of disease in their patients.

In this chapter, we describe the composition and functions of this life-sustaining fluid that serves as a transport "vehicle" for the organs of the cardiovascular system (*cardio* = heart, *vasc* = blood vessels). To get started, we need a brief overview of blood circulation, which is initiated by the pumping action of the heart. Blood exits the *heart* via *arteries*, which branch repeatedly until they become tiny *capillaries* that service all of the tissues in the body. Oxygen and nutrients leave the blood, crossing capillary walls into the body's tissues; carbon dioxide and wastes move from the tissues to the capillaries. Oxygen-deficient blood flows from the capillaries into larger *veins* that carry blood back to the heart. The returning blood then flows from the heart to the lungs, where it picks up oxygen and then returns to the heart to be pumped throughout the body once again.

17.1 The functions of blood are transport, regulation, and protection

Learning Outcome

▶ **List the functions of blood.**

Blood performs a number of functions, all concerned in one way or another with transporting substances, regulating blood levels of particular substances, or protecting the body.

Transport

Transport functions of blood include:

- Delivering oxygen from the lungs and nutrients from the digestive tract to all body cells.
- Transporting metabolic waste products from cells to elimination sites (to the lungs to eliminate carbon dioxide, and to the kidneys to dispose of nitrogenous wastes in urine).
- Transporting hormones from the endocrine organs to their target organs.

Regulation

Regulatory functions of blood include:

- Maintaining appropriate body temperature by absorbing and distributing heat throughout the body and to the skin surface to encourage heat loss.
- Maintaining normal pH in body tissues. Many blood proteins and other bloodborne solutes act as buffers to prevent excessive or abrupt changes in blood pH that could jeopardize normal cell activities. Blood also acts as the reservoir for the body's "alkaline reserve" of bicarbonate ions.
- Maintaining adequate fluid volume in the circulatory system. As we will see, blood proteins prevent excessive fluid loss from the bloodstream into the tissue spaces. As a result, the fluid volume in the blood vessels remains ample to support efficient blood circulation to all parts of the body.

Protection

Protective functions of blood include:

- Preventing blood loss. When a blood vessel is damaged, platelets and plasma proteins initiate clot formation, halting blood loss.
- Preventing infection. Drifting along in blood are antibodies, complement proteins, and leukocytes (white blood cells), all of which help defend the body against foreign invaders such as bacteria and viruses.

Check Your Understanding

1. List two protective functions of blood.

For answers, see Answers Appendix.

17.2 Blood consists of plasma and formed elements

Learning Outcomes

▶ **Describe the composition and physical characteristics of whole blood. Explain why it is classified as a connective tissue.**

▶ **Discuss the composition and functions of plasma.**

Blood is the only fluid tissue in the body. It appears to be a thick, homogeneous liquid, but the microscope reveals that it has both cellular and liquid components. Blood is a specialized connective tissue in which living blood cells, called the *formed elements*, are suspended in a nonliving fluid matrix called *plasma* (plaz′mah). Blood lacks the collagen and elastic fibers typical of other connective tissues, but dissolved fibrous proteins become visible as fibrin strands during blood clotting.

If we spin a sample of blood in a centrifuge, centrifugal force packs down the heavier formed elements and the less dense plasma remains at the top (**Figure 17.1**). Most of the reddish mass at the bottom of the tube is *erythrocytes* (ĕ-rith′ro-sīts; *erythro* = red), the red blood cells that transport oxygen. A thin, whitish layer called the **buffy coat** is present at the erythrocyte-plasma junction. This layer contains *leukocytes* (*leuko* = white),

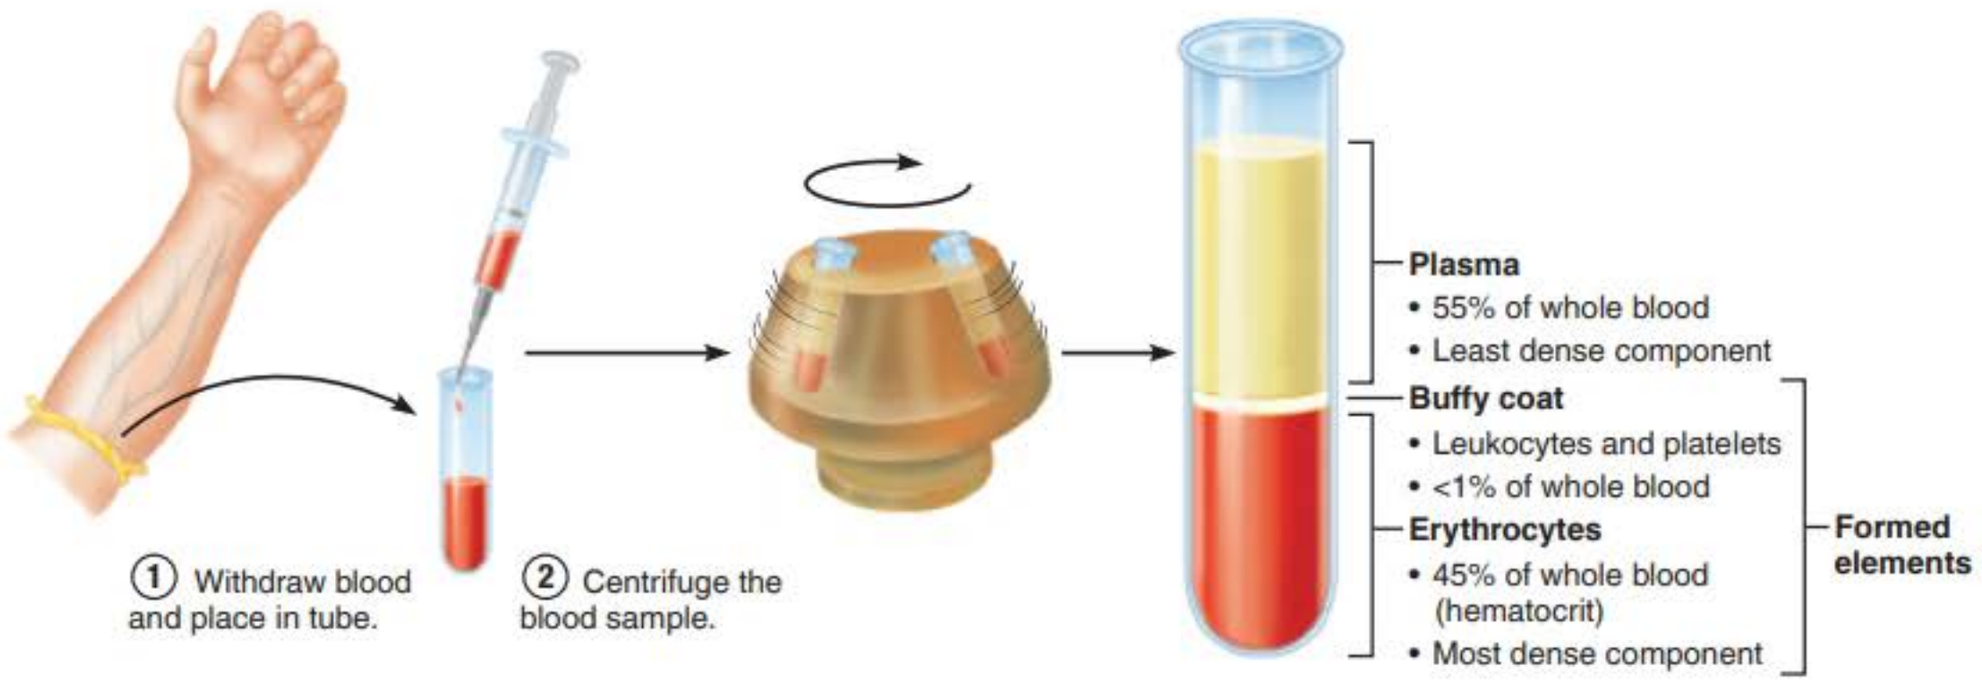

Figure 17.1 The major components of whole blood.

the white blood cells that act in various ways to protect the body, and *platelets*, cell fragments that help stop bleeding.

Erythrocytes normally constitute about 45% of the total volume of a blood sample, a percentage known as the **hematocrit** (he-mat′o-krit; "blood fraction"). Normal hematocrit values vary. In healthy males the norm is 47% ± 5%; in females it is 42% ± 5%. Leukocytes and platelets contribute less than 1% of blood volume. Plasma makes up most of the remaining 55% of whole blood.

Physical Characteristics and Volume

Blood is a sticky, opaque fluid with a characteristic metallic taste. As children, we discover its saltiness the first time we stick a cut finger into our mouth. Depending on the amount of oxygen it is carrying, the color of blood varies from scarlet (oxygen rich) to dark red (oxygen poor). It is slightly alkaline, with a pH between 7.35 and 7.45. Blood is more dense than water and about five times more viscous, largely because of its formed elements.

Erythrocytes are the major factor contributing to blood viscosity. Women typically have a lower red blood cell count than men [4.2–5.4 million cells per microliter (1 µl = 1 mm^3) of blood versus 4.7–6.1 million cells/µl respectively]. When the number of red blood cells increases beyond the normal range, blood becomes more viscous and flows more slowly. Similarly, as the number of red blood cells drops below the lower end of the range, the blood thins and flows more rapidly.

Blood accounts for approximately 8% of body weight. Its average volume in healthy adult males is 5–6 L (about 1.5 gallons), somewhat greater than in healthy adult females (4–5 L).

Blood Plasma

Blood **plasma** is a straw-colored, sticky fluid (Figure 17.1). Although it is mostly water (about 90%), plasma contains over 100 different dissolved solutes, including nutrients, gases, hormones, wastes and products of cell activity, proteins, and inorganic ions (electrolytes). Electrolytes (Na^+, Cl^-, etc.) vastly outnumber the other solutes. **Table 17.1** summarizes the major plasma components.

Although outnumbered by the lighter electrolytes, the heavier **plasma proteins** are the most abundant plasma solutes by weight, accounting for about 8% of plasma weight. Except for hormones and gamma globulins (antibodies), most plasma proteins are produced by the liver. Plasma proteins serve a variety of functions, but they are *not* normally taken up by cells to be used as fuels or metabolic nutrients as are most other organic solutes, such as glucose, fatty acids, and amino acids.

Albumin (al-bu′min) accounts for some 60% of plasma protein. It acts as a carrier to shuttle certain molecules through the circulation, and is the major blood protein contributing to the plasma osmotic pressure (the pressure that helps to keep water in the bloodstream). We will learn more about this critical role of plasma proteins in Chapter 19.

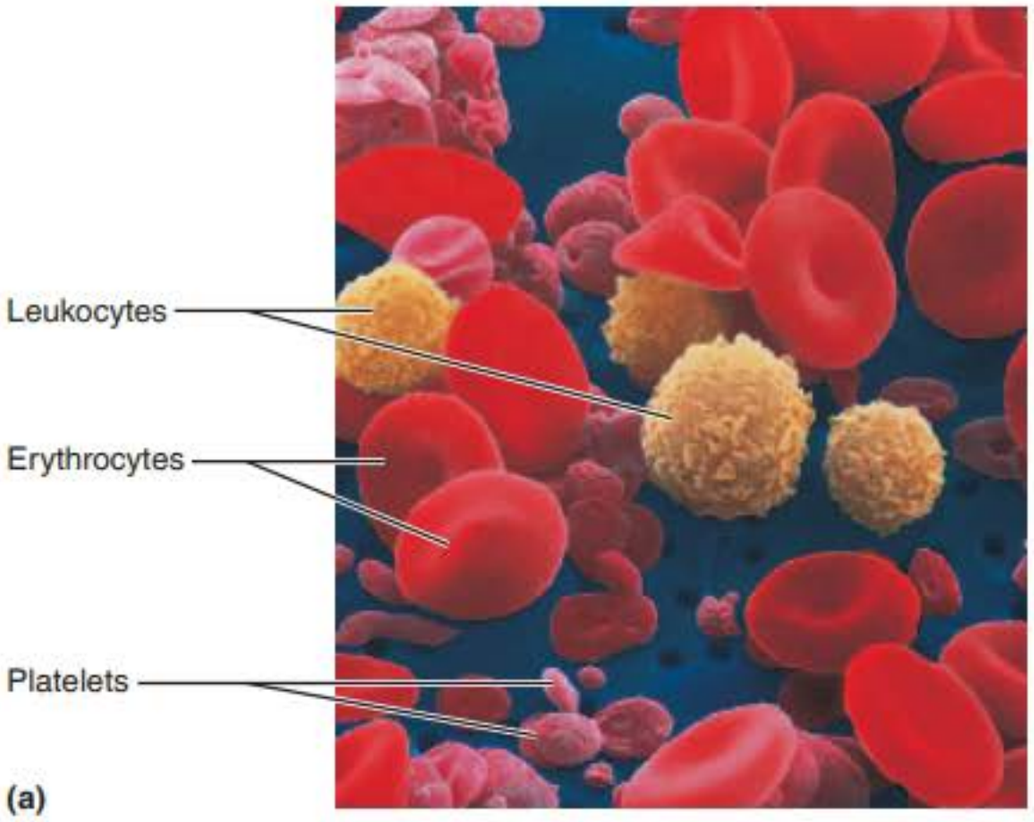
The composition of plasma varies continuously as cells remove or add substances to the blood. However, assuming a healthy diet, plasma composition is kept relatively constant by various homeostatic mechanisms. For example, when blood protein levels drop undesirably, the liver makes more proteins. When the blood starts to become too acidic (acidosis), both the lungs and the kidneys are called into action to restore plasma's normal, slightly alkaline pH. Body organs make dozens of adjustments, day in and day out, to maintain the many plasma solutes at life-sustaining levels.

Table 17.1 Composition of Plasma

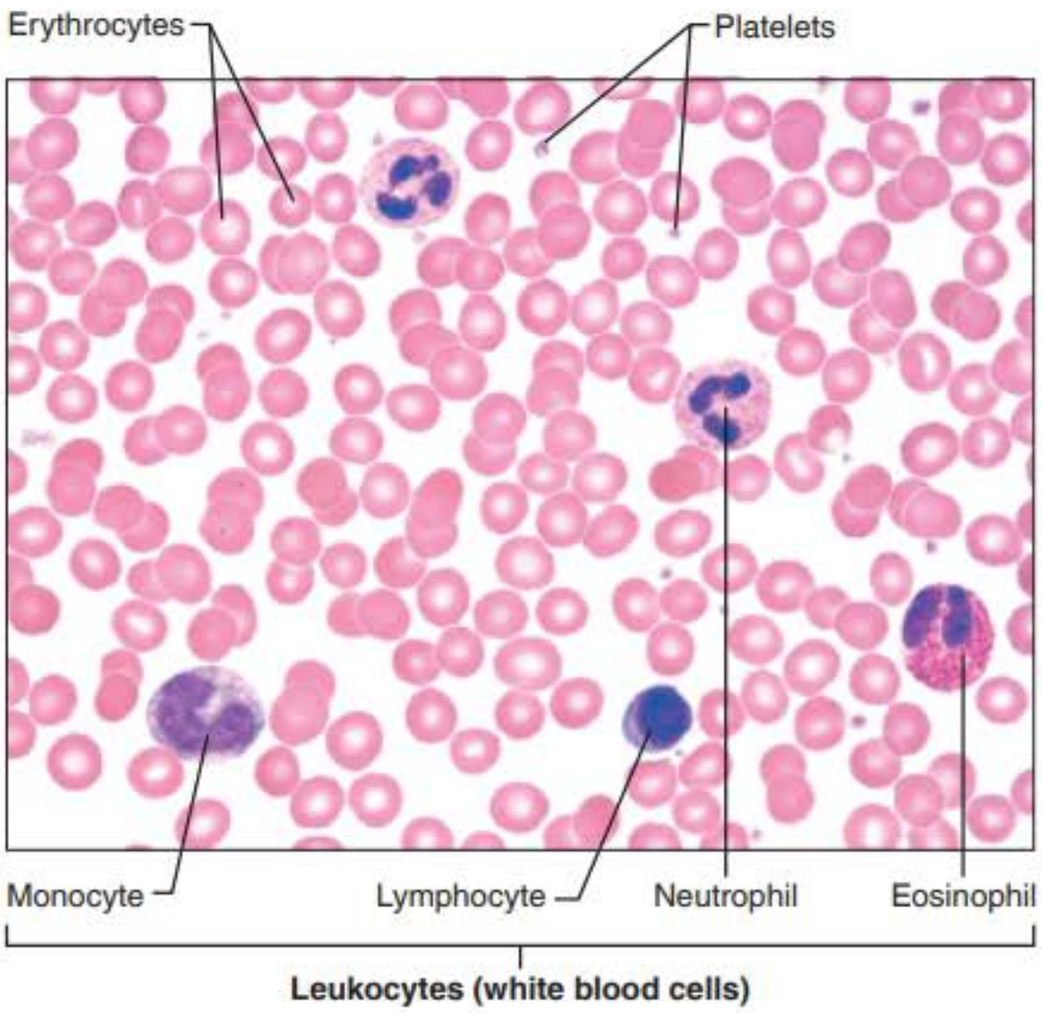
CONSTITUENT	DESCRIPTION AND IMPORTANCE
Water	90% of plasma volume; dissolving and suspending medium for solutes of blood; absorbs heat
Solutes	
Electrolytes	Most abundant solutes by number; cations include sodium, potassium, calcium, magnesium; anions include chloride, phosphate, sulfate, and bicarbonate; help to maintain plasma osmotic pressure and normal blood pH
Plasma proteins	8% (by weight) of plasma; all contribute to osmotic pressure and maintain water balance in blood and tissues; all have other functions (transport, enzymatic, etc.) as well
• Albumin	60% of plasma proteins; produced by liver; main contributor to osmotic pressure
• Globulins	36% of plasma proteins
alpha, beta	Produced by liver; most are transport proteins that bind to lipids, metal ions, and fat-soluble vitamins
gamma	Antibodies released by plasma cells during immune response
• Fibrinogen	4% of plasma proteins; produced by liver; forms fibrin threads of blood clot
Nonprotein nitrogenous substances	By-products of cellular metabolism, such as urea, uric acid, creatinine, and ammonium salts
Nutrients (organic)	Materials absorbed from digestive tract and transported for use throughout body; include glucose and other simple carbohydrates, amino acids (protein digestion products), fatty acids, glycerol and triglycerides (fat digestion products), cholesterol, and vitamins
Respiratory gases	Oxygen and carbon dioxide; oxygen mostly bound to hemoglobin inside RBCs; carbon dioxide transported dissolved as bicarbonate ion or CO_2, or bound to hemoglobin in RBCs
Hormones	Steroid and thyroid hormones carried by plasma proteins

Formed Elements

The **formed elements** of blood—*erythrocytes, leukocytes*, and *platelets*—have some unusual features.



(a)



(b)

Figure 17.2 Blood cells. (a) SEM (1800×, artificially colored). **(b)** Photomicrograph (610×, Wright's stain).

Practice Histology questions: MasteringA&P® > Study Area > Lab Tools > PAL

- Two of the three are not even true cells: Erythrocytes have no nuclei or organelles, and platelets are cell fragments. Only leukocytes are complete cells.
- Most types of formed elements survive in the bloodstream for only a few days.
- Most blood cells do not divide. Instead, stem cells divide continuously in red bone marrow to replace them.

If you examine a stained smear of human blood under the light microscope, you will see disc-shaped red blood cells, a variety of gaudily stained spherical leukocytes, and some scattered platelets that look like debris (**Figure 17.2**). Erythrocytes vastly outnumber the other types of formed elements. Table 17.2 on p. 656 summarizes the important characteristics of the formed elements.

Check Your Understanding

2. What is the hematocrit? What is its normal value?
3. WHAT IF? Suppose you are caring for a patient in liver failure due to chronic alcoholism. What problems would you expect the reduced synthesis of plasma proteins to cause in this patient?

For answers, see Answers Appendix.

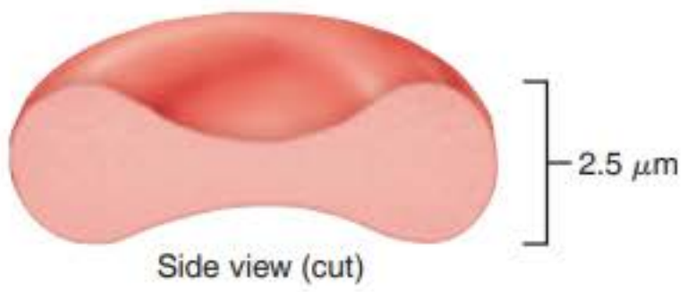
17.3 Erythrocytes play a crucial role in oxygen and carbon dioxide transport

Learning Outcomes

- **Describe the structure, function, and production of erythrocytes.**
- **Describe the chemical composition of hemoglobin.**
- **Give examples of disorders caused by abnormalities of erythrocytes. Explain what goes wrong in each disorder.**

Structural Characteristics

Erythrocytes or **red blood cells (RBCs)** are small cells, about 7.5 μm in diameter. They are shaped like biconcave discs—flattened discs with depressed centers (**Figure 17.3**). Under the microscope, they appear lighter in color at their thin



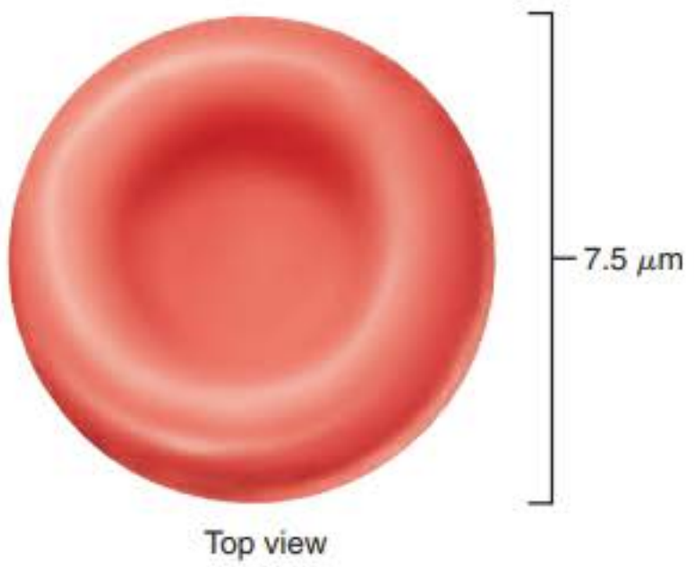


Figure 17.3 Structure of erythrocytes (red blood cells). Notice the distinctive biconcave shape.

centers than at their edges, making them look like miniature doughnuts (Figure 17.2).

Mature erythrocytes are bound by a plasma membrane, but lack a nucleus (are *anucleate*) and have essentially no organelles. In fact, they are little more than "bags" of *hemoglobin* (*Hb*), the RBC protein that functions in gas transport. Other proteins are present, such as antioxidant enzymes that rid the body of harmful oxygen radicals, but most function as structural proteins, allowing the RBC to deform yet spring back into shape.

For example, a network of proteins, especially one called *spectrin*, attached to the cytoplasmic face of RBC plasma membranes maintains the biconcave shape of an erythrocyte. The spectrin net is deformable, allowing erythrocytes to change shape as necessary—to twist, turn, and become cup shaped as they are carried passively through capillaries with diameters smaller than themselves—and then to resume their biconcave shape.

The erythrocyte is a superb example of complementarity of structure and function. It picks up oxygen in the capillaries of the lungs and releases it to tissue cells across other capillaries throughout the body. It also transports some 20% of the carbon dioxide released by tissue cells back to the lungs. Three structural characteristics contribute to erythrocyte gas transport functions:

- Its small size and shape provide a huge surface area relative to volume (about 30% more surface area than comparable spherical cells). The disc shape is ideally suited for gas exchange because no point within the cytoplasm is far from the surface.
- Discounting water content, an erythrocyte is over 97% hemoglobin, the molecule that binds to and transports respiratory gases.
- Because erythrocytes lack mitochondria and generate ATP by anaerobic mechanisms, they do not consume any of the oxygen they carry, making them very efficient oxygen transporters.

Functions of Erythrocytes

Erythrocytes are completely dedicated to their job of transporting respiratory gases (oxygen and carbon dioxide). **Hemoglobin**, the protein that makes red blood cells red, binds easily and reversibly with oxygen, and most oxygen carried in blood is bound to hemoglobin. Normal values for hemoglobin are 13–18 grams per 100 milliliters of blood (g/100 ml) in adult males, and 12–16 g/100 ml in adult females.

Hemoglobin is made up of the red **heme** pigment bound to the protein **globin**. Globin consists of four polypeptide chains—two alpha (α) and two beta (β)—each binding a red ringlike heme group (**Figure 17.4a**). Each heme group bears an iron ion (Fe^{2+}) set like a jewel in its center (Figure 17.4b). A hemoglobin molecule can transport four molecules of oxygen because each iron atom can combine reversibly with one molecule of oxygen. A single red blood cell contains about 250 million hemoglobin molecules, so each of these tiny cells can scoop up about 1 billion molecules of oxygen!

The fact that hemoglobin is contained in erythrocytes, rather than existing free in plasma, prevents it from leaking out of the

(b) Iron-containing heme pigment.

Figure 17.4 Structure of hemoglobin. Hemoglobin's structure makes it a highly efficient oxygen carrier.

bloodstream (through porous capillary walls) and clogging up the kidneys. Large amounts of free hemoglobin in the blood would also make blood more viscous and would draw water from the tissues into the bloodstream by osmosis.

Oxygen loading occurs in the lungs, and the direction of transport is from lungs to tissue cells. As oxygen-deficient blood moves through the lungs, oxygen diffuses from the air sacs of the lungs into the blood and then into the erythrocytes, where it binds to the iron in hemoglobin. The iron is partially oxidized by the oxygen (◀ p. 37). As a result, the protein, now called **oxyhemoglobin**, assumes a new three-dimensional shape and becomes ruby red.

In body tissues, the process is reversed. Oxygen detaches from iron, hemoglobin resumes its former shape, and the resulting **deoxyhemoglobin**, or *reduced hemoglobin*, becomes dark red. The released oxygen diffuses from the blood into the tissue fluid and then into tissue cells.

About 20% of the carbon dioxide transported in the blood combines with hemoglobin, but it binds to globin's amino acids rather than to the heme group. This formation of **carbaminohemoglobin** (kar-bam″ĭ-no-he″muh″glo′bin) occurs more readily when hemoglobin is in the reduced state (dissociated from oxygen). Carbon dioxide loading occurs in the tissues, and the direction of transport is from tissues to lungs, where carbon dioxide is eliminated from the body (see Chapter 22).

Production of Erythrocytes

Blood cell formation is referred to as **hematopoiesis** (hem″ah-to-poy-e′sis; *hemato* = blood; *poiesis* = to make). Hematopoiesis occurs in the **red bone marrow**, which is composed largely of a soft network of reticular connective tissue (◀ p. 133) bordering on wide blood capillaries called *blood sinusoids*. Within this network are immature blood cells, macrophages, fat cells, and *reticular cells* (which secrete the connective tissue fibers). In adults, red marrow is found chiefly in the bones of the axial skeleton and girdles, and in the proximal epiphyses of the humerus and femur.

The production of each type of blood cell varies in response to changing body needs and regulatory factors. As blood cells mature, they migrate through the porous walls of the sinusoids to enter the bloodstream. On average, the marrow turns out an ounce of new blood containing 100 billion new cells every day.

The various formed elements have different functions, but there are similarities in their life histories. All arise from the **hematopoietic stem cell**, sometimes called a *hemocytoblast* (*cyte* = cell, *blast* = bud). These undifferentiated precursor cells reside in the red bone marrow. However, the maturation pathways of the various formed elements differ, and once a cell is *committed* to a specific blood cell pathway, it cannot change. This commitment is signaled by the appearance of membrane surface receptors that respond to specific hormones or growth factors, which in turn "push" the cell toward further specialization.

Stages of Erythropoiesis

Erythrocyte production, or **erythropoiesis** (ĕ-rith″ro-poy-e′sis), begins when a hematopoietic stem cell descendant called a **myeloid stem cell** transforms into a **proerythroblast** (**Figure 17.5**). Proerythroblasts, in turn, give rise to **basophilic erythroblasts** that produce huge numbers of ribosomes. During these first two phases, the cells divide many times. Hemoglobin is synthesized and iron accumulates as the basophilic erythroblast transforms into a **polychromatic erythroblast** and then an **orthochromatic erythroblast**. The "color" of the cell cytoplasm changes as the blue-staining ribosomes become masked by the pink color of hemoglobin. When an orthochromatic erythroblast has accumulated almost all of its hemoglobin, it ejects most of its organelles. Additionally, its nucleus degenerates and is pinched off, allowing the cell to collapse inward and eventually assume the biconcave shape. The result is the **reticulocyte** (essentially a young erythrocyte), so named because it still contains a scant *reticulum* (network) of clumped ribosomes.

The entire process from hematopoietic stem cell to reticulocyte takes about 15 days. The reticulocytes, filled almost to bursting with hemoglobin, enter the bloodstream to begin their

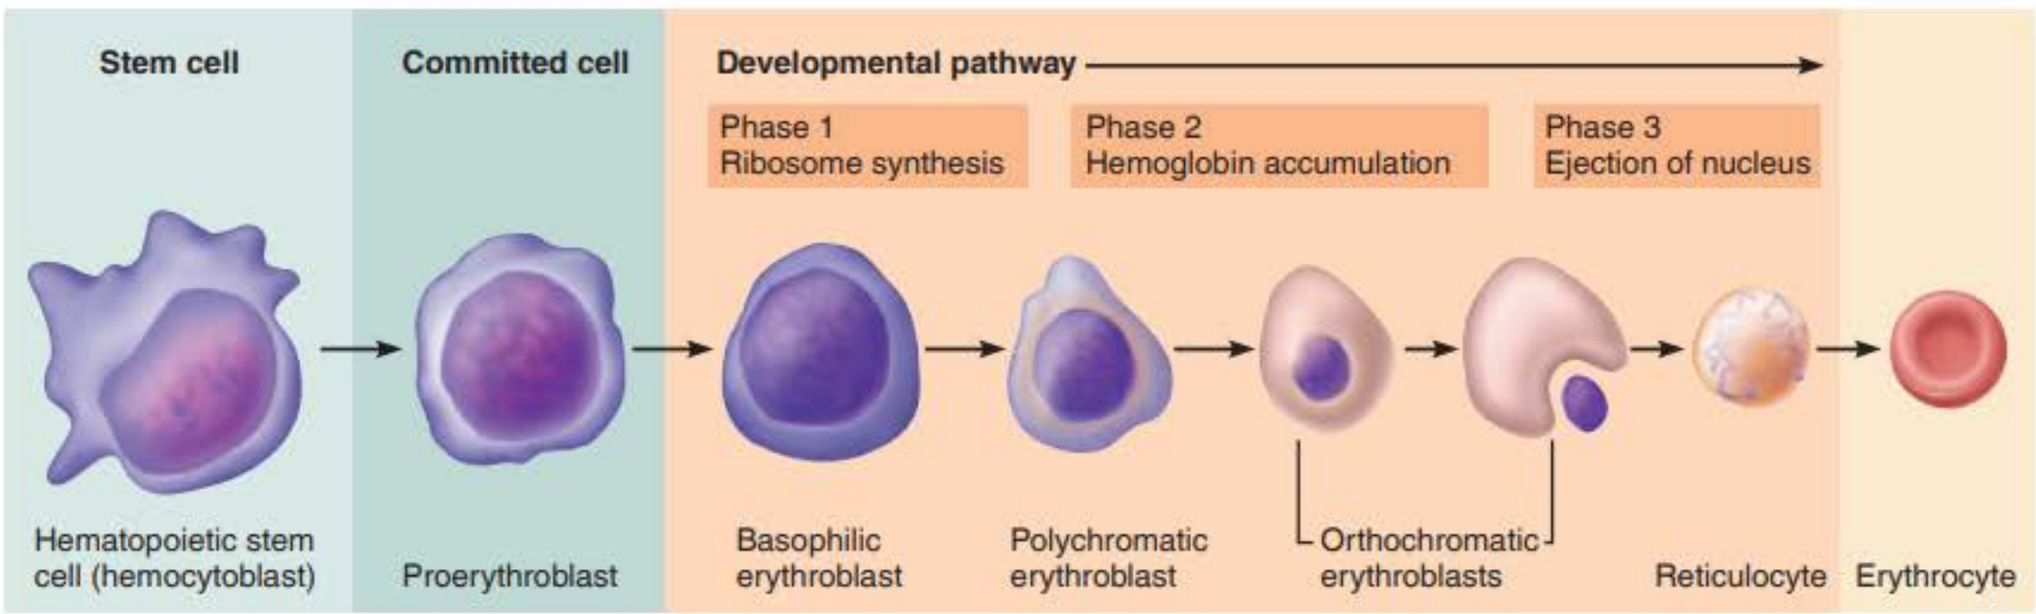

Figure 17.5 Erythropoiesis: formation of red blood cells. Reticulocytes are released into the bloodstream. The myeloid stem cell, the phase intermediate between the hematopoietic stem cell and the proerythroblast, is not illustrated.

task of oxygen transport. Usually they become fully mature erythrocytes within two days of release as their ribosomes are degraded by intracellular enzymes.

Reticulocytes account for 1–2% of all erythrocytes in the blood of healthy people. **Reticulocyte counts** provide a rough index of the *rate* of RBC formation—reticulocyte counts below or above this range indicate abnormal rates of erythrocyte formation.

Regulation and Requirements for Erythropoiesis

The number of circulating erythrocytes in a given individual is remarkably constant and reflects a balance between red blood cell production and destruction. This balance is important because having too few erythrocytes leads to tissue hypoxia (oxygen deprivation), whereas having too many makes the blood undesirably viscous.

To ensure that the number of erythrocytes in blood remains within the homeostatic range, new cells are produced at the incredibly rapid rate of more than 2 million per second in healthy people. This process is controlled hormonally and depends on adequate supplies of iron, amino acids, and certain B vitamins.

Hormonal Controls

Erythropoietin (EPO), a glycoprotein hormone, stimulates the formation of erythrocytes (**Figure 17.6**). Normally, a small amount of EPO circulates in the blood at all times and sustains red blood cell production at a basal rate. The kidneys play the major role in EPO production, although the liver also produces some. When certain kidney cells become *hypoxic* (oxygen deficient), oxygen-sensitive enzymes are unable to carry out their normal functions of degrading an intracellular signaling molecule called hypoxia-inducible factor (HIF). As HIF accumulates, it accelerates the synthesis and release of erythropoietin.

The drop in normal blood oxygen levels that triggers EPO formation can result from:

- Reduced numbers of red blood cells due to hemorrhage (bleeding) or excessive RBC destruction
- Insufficient hemoglobin per RBC (as in iron deficiency)
- Reduced availability of oxygen, as might occur at high altitudes or during pneumonia

Conversely, too many erythrocytes or excessive oxygen in the bloodstream depresses erythropoietin production. Note that it is not the number of erythrocytes in blood that controls the rate of erythropoiesis. Instead, control is based on their ability to transport enough oxygen to meet tissue demands.

Bloodborne erythropoietin stimulates red marrow cells that *are already committed* to becoming erythrocytes, causing them to mature more rapidly. Two to three days after erythropoietin levels rise in the blood, the rate of reticulocyte release and the reticulocyte count rise markedly. Notice that hypoxia does not activate the bone marrow directly. Instead it stimulates the kidneys, which in turn provide the hormonal stimulus that activates the bone marrow.

HOMEOSTATIC IMBALANCE 17.1 CLINICAL

Some athletes abuse recombinant EPO—particularly professional bike racers and marathon runners seeking increased stamina and performance. However, the consequences can be deadly. By injecting EPO, healthy athletes increase their normal hematocrit from 45% to as much as 65%. Then, with the dehydration that occurs in a long race, the blood concentrates even

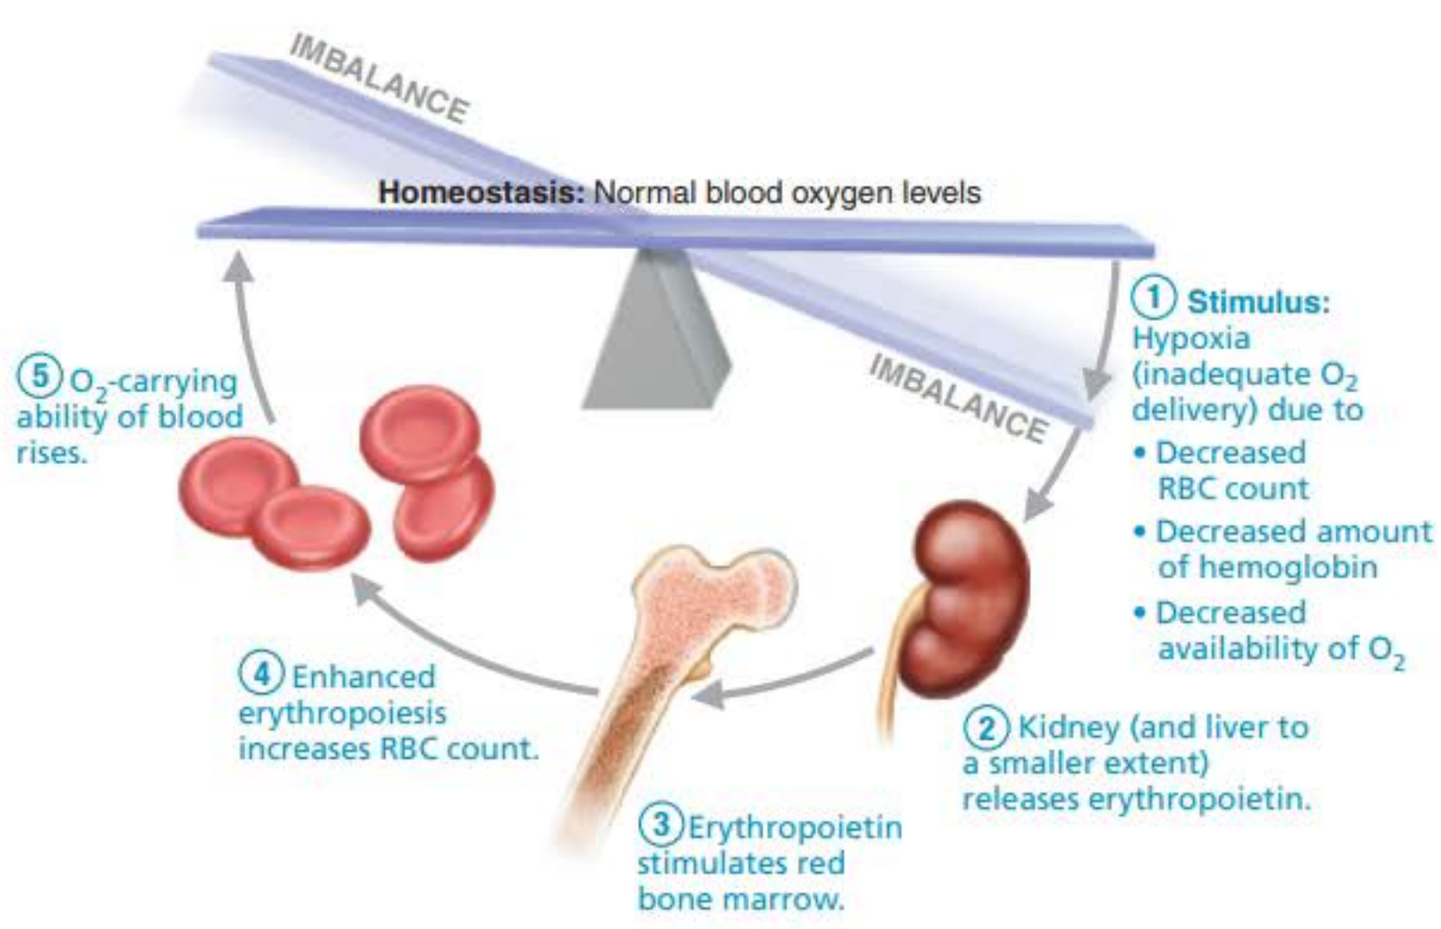

Figure 17.6 **Erythropoietin (EPO) mechanism for regulating erythropoiesis.**

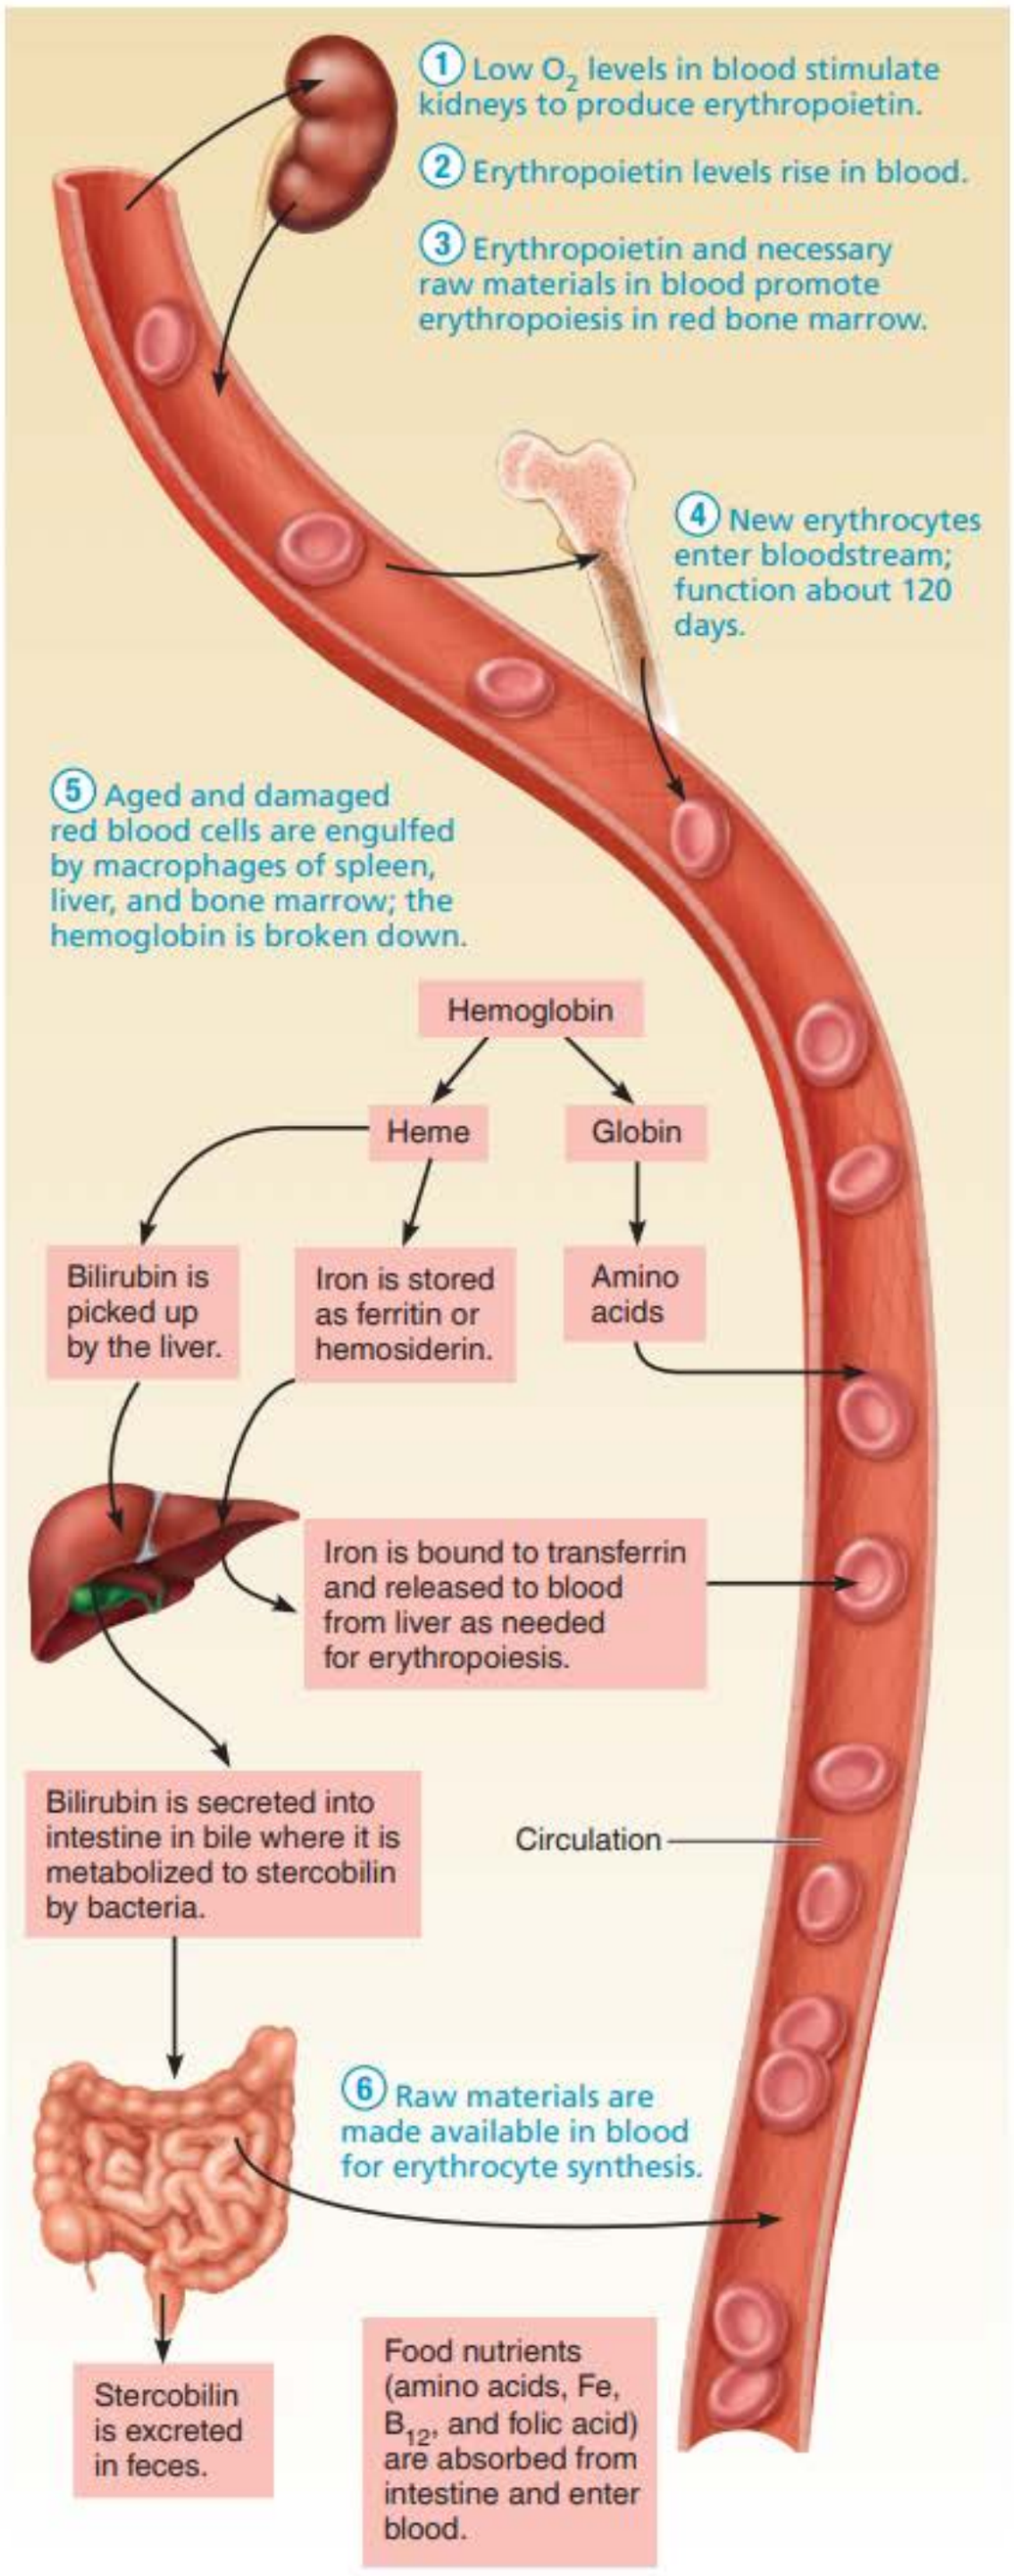

Figure 17.7 Life cycle of red blood cells.

further, becoming a thick, sticky "sludge" that can cause clotting, stroke, or heart failure.

The male sex hormone *testosterone* also enhances the kidneys' production of EPO. Because female sex hormones do not have similar stimulatory effects, testosterone may be at least partially responsible for the higher RBC counts and hemoglobin levels seen in males.

Dietary Requirements

The raw materials required for erythropoiesis include:

- *Nutrients.* Amino acids, lipids, and carbohydrates are essential for the synthesis of all cells.
- *Two B-complex vitamins.* Vitamin B_{12} and folic acid are necessary for normal DNA synthesis. Even slight deficits jeopardize rapidly dividing cell populations, such as developing erythrocytes.
- *Iron.* Iron is essential for hemoglobin synthesis.

Iron is available from the diet, and intestinal cells precisely control its absorption into the bloodstream in response to changing body stores of iron. Approximately 65% of the body's iron supply (about 4000 mg) is in hemoglobin. Most of the remainder is stored in the liver, spleen, and (to a much lesser extent) bone marrow. Free iron ions (Fe^{2+}, Fe^{3+}) are toxic, so iron is stored inside cells as protein-iron complexes such as **ferritin** (fer′ĭ-tin) and **hemosiderin** (he″mo-sid′er-in). In blood, iron is transported loosely bound to a transport protein called **transferrin**, and developing erythrocytes take up iron as needed to form hemoglobin (**Figure 17.7**).

Small amounts of iron are lost each day in feces, urine, and perspiration. The average daily loss of iron is 1.7 mg in women and 0.9 mg in men. In women, the menstrual flow accounts for the additional losses.

Fate and Destruction of Erythrocytes

Red blood cells have a useful life span of 100 to 120 days. Their anucleate condition carries with it some important limitations. Red blood cells are unable to synthesize new proteins, grow, or divide. Erythrocytes become "old" as they lose their flexibility, become increasingly rigid and fragile, and their hemoglobin begins to degenerate. They become trapped and fragment in smaller circulatory channels, particularly in those of the spleen. For this reason, the spleen is sometimes called the "red blood cell graveyard."

Macrophages engulf and destroy dying erythrocytes. The heme of their hemoglobin is split off from globin (Figure 17.7). Its core of iron is salvaged, bound to protein (as ferritin or hemosiderin), and stored for reuse. The balance of the heme group is degraded to **bilirubin** (bil″ĭ-roo′bin), a yellow pigment that is released to the blood and binds to albumin for transport. Liver cells pick up bilirubin and in turn secrete it (in bile) into the intestine, where it is metabolized to *urobilinogen*. Most of this degraded pigment leaves the body in feces, as a brown pigment called *stercobilin*. The protein (globin) part of hemoglobin is metabolized or broken down to amino acids, which are released to the circulation.

Erythrocyte Disorders CLINICAL

Most erythrocyte disorders can be classified as anemia or polycythemia.

Anemia

Anemia (ah-ne′me-ah; "lacking blood") is a condition in which the blood's oxygen-carrying capacity is too low to support normal metabolism. It is a *sign* of some disorder rather than a disease in itself. Its hallmark is blood oxygen levels that are inadequate to support normal metabolism. Anemic individuals are fatigued, often pale, short of breath, and chilled.

The causes of anemia can be divided into three groups: blood loss, not enough red blood cells produced, or too many of them destroyed.

Blood Loss *Hemorrhagic anemia* (hem″o-raj′ik) is caused by blood loss. In acute hemorrhagic anemia, blood loss is rapid (as might follow a severe stab wound); it is treated by replacing the lost blood. Slight but persistent blood loss (due to hemorrhoids or an undiagnosed bleeding ulcer, for example) causes chronic hemorrhagic anemia. Once the primary problem is resolved, normal erythropoietic mechanisms replace the lost blood cells.

Not Enough Red Blood Cells Produced A number of problems can decrease erythrocyte production. These problems range from lack of essential raw materials (such as iron) to complete failure of the red bone marrow.

- *Iron-deficiency anemia* is generally a secondary result of hemorrhagic anemia, but it also results from inadequate intake of iron-containing foods or impaired iron absorption. The erythrocytes produced under these conditions, called **microcytes**, are small and pale because they cannot synthesize their normal complement of hemoglobin. The treatment is to increase iron intake in diet or through iron supplements.
- *Pernicious anemia* is an autoimmune disease that most often affects the elderly. The immune system of these individuals destroys cells of their own stomach mucosa. These cells normally produce a substance called **intrinsic factor** that must be present for vitamin B_{12} to be absorbed by intestinal cells. Without vitamin B_{12}, the developing erythrocytes grow but cannot divide, and large, pale cells called **macrocytes** result. Treatment involves regular intramuscular injections of vitamin B_{12} or application of a B_{12}-containing gel to the nasal lining once a week.

  As you might expect, lack of vitamin B_{12} in the diet also leads to anemia. However, this is usually a problem only in strict vegetarians because meats, poultry, and fish provide ample vitamin B_{12}.
- *Renal anemia* is caused by the lack of EPO, the hormone that controls red blood cell production. Renal anemia frequently accompanies renal disease because damaged or diseased kidneys cannot produce enough EPO. Fortunately, it can be treated by administering EPO.
- *Aplastic anemia* may result from destruction or inhibition of the red marrow by certain drugs and chemicals, ionizing radiation, or viruses. In most cases, though, the cause is unknown. Because marrow destruction impairs formation of *all* formed elements, anemia is just one of its signs. Defects in blood clotting and immunity are also present. Blood transfusions provide a stopgap treatment until stem cells harvested from a donor's blood, bone marrow, or umbilical cord blood can be transplanted.

Too Many Red Blood Cells Destroyed In *hemolytic anemias* (he″mo-lit′ik), erythrocytes rupture, or lyse, prematurely. Hemoglobin abnormalities, transfusion of mismatched blood, and certain bacterial and parasitic infections are possible causes. Here we focus on the hemoglobin abnormalities.

Production of abnormal hemoglobin usually has a genetic basis. Two such examples, thalassemia and sickle-cell anemia, can be serious, incurable, and sometimes fatal diseases. In both diseases the globin part of hemoglobin is abnormal and the erythrocytes produced are fragile and rupture prematurely.

Thalassemias (thal″ah-se′me-ahs; "sea blood") typically occur in people of Mediterranean ancestry. One of the globin chains is absent or faulty, and the erythrocytes are thin, delicate, and deficient in hemoglobin. There are many subtypes of thalassemia that range in severity from mild to so severe that monthly blood transfusions are required.

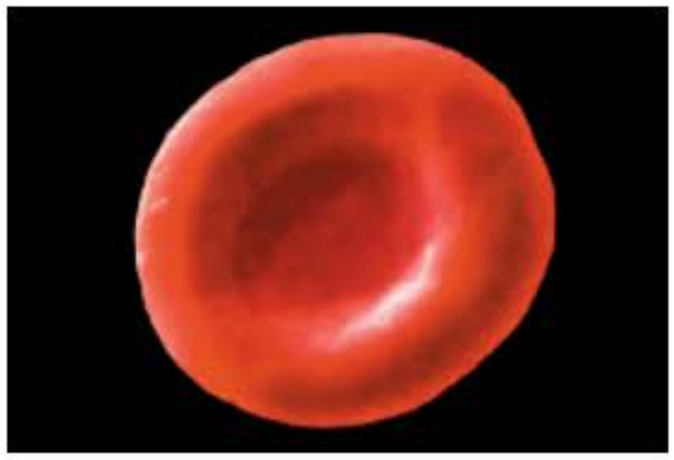
In **sickle-cell anemia**, the havoc caused by the abnormal hemoglobin, *hemoglobin S* (*HbS*), results from a change in just one of the 146 amino acids in a beta chain of the globin molecule! (See **Figure 17.8**.) This alteration causes the beta chains to link together under low-oxygen conditions, forming stiff rods so that hemoglobin S becomes spiky and sharp. This, in turn, causes the red blood cells to become crescent shaped when they unload oxygen molecules or when the oxygen content of the blood is lower than normal, as during vigorous exercise and other activities that increase metabolic rate.

The stiff, deformed erythrocytes rupture easily and tend to jam up in small blood vessels. These events interfere with oxygen delivery, leaving the victims gasping for air and in extreme pain. Bone and chest pain are particularly severe, and infection and stroke often follow. Blood transfusion is still the standard treatment for an acute sickle-cell crisis, but preliminary results using inhaled nitric oxide to dilate blood vessels are promising.

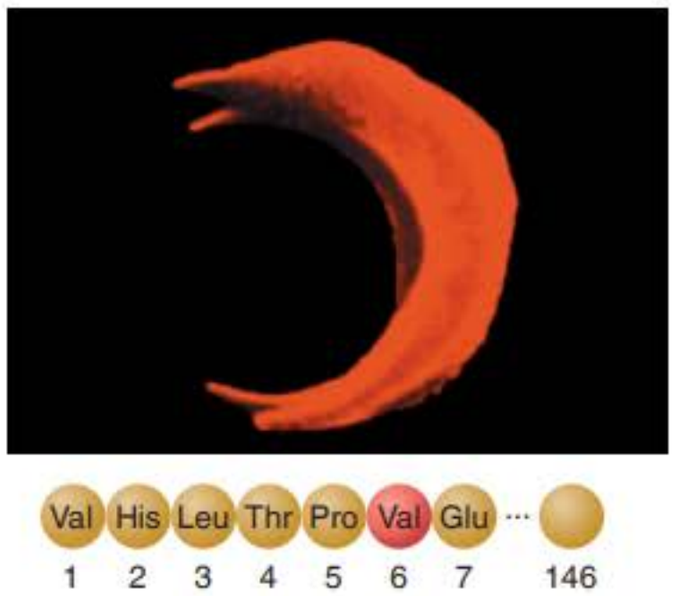
Sickle-cell anemia occurs chiefly in black people who live in the malaria belt of Africa and among their descendants. It strikes nearly one of every 500 African-American newborns.

Why would such a dangerous genetic trait persist in a population? Globally, about 250 million people are infected with malaria and about a million die each year. While individuals with two copies of the sickle-cell gene have sickle-cell anemia, individuals with only one copy of the gene (sickle-cell trait) have a better chance of surviving malaria. Their cells only sickle under abnormal circumstances, most importantly when they are infected with malaria. Sickling reduces the malaria parasites' ability to survive and enhances macrophages' ability to destroy infected RBCs and the parasites they contain.

Several treatment approaches for sickle-cell anemia focus on preventing RBCs from sickling. Fetal hemoglobin (HbF) does



(a) Normal erythrocyte has normal hemoglobin amino acid sequence in the beta chain.



(b) Sickled erythrocyte results from a single amino acid change in the beta chain of hemoglobin.

Figure 17.8 Sickle-cell anemia. Scanning electron micrographs (4950×).

not "sickle," even in those destined to have sickle-cell anemia. *Hydroxyurea*, a drug used to treat chronic leukemia, switches the fetal hemoglobin gene back on. This drug dramatically reduces the excruciating pain and overall severity and complications of sickle-cell anemia (by 50%). In children who are severely affected, bone marrow stem cell transplants offer a complete cure, but carry high risks.

Polycythemia

Polycythemia (pol″e-si-the′me-ah; "many blood cells") is an abnormal excess of erythrocytes that increases blood viscosity, causing it to flow sluggishly. *Polycythemia vera*, a bone marrow cancer, is characterized by dizziness and an exceptionally high RBC count (8–11 million cells/μl). The hematocrit may be as high as 80% and blood volume may double, causing the vascular system to become engorged with blood and severely impairing circulation. Severe polycythemia is treated by removing some blood (a procedure called a therapeutic phlebotomy).

Secondary polycythemias result when less oxygen is available or EPO production increases. The secondary polycythemia that appears in individuals living at high altitudes is a normal physiological response to the reduced atmospheric pressure and lower oxygen content of the air in such areas. RBC counts of 6–8 million/μl are common in such people.

Blood doping, practiced by some athletes competing in aerobic events, is artificially induced polycythemia. Some of the athlete's red blood cells are drawn off and stored. The body quickly replaces these erythrocytes because removing blood triggers the erythropoietin mechanism. Then, when the stored blood is reinfused a few days before the athletic event, a temporary polycythemia results.

Since red blood cells carry oxygen, the additional infusion should translate into increased oxygen-carrying capacity due to a higher hematocrit, and greater endurance and speed should result. Other than the risk of stroke and heart failure due to high hematocrit and high blood viscosity, blood doping seems to work. However, the practice is considered unethical and has been banned from competitive sports.

17.4 Leukocytes defend the body

Learning Outcomes

- **List the classes, structural characteristics, and functions of leukocytes.**
- **Describe how leukocytes are produced.**
- **Give examples of leukocyte disorders, and explain what goes wrong in each disorder.**

General Structural and Functional Characteristics

Leukocytes (*leuko* = white), or **white blood cells (WBCs)**, are the only formed elements that are complete cells, with nuclei and the usual organelles. Accounting for less than 1% of total blood volume, leukocytes are far less numerous than red blood cells. On average, there are 4800–10,800 WBCs/μl of blood.

Leukocytes are crucial to our defense against disease. They form a mobile army that helps protect the body from damage by bacteria, viruses, parasites, toxins, and tumor cells. As such, they have special functional characteristics. Red blood cells are confined to the bloodstream, and they carry out their functions in the blood. However, white blood cells are able to slip out of the capillary blood vessels—a process called **diapedesis** (di″ah-pĕ-de′sis; "leaping across"). The circulatory system is simply their means of transport to areas of the body (mostly loose connective tissues or lymphoid tissues) where they mount inflammatory or immune responses.

As we explain in more detail in Chapter 21, the signals that prompt WBCs to leave the bloodstream at specific locations are cell adhesion molecules displayed by endothelial cells

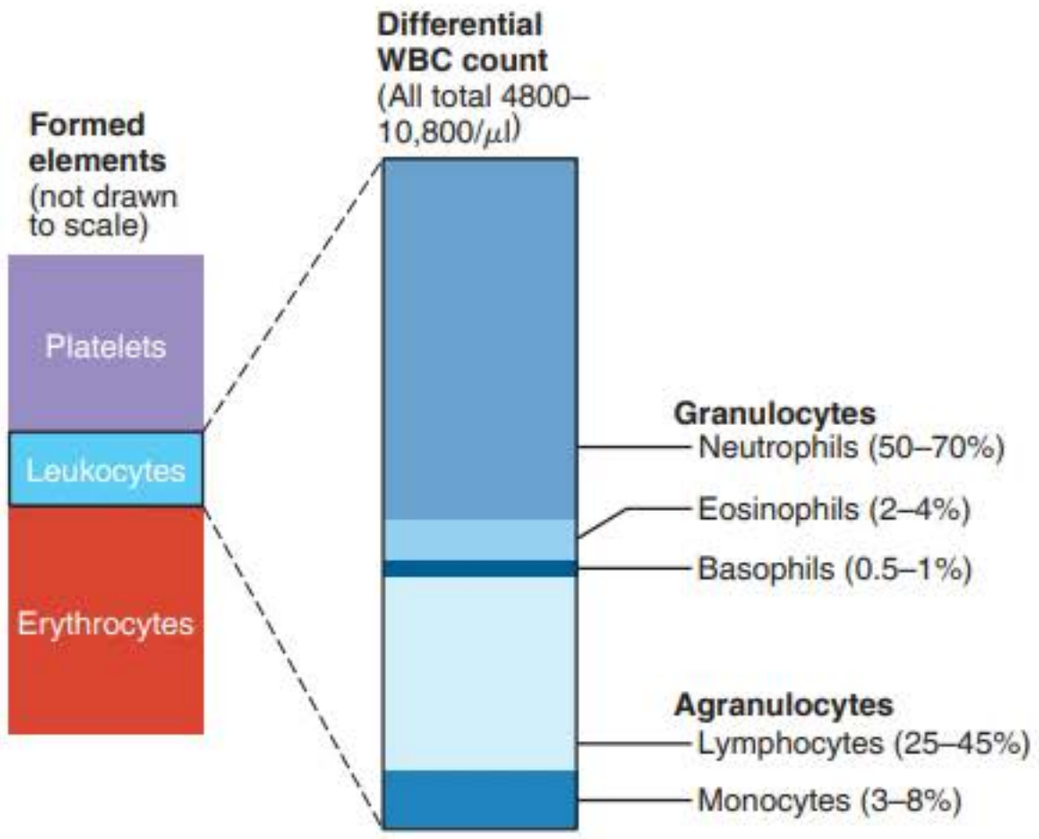

Figure 17.9 Types and relative percentages of leukocytes in normal blood. Erythrocytes comprise nearly 98% of the formed elements, and leukocytes and platelets together account for the remaining 2+%.

forming the capillary walls at sites of inflammation. Once out of the bloodstream, leukocytes move through the tissue spaces by **amoeboid motion** (they form flowing cytoplasmic extensions that move them along). By following the chemical trail of molecules released by damaged cells or other leukocytes, a phenomenon called **positive chemotaxis**, they pinpoint areas of tissue damage and infection and gather there in large numbers to destroy foreign substances and dead cells.

Whenever white blood cells are mobilized for action, the body speeds up their production and their numbers may double within a few hours. A *white blood cell count* of over 11,000 cells/μl is **leukocytosis**. This condition is a normal response to an infection in the body.

Leukocytes are grouped into two major categories on the basis of structural and chemical characteristics (**Figure 17.9**, and **Table 17.2** on p. 656):

- *Granulocytes* contain obvious membrane-bound cytoplasmic granules.
- *Agranulocytes* lack obvious granules.

Students are often asked to list the leukocytes in order from most abundant to least abundant. The following phrase may help you with this task: **N**ever **l**et **m**onkeys **e**at **b**ananas (neutrophils, lymphocytes, monocytes, eosinophils, basophils).

Granulocytes

Granulocytes (gran′u-lo-sīts), which include neutrophils, eosinophils, and basophils, are all roughly spherical in shape. They are larger and much shorter-lived (in most cases) than erythrocytes. They characteristically have lobed nuclei (rounded nuclear masses connected by thinner strands of nuclear material), and their membrane-bound cytoplasmic granules stain quite specifically with Wright's stain.

Neutrophils

Neutrophils (nu′tro-filz), the most numerous white blood cells, account for 50–70% of the WBC population. Neutrophils are about twice as large as erythrocytes.

The neutrophil cytoplasm contains very fine granules (of two varieties) that are difficult to see (Table 17.2 and **Figure 17.10a**). Neutrophils get their name (literally, "neutral-loving") because their granules take up both *basic* (blue) and *acidic* (red) *dyes*. Together, the two types of granules give the cytoplasm a lilac color. Some of these granules contain hydrolytic enzymes, and are regarded as lysosomes. Others, especially the smaller granules, contain a potent "brew" of antimicrobial proteins, called **defensins**.

Neutrophil nuclei typically have three to six lobes. Because of this nuclear variability, they are often called **polymorphonuclear leukocytes** (*PMNs*) or simply *polys* (*polymorphonuclear* = many shapes of the nucleus).

Neutrophils are our body's bacteria slayers, and their numbers increase explosively during acute bacterial infections such as meningitis and appendicitis. Neutrophils are chemically attracted to sites of inflammation and are active phagocytes. They are especially partial to ingesting bacteria and some fungi, which they enclose in a vesicle called a phagosome (◀ p. 77). One way that neutrophils kill bacteria is a process called a **respiratory burst**. During the respiratory burst, the cells metabolize oxygen to produce potent germ-killer oxidizing substances such as bleach and hydrogen peroxide. In addition, defensin-containing granules merge with the microbe-containing phagosome. As a result, defensins form peptide "spears" that pierce holes in the membrane of the ingested "foe" and the bacterium lyses.

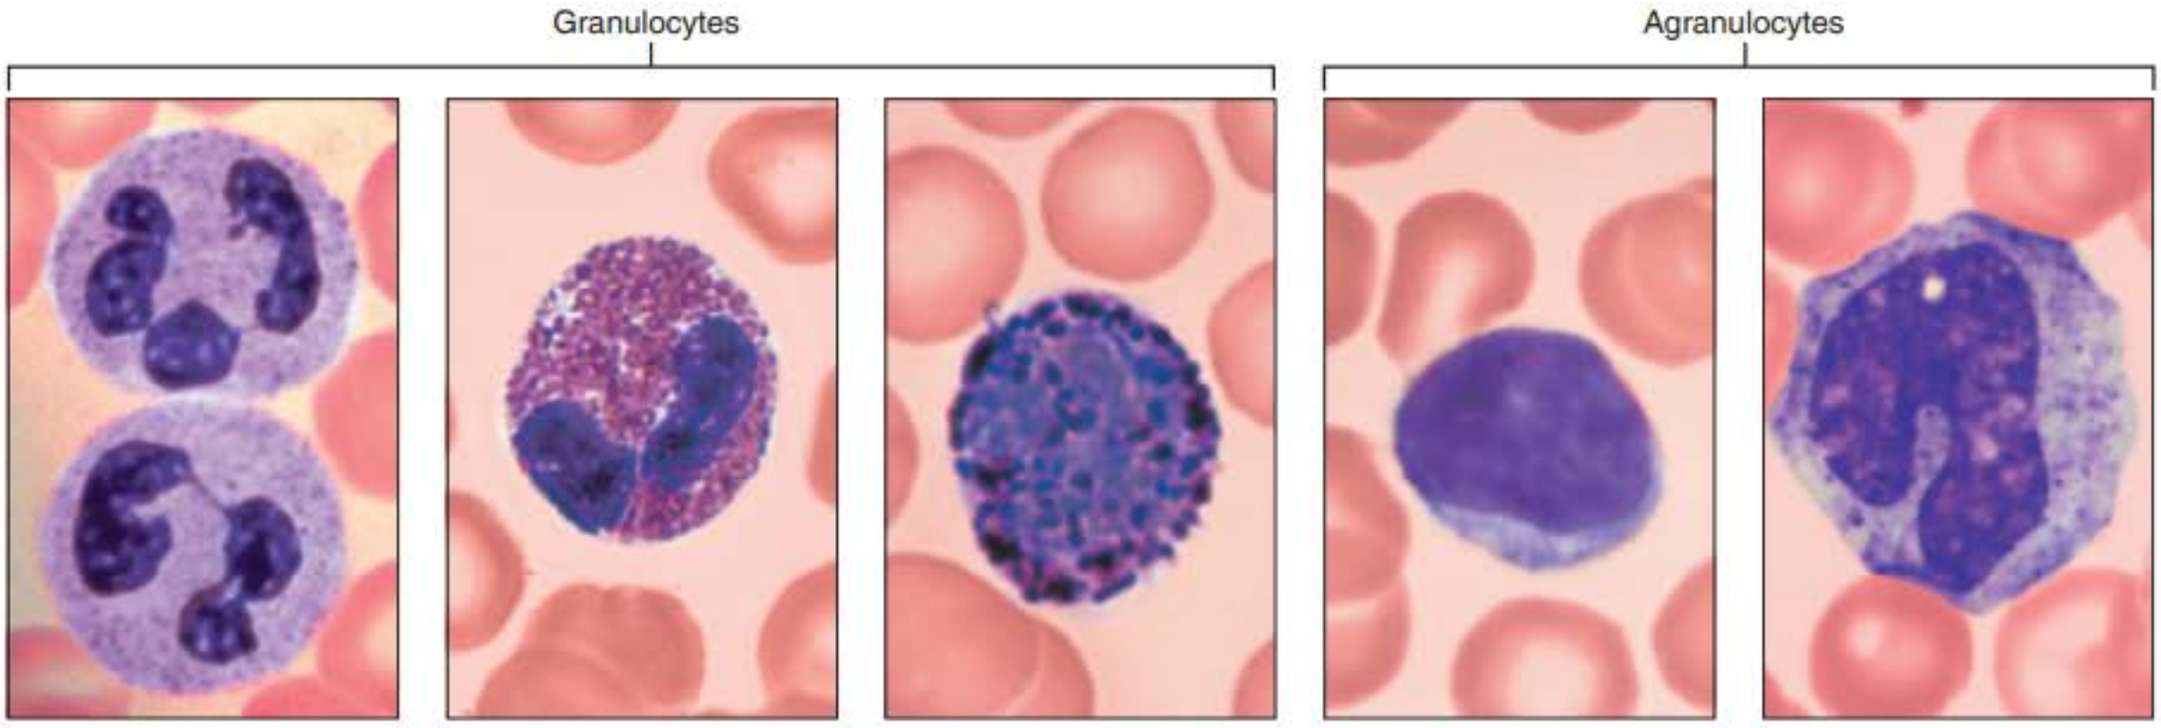
Eosinophils

Eosinophils (e″o-sin′o-filz) account for 2–4% of all leukocytes and are approximately the size of neutrophils. Their nucleus usually has two lobes connected by a broad band of nuclear material (Table 17.2 and Figure 17.10b) and so resembles earmuffs.

Large, coarse granules that stain from brick red to crimson with acid (eosin) dyes pack the cytoplasm. These granules are lysosome-like and filled with a unique variety of digestive enzymes. However, unlike typical lysosomes, they lack enzymes that specifically digest bacteria.

The most important role of eosinophils is to lead the counterattack against parasitic worms, such as flatworms (tapeworms and flukes) and roundworms (pinworms and hookworms) that are too large to be phagocytized. These worms are ingested in food (especially raw fish) or invade the body via the skin and then typically burrow into the intestinal or respiratory mucosae. Eosinophils reside in the loose connective tissues at the same body sites, and when they encounter a parasitic worm "prey," they gather around and release the enzymes from their cytoplasmic granules onto the parasite's surface, digesting it away.

Eosinophils have complex roles in many other diseases including allergies and asthma. While they contribute to the tissue damage that occurs in many immune processes, we are also beginning to recognize them as important modulators of the immune response.



(a) Neutrophils (2 shown): Multilobed nucleus, pale red and blue cytoplasmic granules

(b) Eosinophil: Bilobed nucleus, red cytoplasmic granules

(c) Basophil: Bilobed nucleus, purplish-black cytoplasmic granules

(d) Lymphocyte (small): Large spherical nucleus, thin rim of pale blue cytoplasm

(e) Monocyte: Kidney-shaped nucleus, abundant pale blue cytoplasm

Figure 17.10 Leukocytes. In each case the leukocytes are surrounded by erythrocytes. (All 2100×, Wright's stain.)

Practice Histology questions: MasteringA&P® > Study Area > Lab Tools > PAL

Basophils

Basophils are the rarest white blood cells, accounting for only 0.5–1% of the leukocyte population. Their cytoplasm contains large, coarse, histamine-containing granules that have an affinity for the basic dyes (*basophil* = base loving) and stain purplish-black (Figure 17.10c). *Histamine* is an inflammatory chemical that acts as a vasodilator (makes blood vessels dilate) and attracts other white blood cells to the inflamed site; drugs called antihistamines counter this effect. The deep purple nucleus is generally U or S shaped with one or two constrictions.

Granulated cells similar to basophils, called *mast cells*, are found in connective tissues. Although mast cell nuclei tend to be more oval than lobed, the cells are similar microscopically, and both cell types bind to a particular antibody (immunoglobulin E) that causes the cells to release histamine. However, mast cells and basophils arise from different cell lines.

Agranulocytes

The **agranulocytes** include lymphocytes and monocytes, WBCs that lack *visible* cytoplasmic granules. Although similar to each other structurally, lymphocytes and monocytes are functionally distinct and unrelated cell types. Their nuclei are typically spherical or kidney shaped.

Lymphocytes

Lymphocytes, accounting for 25% or more of the WBC population, are the second most numerous leukocytes in the blood. When stained, a typical lymphocyte has a large, dark-purple nucleus that occupies most of the cell volume. The nucleus is usually spherical but may be slightly indented, and it is surrounded by a thin rim of pale-blue cytoplasm (Table 17.2 and Figure 17.10d). Lymphocytes are often classified by size (diameter) as small (5–8 μm), medium (10–12 μm), and large (14–17 μm).

Large numbers of lymphocytes exist in the body, but relatively few (mostly the small lymphocytes) are found in the bloodstream. In fact, lymphocytes are so called because most are closely associated with lymphoid tissues (lymph nodes, spleen, etc.), where they play a crucial role in immunity.

- **T lymphocytes (T cells)** function in the immune response by acting directly against virus-infected cells and tumor cells.
- **B lymphocytes (B cells)** give rise to *plasma cells*, which produce **antibodies** (immunoglobulins) that are released to the blood. (We describe B and T lymphocyte functions in Chapter 21.)

Monocytes

Monocytes account for 3–8% of WBCs. With an average diameter of 18 μm, they are the largest leukocytes. They have abundant pale-blue cytoplasm and a darkly staining purple nucleus, which is often U or kidney shaped (Table 17.2 and Figure 17.10e).

When circulating monocytes leave the bloodstream and enter the tissues, they differentiate into highly mobile **macrophages** with prodigious appetites. Macrophages are actively phagocytic, and they are crucial in the body's defense against viruses, certain intracellular bacterial parasites, and *chronic* infections such as tuberculosis. As we explain in Chapter 21, macrophages can also activate lymphocytes to mount an immune response.

Production and Life Span of Leukocytes

Like erythropoiesis, **leukopoiesis**, or the production of white blood cells, is stimulated by chemical messengers. These messengers, which can act either as paracrines or hormones, are

glycoproteins that fall into two families of hematopoietic factors, **interleukins** and **colony-stimulating factors**, or **CSFs**. The interleukins are numbered (e.g., IL-3, IL-5), but most CSFs are named for the leukocyte population they stimulate—for example, *granulocyte-CSF* (*G-CSF*) stimulates production of granulocytes. Hematopoietic factors, released by supporting cells of the red bone marrow and mature WBCs, not only prompt the white blood cell precursors to divide and mature, but also enhance the protective potency of mature leukocytes.

HOMEOSTATIC IMBALANCE 17.2 CLINICAL

Many of the hematopoietic hormones (EPO and several of the CSFs) are used clinically. These hormones stimulate the bone marrow of cancer patients who are receiving chemotherapy (which suppresses the marrow) and of those who have received stem cell transplants. They are also used to beef up the protective responses of AIDS patients.

Figure 17.11 shows the pathways of leukocyte differentiation, starting with the hematopoietic stem cell that gives rise to all of the formed elements in the blood. An early branching of the pathway divides the **lymphoid stem cells**, which produce lymphocytes, from the **myeloid stem cells**, which give rise to all other formed elements. In each granulocyte line, the committed cells, called **myeloblasts** (mi′ĕ-lo-blasts″), accumulate lysosomes, becoming **promyelocytes**. The distinctive granules of each granulocyte type appear next in the **myelocyte** stage and then cell division stops. Next, the nuclei become U shaped, producing the **band cell** stage. Just before granulocytes leave the marrow and enter the circulation, their nuclei constrict, beginning the process of nuclear segmentation.

The bone marrow stores mature granulocytes and usually contains about ten times more granulocytes than are found in the blood. The normal ratio of granulocytes to erythrocytes produced is about 3:1, which reflects granulocytes' much shorter life span (0.25 to 9.0 days). Most die fighting invading microorganisms.

Despite their similar appearance, the two types of agranulocytes have very different lineages.

- Monocytes are derived from myeloid stem cells, and share a common precursor with neutrophils that is not shared with the other granulocytes.* Cells following the monocyte line pass through the **monoblast** and **promonocyte** stages before leaving the bone marrow and becoming monocytes (Figure 17.11d).
- T and B lymphocytes are derived from **T** and **B lymphocyte precursors**, which arise from the lymphoid stem cell. The T lymphocyte precursors leave the bone marrow and travel to the thymus, where their further differentiation occurs (as we describe in Chapter 21). B lymphocyte precursors remain and mature in the bone marrow.

*Recent research suggests that monocytes may share a common precursor with lymphocytes rather than granulocytes.

Monocytes may live for several months, whereas the life span of lymphocytes varies from a few hours to decades.

Leukocyte Disorders CLINICAL

Overproduction of abnormal leukocytes occurs in leukemia and infectious mononucleosis. At the opposite pole, **leukopenia** (loo″ko-pe′ne-ah) is an abnormally low white blood cell count (*penia* = poverty), commonly induced by drugs, particularly glucocorticoids and anticancer agents.

Leukemias

The term *leukemia*, literally "white blood," refers to a group of cancerous conditions involving overproduction of abnormal white blood cells. As a rule, the renegade leukocytes are members of a single *clone* (descendants of a single cell) that remain unspecialized and proliferate out of control, impairing normal red bone marrow function. The leukemias are named according to the rate at which they progress and the type of cell primarily involved. For example:

- *Acute leukemia* is quickly advancing because it derives from stem cells.
- *Chronic leukemia* is slowly advancing because it involves proliferation of later cell stages.
- *Myeloid leukemia* involves myeloblast descendants.
- *Lymphocytic leukemia* involves lymphocytes.

The more serious acute forms primarily affect children. Chronic leukemia occurs more often in elderly people. Without therapy, all leukemias are fatal, and only the time course differs.

In all leukemias, cancerous leukocytes fill the red bone marrow and immature WBCs flood into the bloodstream. The other blood cell lines are crowded out, so severe anemia and bleeding problems result. Other symptoms include fever, weight loss, and bone pain. Although tremendous numbers of leukocytes are produced, they are nonfunctional and cannot defend the body in the usual way. The most common causes of death are internal hemorrhage and overwhelming infections.

Irradiation and antileukemic drugs can destroy the rapidly dividing cells and induce remissions (symptom-free periods) lasting from months to years. Stem cell transplants are used in selected patients when compatible donors are available.

Infectious Mononucleosis

Sometimes called the "kissing disease," *infectious mononucleosis* is a highly contagious viral disease most often seen in young adults. Caused by the Epstein-Barr virus, the disease has a hallmark of excessive numbers of lymphocytes. Many of these lymphocytes are so large and atypical that they were originally misidentified as monocytes, and the disease was mistakenly named mononucleosis. The affected individual complains of being tired and achy, and has a chronic sore throat and a low-grade fever. There is no cure, but with rest the condition typically runs its course to recovery in four to six weeks.

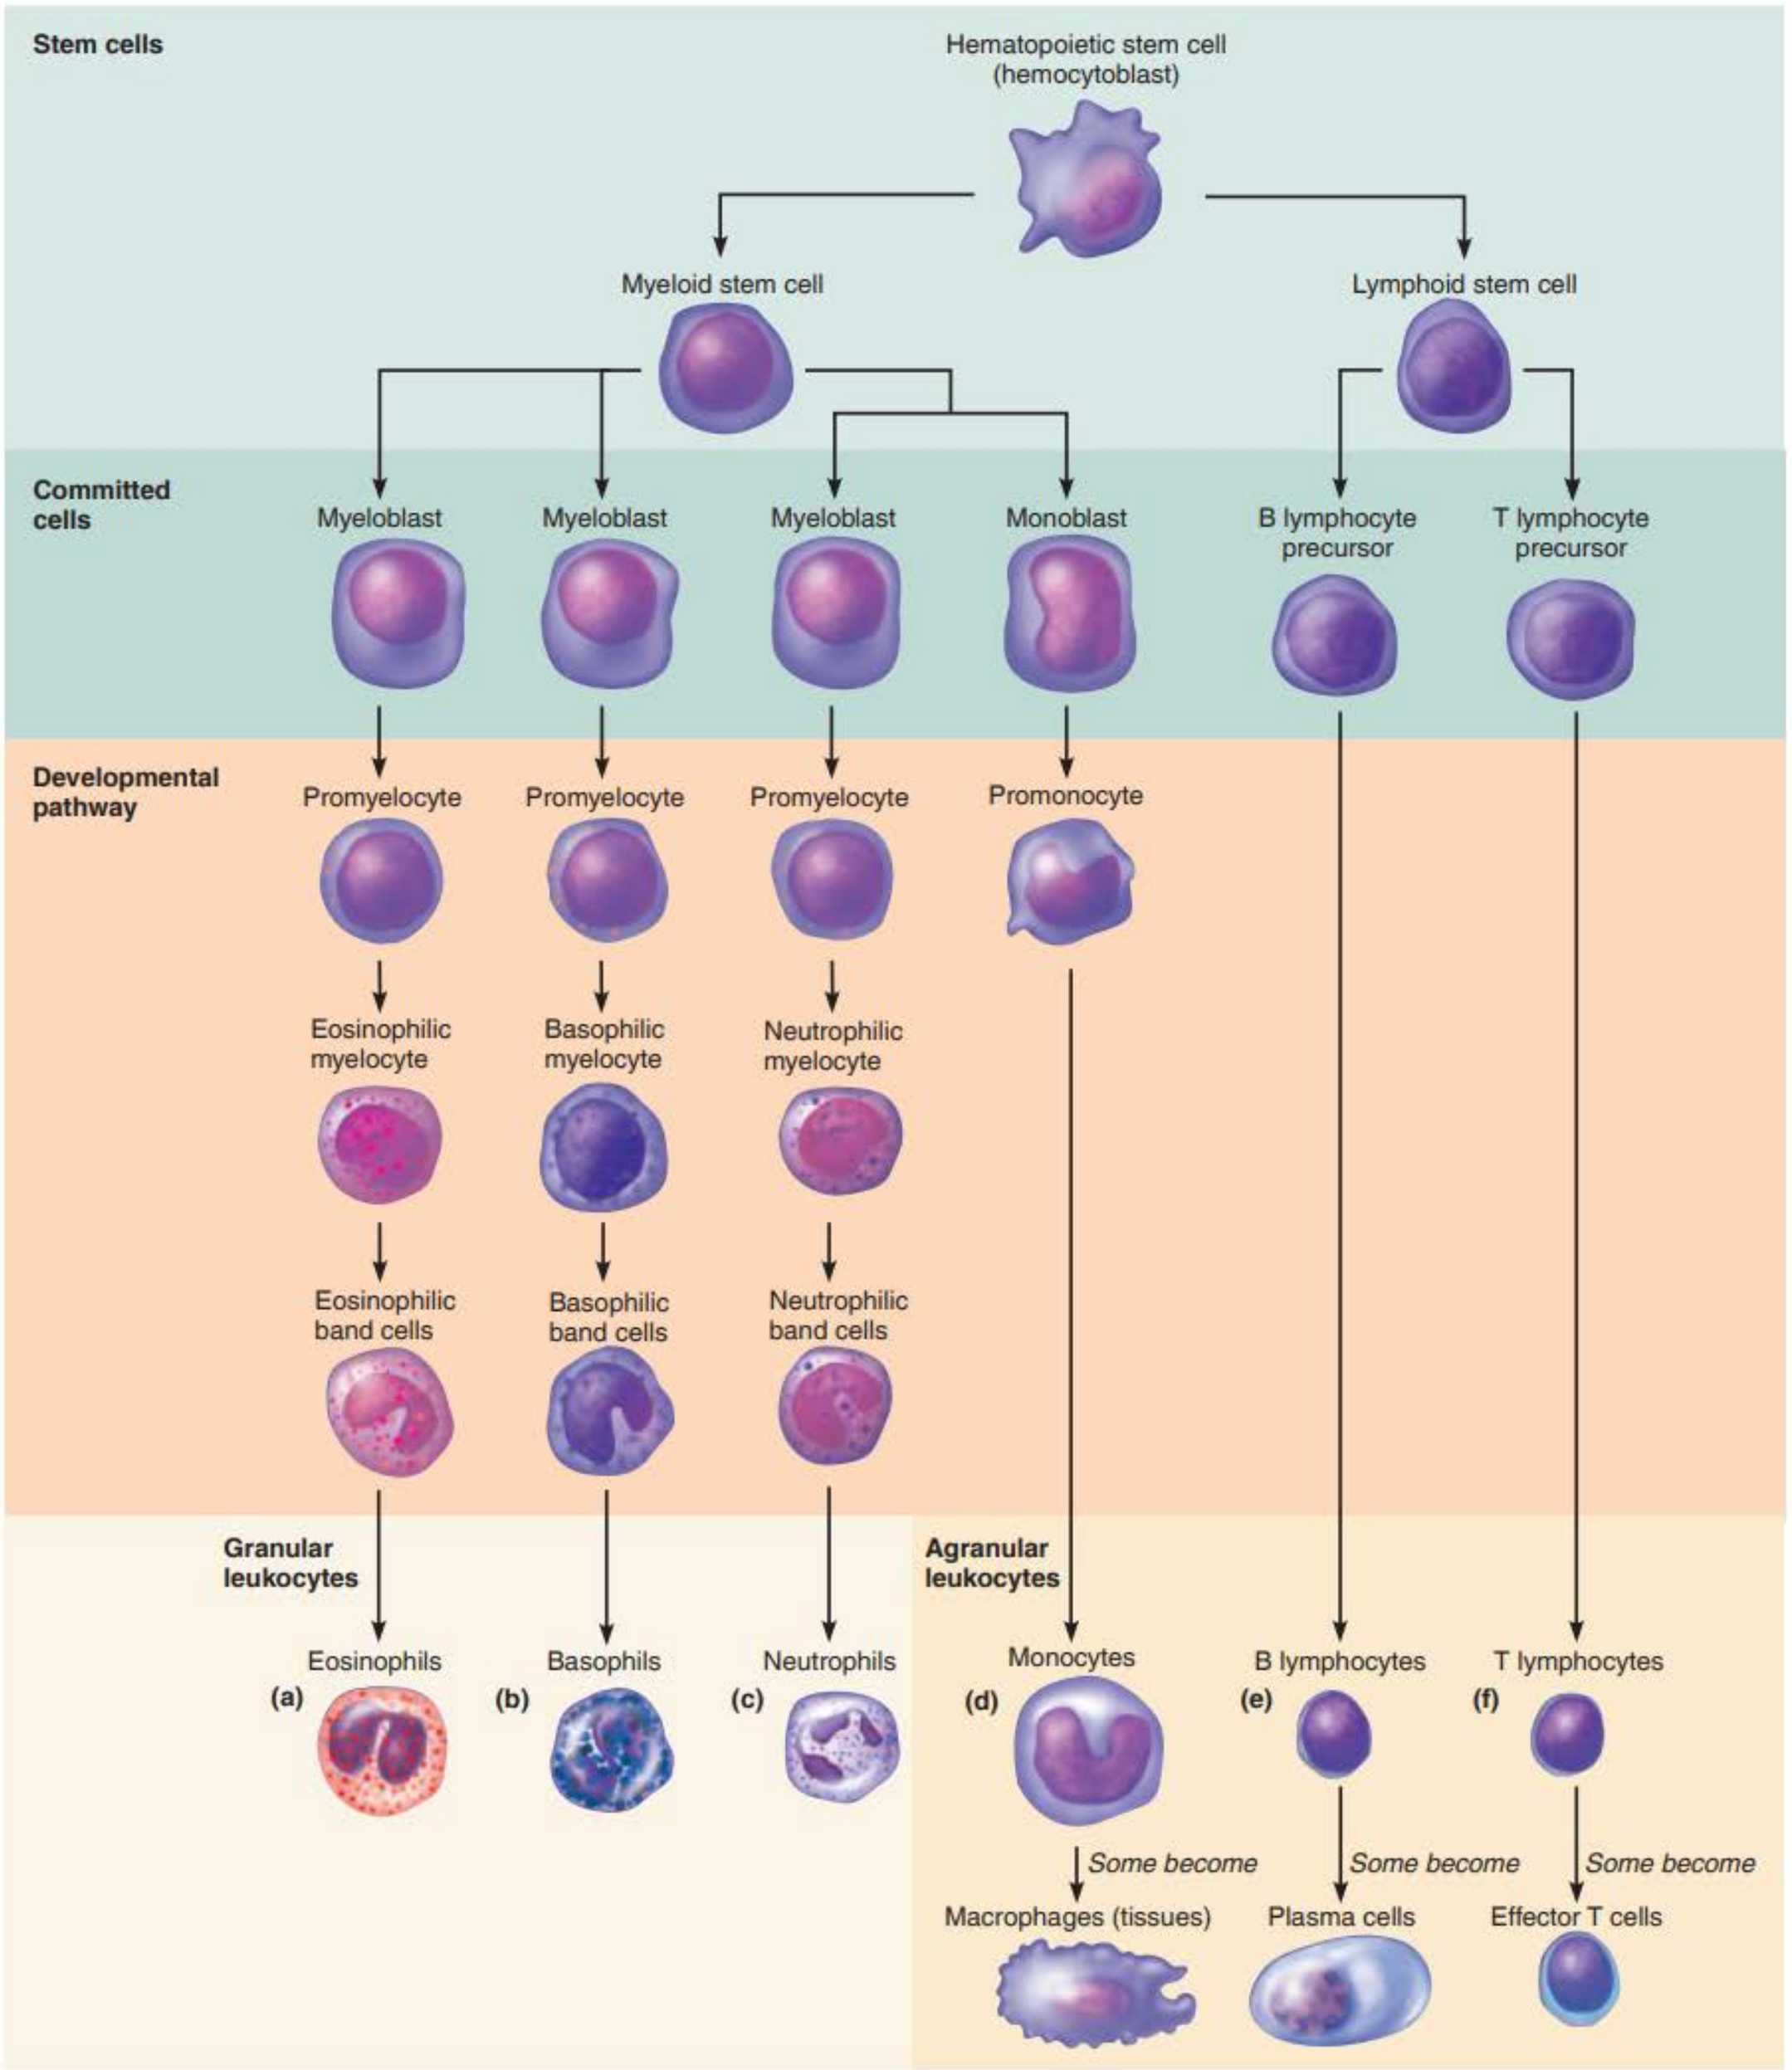


Figure 17.11 Leukocyte formation. Leukocytes arise from ancestral stem cells called hematopoietic stem cells. **(a–c)** Granular leukocytes develop via a sequence involving myeloblasts. **(d)** Monocytes, like granular leukocytes, are progeny of the myeloid stem cell and share a common precursor with neutrophils (not shown). **(e, f)** Only lymphocytes arise via the lymphoid stem cell line.

Table 17.2 Summary of Formed Elements of the Blood

CELL TYPE	ILLUSTRATION	DESCRIPTION*	CELLS/μL (mm^3) OF BLOOD	DURATION OF DEVELOPMENT (D) AND LIFE SPAN (LS)	FUNCTION
Erythrocytes (red blood cells, RBCs)		Biconcave, anucleate disc; salmon-colored; diameter 7–8 μm	4–6 million	D: about 15 days LS: 100–120 days	Transport oxygen and carbon dioxide
Leukocytes (white blood cells, WBCs)		Spherical, nucleated cells	4800–10,800		
Granulocytes					
• Neutrophil		Multilobed nucleus; inconspicuous cytoplasmic granules; diameter 10–12 μm	3000–7000	D: about 14 days LS: 6 hours to a few days	Phagocytize bacteria
• Eosinophil		Bilobed nucleus; red cytoplasmic granules; diameter 10–14 μm	100–400	D: about 14 days LS: about 5 days	Kill parasitic worms; complex role in allergy and asthma
• Basophil		Bilobed nucleus; large purplish-black cytoplasmic granules; diameter 10–14 μm	20–50	D: 1–7 days LS: a few hours to a few days	Release histamine and other mediators of inflammation; contain heparin, an anticoagulant
Agranulocytes					
• Lymphocyte		Spherical or indented nucleus; pale blue cytoplasm; diameter 5–17 μm	1500–3000	D: days to weeks LS: hours to years	Mount immune response by direct cell attack or via antibodies
• Monocyte		U- or kidney-shaped nucleus; gray-blue cytoplasm; diameter 14–24 μm	100–700	D: 2–3 days LS: months	Phagocytosis; develop into macrophages in the tissues
Platelets		Discoid cytoplasmic fragments containing granules; stain deep purple; diameter 2–4 μm	150,000–400,000	D: 4–5 days LS: 5–10 days	Seal small tears in blood vessels; instrumental in blood clotting

*Appearance when stained with Wright's stain.

__, __ 1. Are or become important phagocytes.
__, __, __ 2. Granulocytes.
__ 3. Abundant in lymph nodes and in the spleen.
__ 4. Granule contents similar to those of mast cells.

7. APPLY Amos has leukemia. Even though his WBC count is abnormally high, Amos is prone to severe infections, bleeding, and anemia. Explain.

8. MAKE CONNECTIONS Because of the blood brain barrier, brain tissue is somewhat less accessible to circulating macrophages. Because of this, one type of CNS cell (related to macrophages and discussed in Chapter 11), can become phagocytic. Which type of cell is this?

For answers, see Answers Appendix.

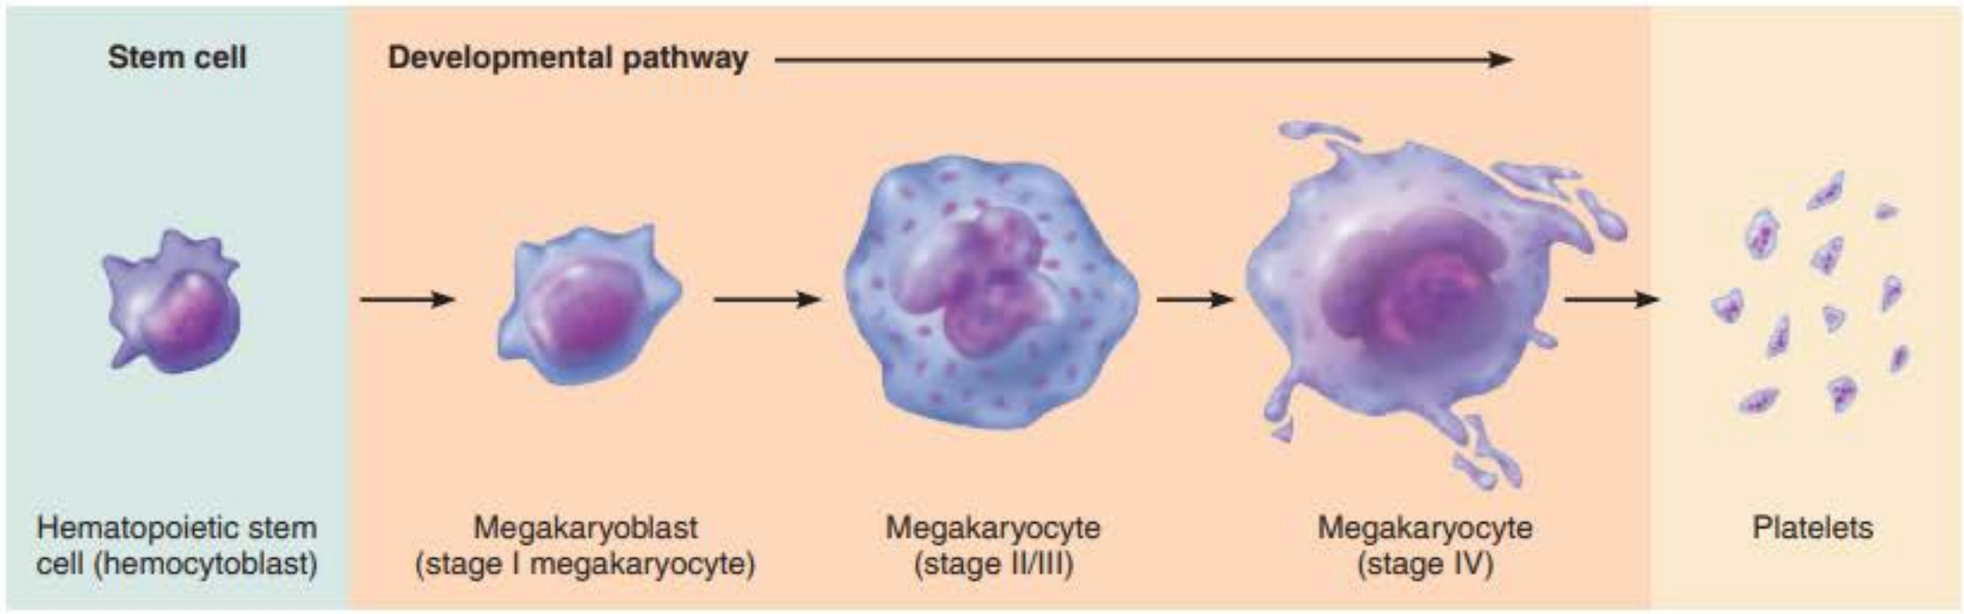

Figure 17.12 Formation of platelets. The hematopoietic stem cell gives rise to cells that undergo several mitotic divisions unaccompanied by cytoplasmic division to produce megakaryocytes. The plasma membrane of the megakaryocyte fragments, liberating the platelets. (Intermediate stages between the hematopoietic stem cell and megakaryoblast are not illustrated.)

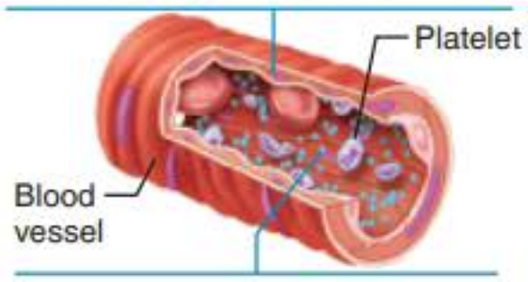
17.5 Platelets are cell fragments that help stop bleeding

Learning Outcome

- **Describe the structure and function of platelets.**

Platelets are not cells in the strict sense. Rather, they are fragments of extraordinarily large cells (up to 60 μm in diameter) called **megakaryocytes** (meg″ah-kar′e-o-sītz). Platelets are about one-fourth the diameter of a lymphocyte. In blood smears, each platelet exhibits a blue-staining outer region and an inner area containing granules that stain purple. The granules contain an impressive array of chemicals that act in the clotting process, including serotonin, Ca^{2+}, a variety of enzymes, ADP, and platelet-derived growth factor (PDGF).

Platelets are essential for the clotting process that occurs in plasma when blood vessels are ruptured or their lining is injured. By sticking to the damaged site, platelets form a temporary plug that helps seal the break. (We explain this process shortly.) Because they are anucleate, platelets age quickly and degenerate in about 10 days if they are not involved in clotting. In the meantime, they circulate freely, kept mobile but inactive by molecules (nitric oxide, prostacyclin) secreted by endothelial cells lining the blood vessels.



Normal, undamaged endothelial cells secrete molecules (such as nitric oxide and prostacyclin) that keep platelets from sticking.

A hormone called **thrombopoietin** regulates the formation of platelets. Their immediate ancestral cells, the megakaryocytes, are progeny of the hematopoietic stem cell and the myeloid stem cell, but their formation is quite unusual (**Figure 17.12**). In this line, repeated mitoses of the **megakaryoblast** (also called a stage I megakaryocyte) occur, but cytokinesis does not. The final result is the mature (stage IV) megakaryocyte (literally "big nucleus cell"), a bizarre cell with a huge, multilobed nucleus and a large cytoplasmic mass.

After it forms, the megakaryocyte presses against a sinusoid (the specialized type of capillary in the red marrow) and sends cytoplasmic extensions through the sinusoid wall into the bloodstream. These extensions rupture, releasing platelets like leaves blowing off a tree, seeding the blood with platelets. The plasma membranes associated with each fragment quickly seal around the cytoplasm to form the grainy, roughly disc-shaped platelets (see Table 17.2), each with a diameter of 2–4 μm. Each microliter of blood contains 150,000 to 400,000 tiny platelets.

Check Your Understanding

9. What is a megakaryocyte? What does its name mean?

For answers, see Answers Appendix.

17.6 Hemostasis prevents blood loss

Learning Outcomes

- **Describe the process of hemostasis. List factors that limit clot formation and prevent undesirable clotting.**
- **Give examples of hemostatic disorders. Indicate the cause of each condition.**

Normally, blood flows smoothly past the intact blood vessel lining (endothelium). But if a blood vessel wall breaks, a whole series of reactions is set in motion to accomplish **hemostasis** (he″mo-sta′sis), which stops the bleeding (*stasis* = halting). Without this plug-the-hole defensive reaction, we would quickly bleed out our entire blood volume from even the smallest cuts.

The hemostasis response is fast, localized, and carefully controlled. It involves many *clotting factors* normally present in plasma as well as several substances that are released by platelets and injured tissue cells. During hemostasis, three steps occur in

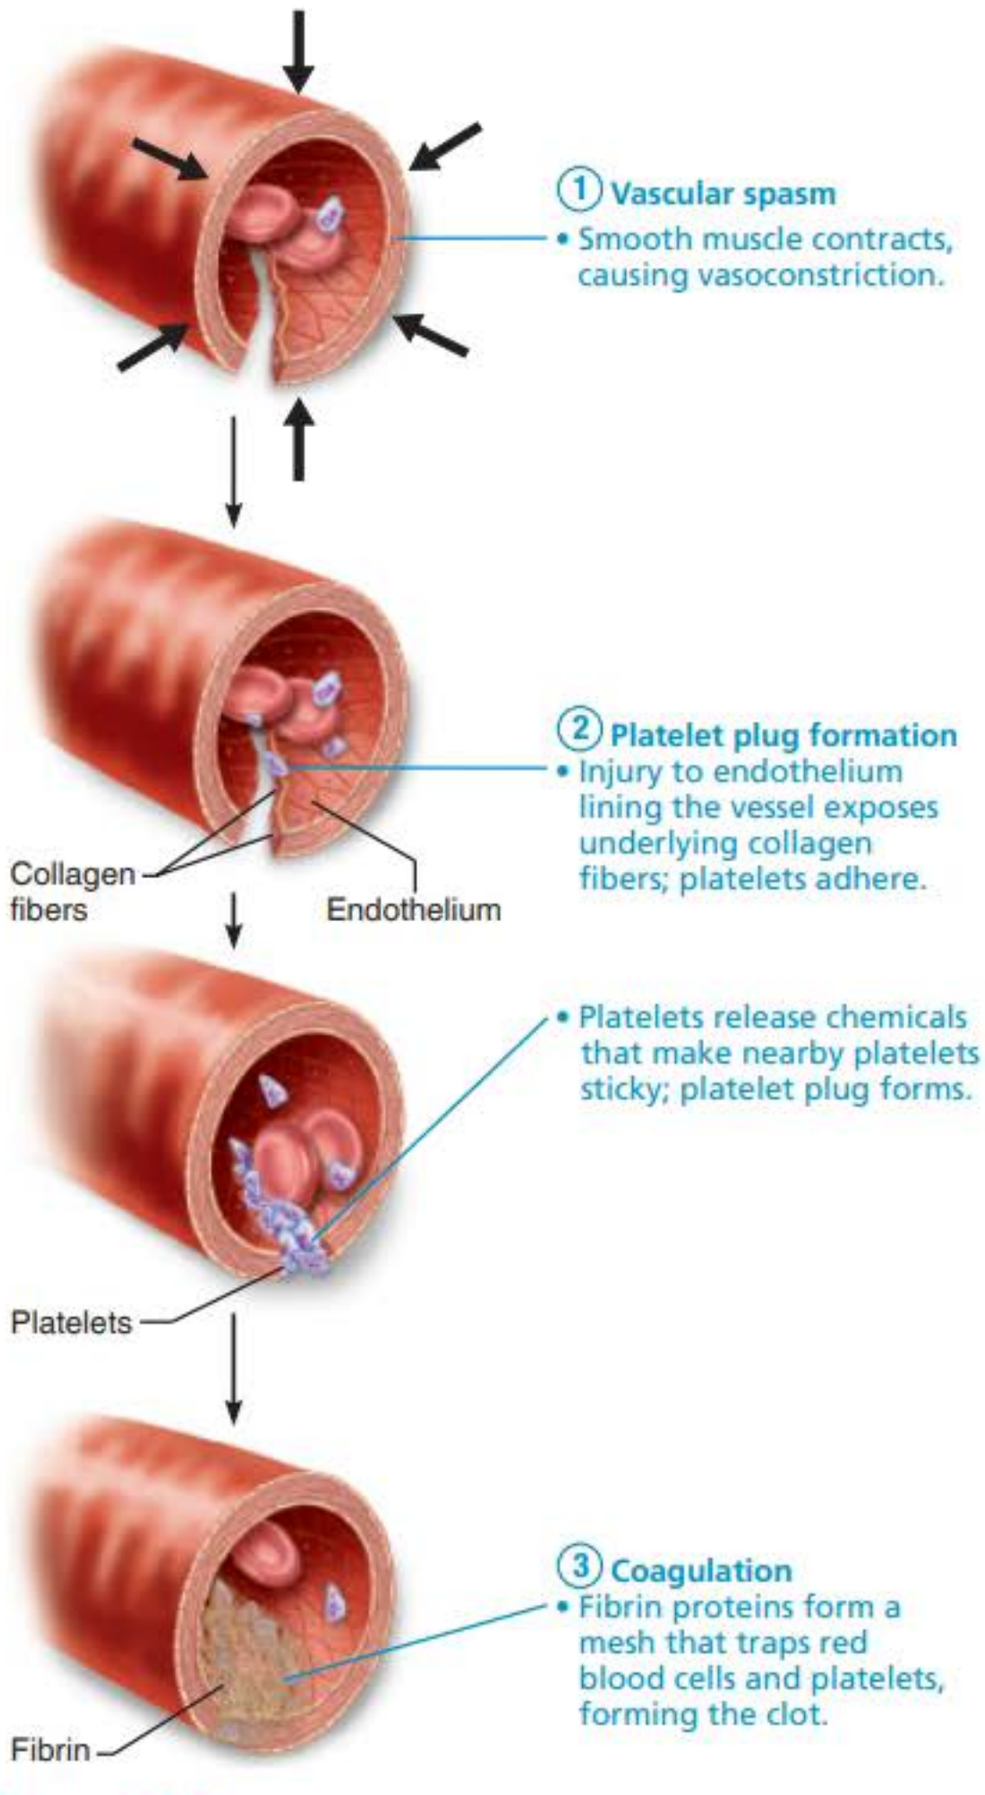


Figure 17.13 Events of hemostasis.

rapid sequence (**Figure 17.13**): ① vascular spasm, ② platelet plug formation, and ③ coagulation (blood clotting). Following hemostasis, the clot retracts. It then dissolves as it is replaced by fibrous tissue that permanently prevents blood loss.

Step 1: Vascular Spasm

In the first step, the damaged blood vessels respond to injury by constricting (vasoconstriction) (Figure 17.13 ①). Factors that trigger this **vascular spasm** include direct injury to vascular smooth muscle, chemicals released by damaged endothelial cells and activated platelets (discussed next), and reflexes initiated by local pain receptors. The spasm mechanism becomes more and more efficient as the amount of tissue damage increases, and is most effective in the smaller blood vessels. The spasm response is valuable because a strongly constricted artery can significantly reduce blood loss for 20–30 minutes, allowing time for the next two steps to occur.

Step 2: Platelet Plug Formation

In the second step, platelets play a key role in hemostasis by aggregating (sticking together), forming a plug that temporarily seals the break in the vessel wall (Figure 17.13 ②). They also help orchestrate subsequent events that form a blood clot.

As a rule, platelets do not stick to each other or to the smooth endothelium that lines blood vessels. (Recall that endothelium is a type of epithelium; ◀ p. 121.) Intact endothelial cells release nitric oxide and a prostaglandin called **prostacyclin** (or PGI_2). Both chemicals prevent platelet aggregation (clumping) in undamaged tissue and restrict aggregation to the site of injury.

However, when the endothelium is damaged and the collagen fibers of the underlying connective tissue (◀ p. 128) are exposed, platelets adhere tenaciously to the collagen fibers. A large plasma protein called *von Willebrand factor* stabilizes bound platelets by forming a bridge between collagen and platelets. Platelets become *activated*: They swell, form spiked processes, and become stickier. In addition, they release chemical messengers including the following:

- **Adenosine diphosphate (ADP)**—a potent aggregating agent that causes more platelets to stick to the area and release their contents
- **Serotonin** and **thromboxane A_2** (throm-boks′ān; a short-lived prostaglandin derivative)—messengers that enhance vascular spasm and platelet aggregation

As more platelets aggregate, they release more chemicals, aggregating more platelets, and so on, in a positive feedback cycle (◀ Figure 1.7, p. 12). Within one minute, a platelet plug is built up, further reducing blood loss. Platelets alone are sufficient for sealing the thousands of minute rips and holes that occur unnoticed as part of the daily wear and tear in your smallest blood vessels. Larger breaks, however, need additional reinforcement because platelet plugs are loosely knit.

Step 3: Coagulation

The third step, **coagulation** or **blood clotting**, reinforces the platelet plug with fibrin threads that act as a "molecular glue" for the aggregated platelets (Figure 17.13 ③). The resulting blood clot (fibrin mesh) is quite effective in sealing larger breaks in a blood vessel. Blood is transformed from a liquid to a gel when dissolved blood proteins assemble into fibrin threads. This multistep process involves a series of substances called **clotting factors**, or **procoagulants** (**Table 17.3** on p. 661).

Most clotting factors are plasma proteins synthesized by the liver. They are numbered I to XIII according to the order of their discovery; as a result, the numerical order does not reflect their reaction sequence. All (except tissue factor) normally circulate in blood in inactive form until mobilized. Although vitamin K is not directly involved in coagulation, this fat-soluble vitamin is required for synthesizing four of the clotting factors (Table 17.3).

The coagulation sequence shows how clotting factors work together to form a clot (**Figure 17.14**). This sequence will

look intimidating at first glance, but don't panic—two things will help you cope with its complexity. First, realize that in most cases, *activation turns clotting factors into enzymes* by clipping off a piece of the protein, causing it to change shape. Once one clotting factor is activated, it activates the next in sequence, and so on, in a cascade. (Two important exceptions to this generalization are fibrinogen and Ca^{2+}.)

The second strategy that will help you cope is to recognize that coagulation occurs in three phases. Each phase has a specific end point, as you will see next.

Phase 1: Two Pathways to Prothrombin Activator

Coagulation may be initiated by either the **intrinsic** or the **extrinsic pathway** (Figure 17.14). In the body, the same tissue-damaging events usually trigger both pathways. Before we examine how these pathways are different, let's see what they have in common.

Crucial components in both pathways are negatively charged membranes. In particular, activated platelets display negatively charged phosphatidylserine, once known as *PF3* (platelet factor 3). Many intermediates of both pathways can be activated only when on such phospholipid surfaces. The intermediate steps of each pathway *cascade* toward a common intermediate, factor X (Figure 17.14). Once factor X has been activated, it complexes with calcium ions and factor V on a phospholipid surface to form **prothrombin activator**. This is usually the slowest step of the blood clotting process, but once prothrombin activator is present, the clot forms in 10 to 15 seconds.

The intrinsic and extrinsic pathways usually work together and are interconnected in many ways, but there are significant differences between them. The *intrinsic pathway* is:

- Called *intrinsic* because the factors needed for clotting are present *within* (intrinsic to) the blood.
- Triggered by negatively charged surfaces such as activated platelets, collagen, or glass. (The negative charges on glass explain why this is the pathway that initiates clotting outside the body in test tubes.)
- Slower because it has many intermediate steps.

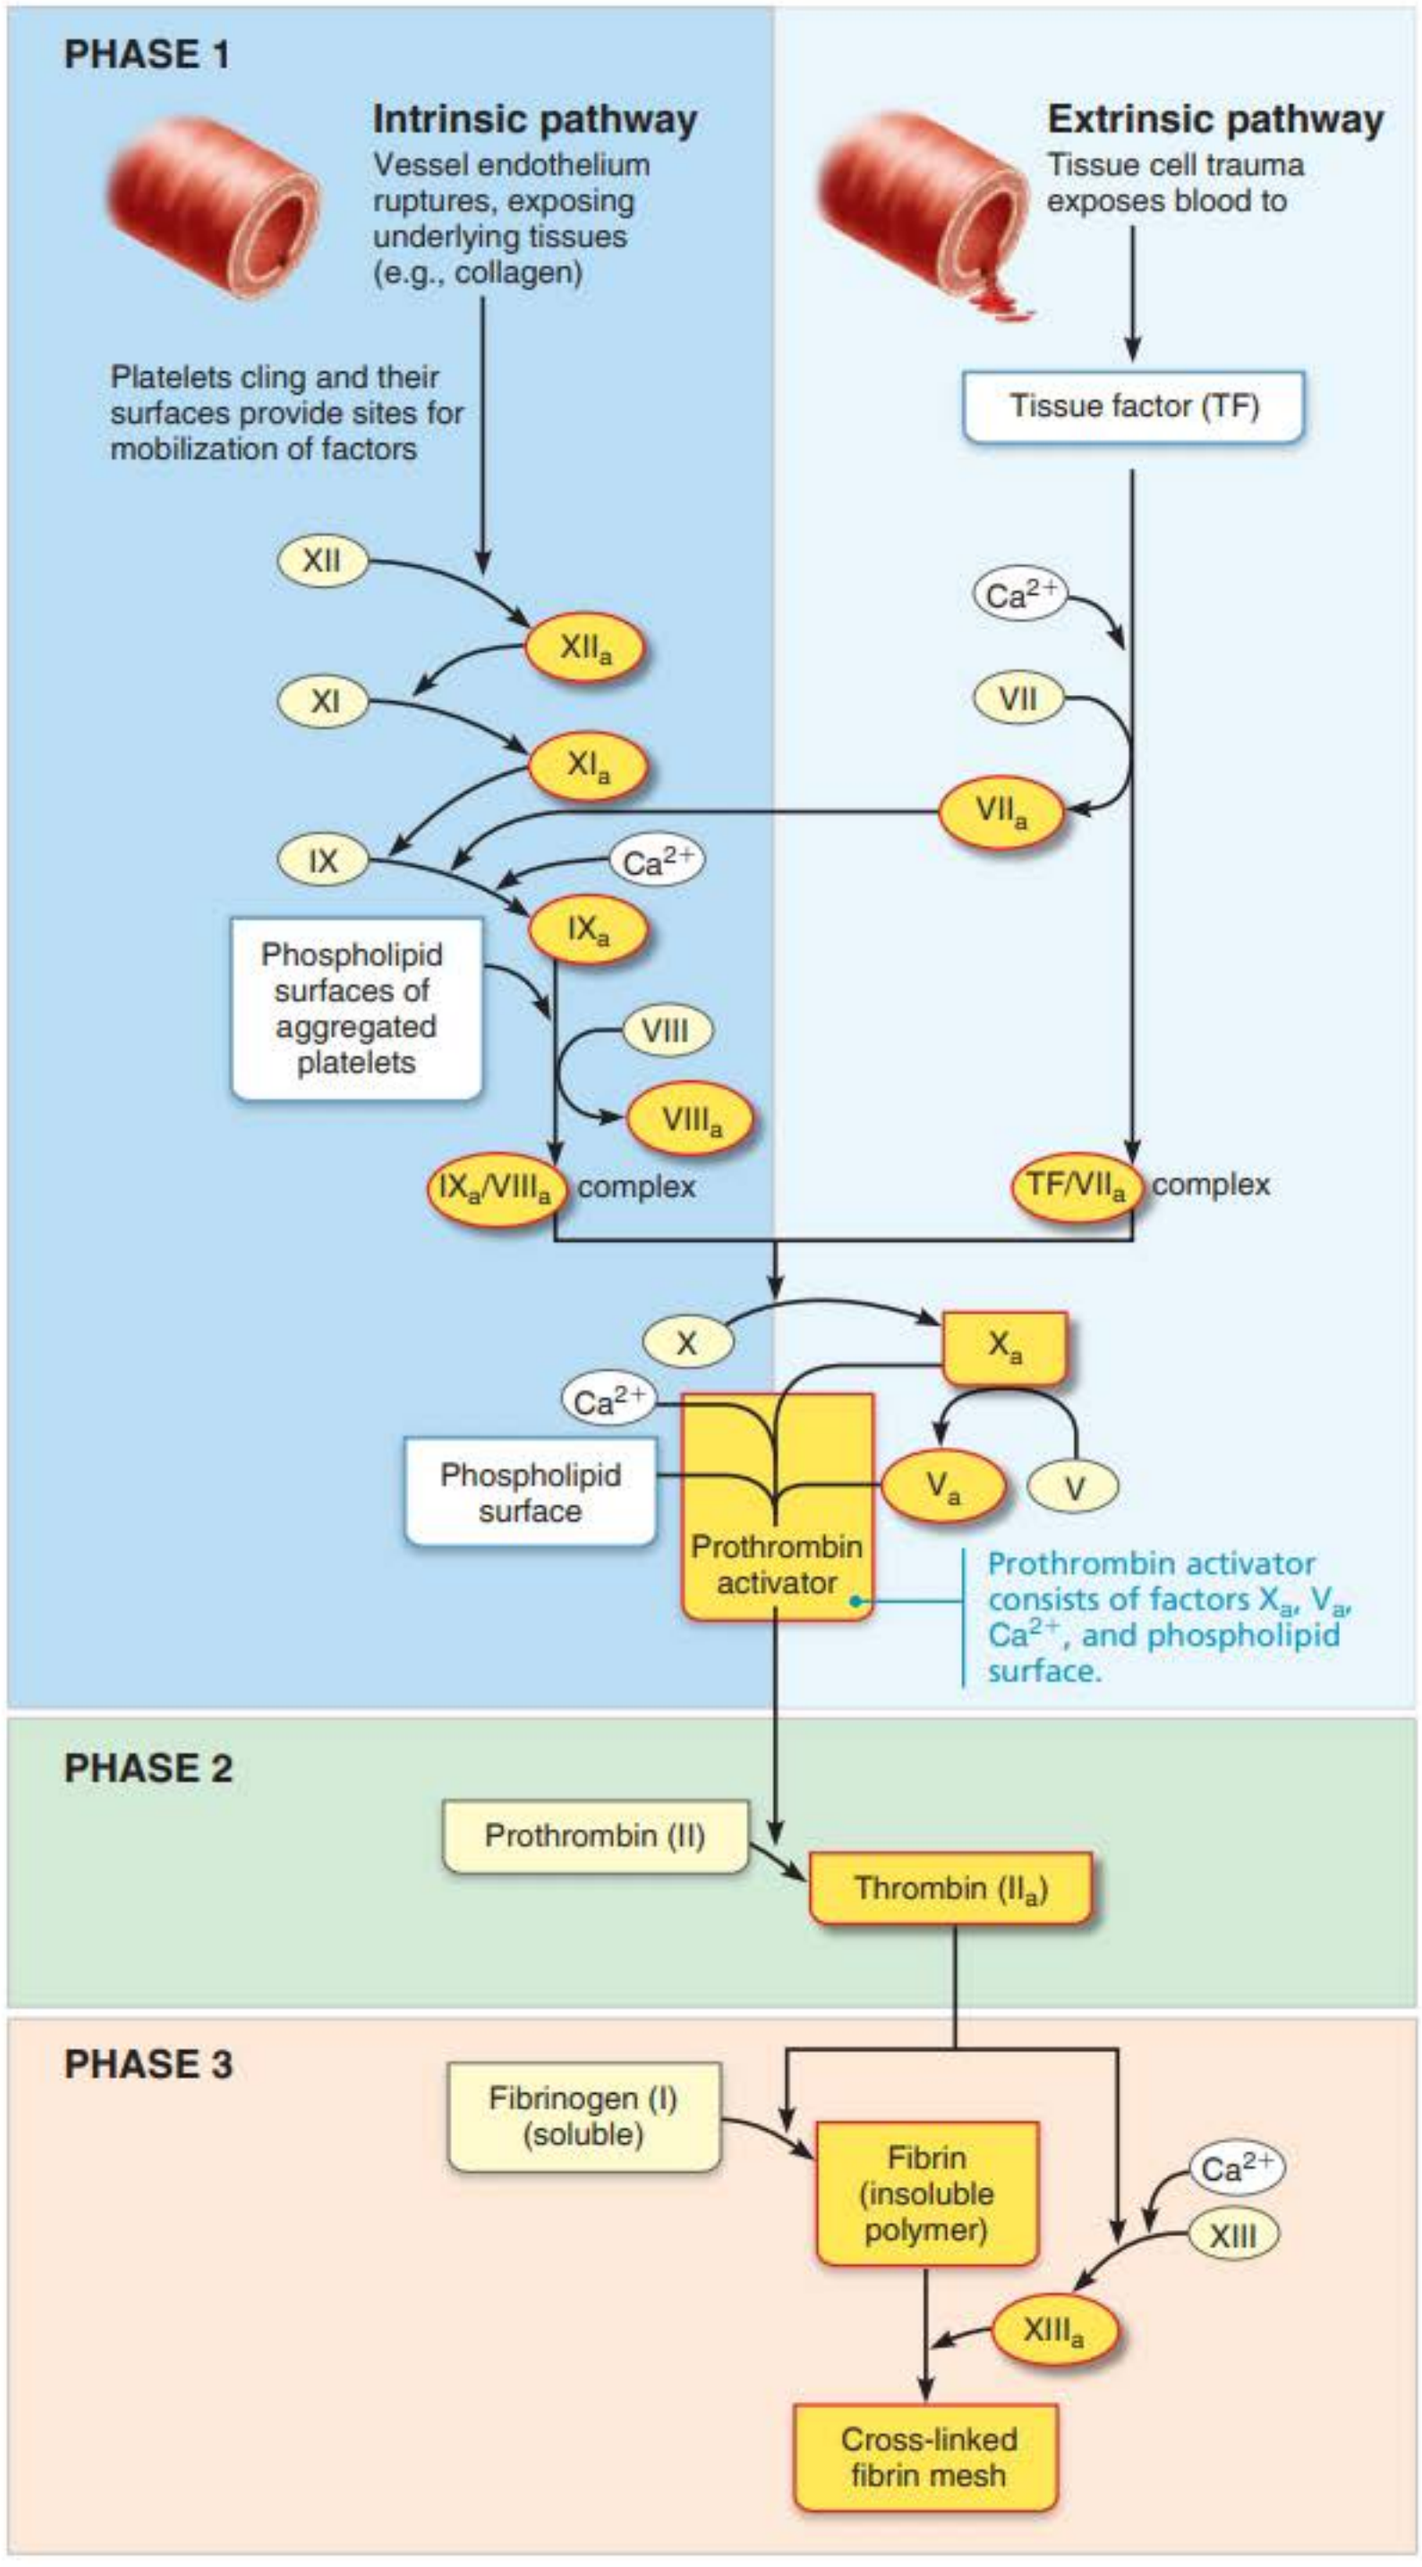

Figure 17.14 The intrinsic and extrinsic pathways of blood clotting (coagulation). The subscript "a" indicates the activated clotting factor (procoagulant).

The *extrinsic pathway* is:

- Called *extrinsic* because the tissue factor it requires is *outside* of blood.
- Triggered by exposing blood to a factor found on cells in tissues surrounding the blood vessel. This factor is called **tissue factor (TF)** or **factor III**.
- Faster because it bypasses several steps of the intrinsic pathway. In severe tissue trauma, it can form a clot in 15 seconds.

Phase 1 ends with the formation of a complex substance called *prothrombin activator*.

Phase 2: Common Pathway to Thrombin

Prothrombin activator catalyzes the conversion of a plasma protein called **prothrombin** into the active enzyme **thrombin**.

Phase 3: Common Pathway to the Fibrin Mesh

The end point of phase 3 is a *fibrin mesh* that traps blood cells and effectively seals the hole until the blood vessel can be permanently repaired. Thrombin catalyzes the transformation of the *soluble* clotting factor **fibrinogen** into **fibrin**. The fibrin molecules then polymerize (join together) to form long, hairlike, *insoluble* fibrin strands. (Notice that, unlike other clotting factors, activating fibrinogen does not convert it into an enzyme, but instead allows it to polymerize.) The fibrin strands glue the platelets together and make a web that forms the structural basis of the clot. Fibrin makes the liquid plasma become gel-like and traps formed elements that try to pass through it (**Figure 17.15**).

In the presence of calcium ions, thrombin also activates **factor XIII (fibrin stabilizing factor)**, a cross-linking enzyme that binds the fibrin strands tightly together, forming a fibrin mesh. Cross-linking further strengthens and stabilizes the clot, effectively sealing the hole until the blood vessel can be permanently repaired.

Role of Anticoagulants

Substances that inhibit clotting are called **anticoagulants**. Whether or not blood clots depends on a delicate balance between clotting factors and anticoagulants. Normally, anticoagulants dominate and prevent clotting, but when a vessel is ruptured, clotting factor activity in that area increases dramatically and a clot begins to form. Clot formation is normally complete within 3 to 6 minutes after blood vessel damage.

Clot Retraction and Fibrinolysis

Although the process of hemostasis is complete when the fibrin mesh is formed, there are still things that need to be done to stabilize the clot and then remove it when the injury is healed.

Clot Retraction

Within 30 to 60 minutes, a platelet-induced process called **clot retraction** further stabilizes the clot. Platelets contain contractile proteins (actin and myosin), and they contract in much the same manner as smooth muscle cells. As the platelets contract, they pull on the surrounding fibrin strands, squeezing **serum** (plasma minus the clotting proteins) from the mass, compacting the clot and drawing the ruptured edges of the blood vessel more closely together.

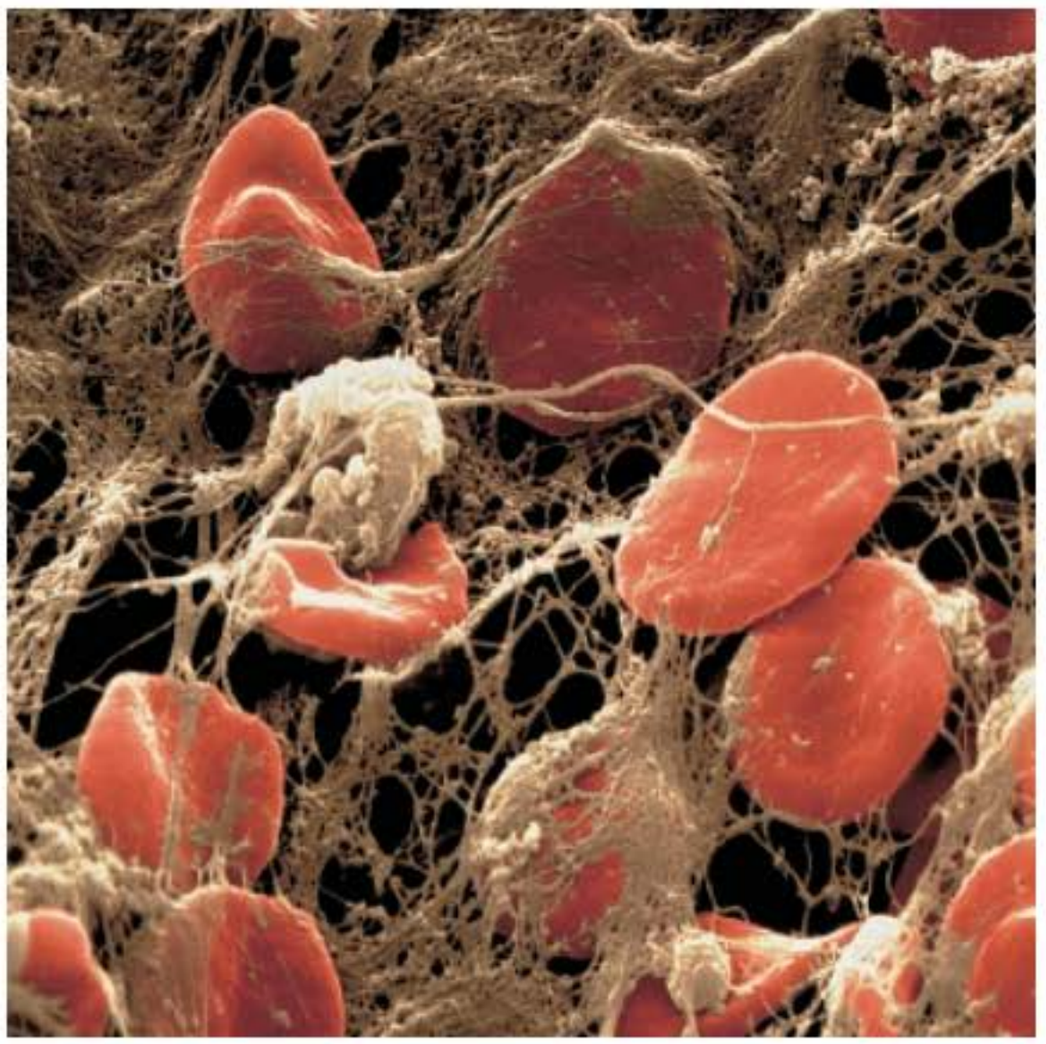

Figure 17.15 Scanning electron micrograph of erythrocytes trapped in a fibrin mesh. (2700×).

Even as clot retraction is occurring, the vessel is healing. **Platelet-derived growth factor (PDGF)** released by platelets stimulates smooth muscle cells and fibroblasts to divide and rebuild the vessel wall. As fibroblasts form a connective tissue patch in the injured area, endothelial cells, stimulated by vascular endothelial growth factor (VEGF), multiply and restore the endothelial lining.

Fibrinolysis

A clot is not a permanent solution to blood vessel injury, and a process called **fibrinolysis** removes unneeded clots when healing has occurred. This cleanup detail is crucial because small clots form continually in vessels throughout the body. Without fibrinolysis, blood vessels would gradually become completely blocked.

The critical natural "clot buster" is a fibrin-digesting enzyme called **plasmin**, which is produced when the plasma protein **plasminogen** is activated. Like a built-in self-destruction mechanism, plasminogen is incorporated into a forming clot, where it remains inactive until appropriate signals reach it. The presence of a clot in and around the blood vessel causes the endothelial cells to secrete **tissue plasminogen activator (tPA).** Activated factor XII and thrombin released during clotting also activate plasminogen. As a result, most plasmin activity is confined to the clot, and circulating enzymes quickly destroy any plasmin that strays into the plasma. Fibrinolysis begins within two days and continues slowly over several days until the clot finally dissolves.

Table 17.3 Blood Clotting Factors (Procoagulants)

FACTOR NUMBER	FACTOR NAME	NATURE	SOURCE	PATHWAY; FUNCTION
I	Fibrinogen	Plasma protein	Liver	Common pathway; converted to fibrin (insoluble weblike substance of clot)
II	Prothrombin	Plasma protein	Liver*	Common pathway; converted to thrombin (converts fibrinogen to fibrin)
III	Tissue factor (TF)	Plasma membrane glycoprotein	Tissue cells	Activates extrinsic pathway
IV	Calcium ions (Ca^{2+})	Inorganic ion	Plasma	Needed for essentially all stages of coagulation process; always present
V	Proaccelerin	Plasma protein	Liver, platelets	Common pathway
VI†				
VII	Proconvertin	Plasma protein	Liver*	Both extrinsic and intrinsic pathways
VIII	Antihemophilic factor (AHF)	Plasma protein	Liver, lung capillaries	Intrinsic pathway; deficiency results in hemophilia A
IX	Plasma thromboplastin component (PTC)	Plasma protein	Liver*	Intrinsic pathway; deficiency results in hemophilia B
X	Stuart factor	Plasma protein	Liver*	Common pathway
XI	Plasma thromboplastin antecedent (PTA)	Plasma protein	Liver	Intrinsic pathway; deficiency results in hemophilia C
XII	Hageman factor	Plasma protein; activated by negatively charged surfaces (e.g., glass)	Liver	Intrinsic pathway; activates plasmin; initiates clotting *in vitro*; activation initiates inflammation
XIII	Fibrin stabilizing factor (FSF)	Plasma protein	Liver, bone marrow	Cross-links fibrin, forming a strong, stable clot

*Synthesis requires vitamin K

†Number no longer used; substance now believed to be same as factor V

Factors Limiting Clot Growth or Formation

Factors Limiting Normal Clot Growth

Once the clotting cascade has begun, it continues until a clot forms. Normally, two homeostatic mechanisms prevent clots from becoming unnecessarily large: (1) swift removal of clotting factors, and (2) inhibition of activated clotting factors. For clotting to occur, the concentration of activated clotting factors must reach certain critical levels. Clots do not usually form in rapidly moving blood because the activated clotting factors are washed away and diluted. (This is why vasoconstriction is so important to assist clot formation and also why you apply pressure to a wound to slow bleeding.) For the same reasons, a clot stops growing when it contacts blood flowing normally.

Other mechanisms block the final step in which fibrinogen is polymerized into fibrin. They work by restricting thrombin to the clot or by inactivating it if it escapes into the general circulation. As a clot forms, almost all of the thrombin produced is bound onto the fibrin threads. This is an important safeguard because thrombin also exerts positive feedback effects on the coagulation process prior to the common pathway. Not only does it speed up the production of prothrombin activator by acting indirectly through factor V, but it also accelerates the earliest steps of the intrinsic pathway by activating platelets. By binding thrombin, fibrin effectively acts as an anticoagulant, preventing the clot from enlarging and thrombin from acting elsewhere.

Antithrombin III, a protein present in plasma, quickly inactivates any thrombin not bound to fibrin. Antithrombin III and **protein C**, another protein produced in the liver, also inhibit the activity of other intrinsic pathway clotting factors.

Heparin, the natural anticoagulant contained in basophil and mast cell granules, is also found on the surface of endothelial cells. It inhibits thrombin by enhancing the activity of antithrombin III. Like most other clotting inhibitors, heparin also inhibits the intrinsic pathway.

Factors Preventing Undesirable Clotting

As long as the endothelium is smooth and intact, platelets are prevented from clinging and piling up. Also, antithrombic substances—nitric oxide, prostacyclin, and others—secreted by the endothelial cells normally prevent platelet adhesion.

Disorders of Hemostasis CLINICAL

Blood clotting is one of nature's most elegant creations, but it sometimes goes awry. The two major disorders of hemostasis are at opposite poles. **Thromboembolic disorders** result from

conditions that cause undesirable clot formation. **Bleeding disorders** arise from abnormalities that prevent normal clot formation. **Disseminated intravascular coagulation (DIC)**, which has characteristics of both types of disorder, involves both widespread clotting and severe bleeding.

Thromboembolic Disorders

Despite the body's many safeguards, undesirable intravascular clotting sometimes occurs.

Thrombi and Emboli A clot that develops and persists in an *unbroken* blood vessel is called a **thrombus**. If the thrombus is large enough, it may block circulation to the cells beyond the blockage and lead to death of those tissues. For example, if the blockage occurs in the coronary circulation of the heart (coronary thrombosis), the consequences may be death of heart muscle and a fatal heart attack.

If the thrombus breaks away from the vessel wall and floats freely in the bloodstream, it becomes an **embolus** (plural: *emboli*). An embolus ("wedge") is usually no problem until it encounters a blood vessel too narrow for it to pass through. Then it becomes an **embolism**, obstructing the vessel. For example, emboli that become trapped in the lungs (pulmonary embolisms) dangerously impair the body's ability to obtain oxygen. A cerebral embolism may cause a stroke.

Conditions that roughen the vessel endothelium, such as atherosclerosis or inflammation, cause thromboembolic disease by allowing platelets to gain a foothold. Slowly flowing blood or blood stasis is another risk factor, particularly in bedridden patients and those taking a long flight without moving around. In this case, clotting factors are not washed away as usual and accumulate, allowing clots to form.

Anticoagulant Drugs A number of drugs—most importantly aspirin, heparin, and warfarin—are used clinically to prevent undesirable clotting.

- *Aspirin.* **Aspirin** is an antiprostaglandin drug that inhibits thromboxane A_2 formation (blocking platelet aggregation and platelet plug formation). Clinical studies of men taking low-dose aspirin over several years demonstrated a 50% reduction in incidence of heart attack.
- *Heparin.* Heparin, administered in injectable form, is the anticoagulant most used in the hospital (for heart patients undergoing various procedures and to prevent or treat venous thrombosis).
- *Warfarin and direct oral anticoagulants.* **Warfarin** and *direct oral anticoagulants* are mainstays of outpatient treatment to reduce the risk of stroke in those prone to atrial fibrillation, a condition in which blood pools in the heart. Warfarin interferes with the action of vitamin K in the production of some clotting factors (see Impaired Liver Function below). Because treatment with warfarin is difficult to manage, the introduction of direct oral anticoagulants using other mechanisms has been welcomed.

A Closer Look in Chapter 19 (p. 760) describes another drug that dissolves blood clots (tPA; see also p. 660) and innovative medical techniques for treating clots.

Bleeding Disorders

Anything that interferes with the clotting mechanism can result in abnormal bleeding. The most common causes are platelet deficiency (thrombocytopenia) and deficits of some clotting factors, which can result from impaired liver function or genetic conditions such as hemophilia.

Thrombocytopenia **Thrombocytopenia** (throm″bo-si″to-pe′ne-ah) is characterized by a low number of circulating platelets (less than 150,000/μl of blood). In severe cases, it causes spontaneous bleeding from small blood vessels all over the body. Even normal movement leads to widespread hemorrhage, evidenced by many small purplish spots, called *petechiae* (pe-te′ke-e), on the skin (**Figure 17.16**).

Thrombocytopenia can arise from any condition that suppresses or destroys the red bone marrow, such as bone marrow malignancy, exposure to ionizing radiation, or certain drugs. Transfusions of concentrated platelets provide temporary relief from bleeding.

Impaired Liver Function When the liver is unable to synthesize its usual supply of clotting factors, abnormal and often severe bleeding occurs. The causes can range from an easily resolved vitamin K deficiency (common in newborns) to nearly total impairment of liver function (as in hepatitis or cirrhosis).

Liver cells require vitamin K to produce clotting factors. Although intestinal bacteria make some vitamin K, we obtain most of it from vegetables in our diet and dietary deficiencies are rarely a problem. However, vitamin K deficiency can occur if fat absorption is impaired, because vitamin K is a fat-soluble vitamin that is absorbed into the blood along with fats. In liver disease, the nonfunctional liver cells fail to produce not only the clotting factors, but also bile that is required to absorb fat and vitamin K.

Hemophilias The term **hemophilia** refers to several hereditary bleeding disorders that have similar signs and symptoms.

- *Hemophilia A* results from a deficiency of **factor VIII (antihemophilic factor)**. It accounts for 77% of cases.

Figure 17.16 Petechiae. Thrombocytopenia causes small, round dots called petechiae to appear. These are the result of everyday capillary damage that would ordinarily be plugged by platelets.

- *Hemophilia B* results from a deficiency of factor IX.
- *Hemophilia C*, a less severe form seen in both sexes, is due to a lack of factor XI.

Hemophilia A and B occur primarily in males (they are X-linked genetic conditions, discussed in Chapter 29). The relative mildness of hemophilia C reflects the fact that the clotting factor (factor IX) that the missing factor XI activates can also be activated by factor VII (see Figure 17.14).

Symptoms of hemophilia begin early in life. Even minor tissue trauma causes prolonged and potentially life-threatening bleeding into tissues. Commonly, the person's joints become seriously disabled and painful because of repeated bleeding into the joint cavities after exercise or trauma. Hemophilias are managed clinically by transfusions of fresh plasma or injections of the appropriate purified clotting factor. These therapies provide relief for several days but are expensive and inconvenient.

In addition, dependence on transfusions or injections has caused other problems. In the past, many hemophilia patients became infected by the hepatitis virus and, beginning in the early 1980s, by HIV, a blood-transmitted virus that depresses the immune system and causes AIDS (see Chapter 21). New infections are now avoided due to the availability of genetically engineered clotting factors, hepatitis vaccines, and new testing methods for HIV.

Disseminated Intravascular Coagulation (DIC)

DIC involves both widespread clotting and severe bleeding. Clotting occurs in intact blood vessels and the residual blood becomes unable to clot. Blockage of blood flow accompanied by severe bleeding follows. DIC most commonly happens as a complication of pregnancy or a result of septicemia or incompatible blood transfusions.

17.7 Transfusion can replace lost blood

CLINICAL

Learning Outcomes

- **Describe the ABO and Rh blood groups. Explain the basis of transfusion reactions.**
- **Describe fluids used to replace blood volume and the circumstances for their use.**

The human cardiovascular system minimizes the effects of blood loss by (1) reducing the volume of the affected blood vessels, and (2) stepping up production of red blood cells. However, the body can compensate for only so much blood loss. Losing 15–30% causes pallor and weakness. Losing more than 30% of blood volume results in severe shock, which can be fatal.

Restoring Blood Volume

When a patient's blood volume is so low that death from shock is imminent, there may not be time to type blood (see below), or appropriate whole blood may be unavailable. Such emergencies demand that blood *volume* be replaced immediately to restore adequate circulation.

Fundamentally, blood consists of proteins and cells suspended in a salt solution. Replacing lost blood volume essentially consists of replacing that isotonic salt solution. *Normal saline* or a *multiple electrolyte solution* that mimics the electrolyte composition of plasma (for example, *Ringer's solution*) are the preferred choices.

Volume replacement restores adequate circulation but cannot, of course, replace the oxygen-carrying capacity of the lost red blood cells. To date, only transfusion of red blood cells can do that (see below), but research on ways to replace that capability by using artificial blood substitutes is ongoing.

Transfusing Red Blood Cells

Whole blood transfusions are rarely used—only when blood loss is rapid and substantial. In all other cases, infusions of **packed red blood cells** (**PRBCs**; whole blood from which most of the plasma and leukocytes have been removed) are preferred for restoring oxygen-carrying capacity. The usual blood bank procedure involves collecting blood from a donor and mixing it with an anticoagulant that prevents clotting by binding calcium ions. The shelf life of collected blood is about 35 days. Because blood is such a valuable commodity, it is most often separated into its component parts so that each component can be used when and where it is needed.

Human Blood Groups

People have different blood types, and transfusion of incompatible blood can be fatal. RBC plasma membranes, like those of all body cells, bear highly specific molecular markers at their external surfaces, which identify each of us as unique from all others. These glycoprotein and glycolipid markers are called *antigens*. An antigen is anything the body perceives as foreign and that generates an immune response. Examples are toxins and molecules on the surfaces of bacteria, viruses, and cancer cells—and mismatched RBCs.

One person's RBC antigens may be recognized as foreign if transfused into someone with a different red blood cell type, and the transfused cells may be agglutinated (clumped together) and destroyed. Since these RBC antigens promote agglutination, they are more specifically called **agglutinogens** (ag″loo-tin′o-jenz).

Table 17.4 ABO Blood Groups

BLOOD GROUP	RBC ANTIGENS (AGGLUTINOGENS)	PLASMA ANTIBODIES (AGGLUTININS)		BLOOD THAT CAN BE RECEIVED	FREQUENCY (% OF U.S. POPULATION) WHITE	BLACK	ASIAN	HISPANIC	NATIVE AMERICAN
AB	A B	None		A, B, AB, O "Universal recipient"	4	4	7	2	<1
B	B	Anti-A (a)		B, O	11	19	25	10	4
A	A	Anti-B (b)		A, O	40	26	28	31	16
O	None	Anti-A (a) Anti-B (b)		O "Universal donor"	45	51	40	57	79

At least 30 groups of naturally occurring RBC antigens (blood groups) are found in humans, and many variants occur in individual families ("private antigens") rather than in the general population. The presence or absence of various antigens allows a person's blood cells to be classified into each of these different blood groups. Antigens determining the ABO and Rh blood groups cause vigorous transfusion reactions (in which the foreign erythrocytes are destroyed) when they are improperly transfused. For this reason, blood typing for these antigens is always done before blood is transfused.

Other antigens (such as those in the MNS, Duffy, Kell, and Lewis groups) are mainly of legal or academic importance. Because these factors rarely cause transfusion reactions, blood is not specifically typed for them unless the person is expected to need several transfusions, in which case reactions are more likely to occur. Here we describe only the ABO and Rh blood groups.

ABO Blood Groups The **ABO blood groups** are based on the presence or absence of two agglutinogens, type A and type B (**Table 17.4**). Depending on which of these a person inherits, his or her ABO blood group will be one of the following: A, B, AB, or O. The O blood group, which has neither agglutinogen, is the most common ABO group in North America. AB, with both antigens, is least prevalent. The presence of either the A or the B agglutinogen results in group A or B, respectively.

Unique to the ABO blood groups is the presence in the plasma of *preformed antibodies* called **agglutinins**. The agglutinins act against RBCs carrying ABO antigens that are *not* present on a person's own red blood cells. A newborn lacks these antibodies, but they begin to appear in the plasma within two months and reach adult levels between 8 and 10 years of age. As indicated in Table 17.4, a person with neither the A nor the B antigen (group O) possesses both anti-A and anti-B antibodies, also called *a* and *b agglutinins* respectively. Those with group A blood have anti-B antibodies, while those with group B have anti-A antibodies. AB individuals have neither antibody.

Rh Blood Groups There are 52 named Rh agglutinogens, each of which is called an **Rh factor**. Only five of these, the C, D, E, c, and e antigens, are fairly common. The Rh blood typing system is so named because one Rh antigen (agglutinogen D) was originally identified in *rhesus* macaques. Later, the same antigen was discovered in humans.

About 85% of Americans are Rh^+ (Rh positive), meaning that their RBCs carry the D antigen. The remaining 15% of individuals do not carry the D antigen and so are Rh^- (Rh negative). As a rule, a person's ABO and Rh blood groups are reported together, for example, O^+, A^-, and so on.

Unlike the ABO system antibodies, anti-Rh antibodies do not spontaneously form in the blood of Rh^- individuals. However, if an Rh^- person receives Rh^+ blood, the immune system becomes sensitized and begins producing anti-Rh antibodies against the foreign antigen soon after the transfusion. Hemolysis does not occur after the first such transfusion because it takes time for the body to react and start making antibodies. But the second time, and every time thereafter, a typical transfusion reaction occurs in which the recipient's antibodies attack and rupture the donor RBCs.

HOMEOSTATIC IMBALANCE 17.3 CLINICAL

An important problem related to the Rh factor occurs in pregnant Rh^- women who are carrying Rh^+ babies. The first such pregnancy usually results in the delivery of a healthy baby. But during this pregnancy and particularly during delivery, the mother may be sensitized by her baby's Rh^+ antigens that pass into her bloodstream. If so, she will form anti-Rh antibodies unless treated with RhoGAM during pregnancy and around the time of delivery. (The same precautions are taken in women who have miscarried or aborted the fetus.) RhoGAM is a serum containing anti-Rh antibodies. By agglutinating the Rh factor, it blocks the mother's immune response and prevents her sensitization.

If the mother is not treated and becomes pregnant again with an Rh^+ baby, her antibodies will cross through the placenta and destroy the baby's RBCs, producing a condition known as **hemolytic disease of the newborn**, or **erythroblastosis fetalis**. The baby becomes anemic and hypoxic. In severe cases, brain damage and even death may result unless transfusions are done *before* birth to provide the fetus with more erythrocytes for oxygen transport. Additionally, one or two *exchange transfusions* (see Related Clinical Terms, p. 666) are done after birth. The baby's Rh^+ blood is removed, and Rh^- blood is infused. Within six weeks, the transfused Rh^- erythrocytes have been broken down and replaced with the baby's own Rh^+ cells.

Transfusion Reactions

When mismatched blood is infused, a **transfusion reaction** occurs in which the recipient's plasma antibodies attack the donor's red blood cells. (Note that the donor's plasma antibodies may also agglutinate the recipient's RBCs, but these antibodies are so diluted in the recipient's circulation that this does not usually present a problem.)

The initial event, agglutination of the foreign red blood cells, clogs small blood vessels throughout the body. During the next few hours, the clumped red blood cells begin to rupture or are destroyed by phagocytes, and their hemoglobin is released into the bloodstream. When the transfusion reaction is exceptionally severe, the RBCs are lysed almost immediately.

These events lead to two easily recognized problems: (1) The transfused blood cells cannot transport oxygen, and (2) the clumped red blood cells in small vessels hinder blood flow to tissues beyond those points. Less apparent, but more devastating, is the consequence of hemoglobin that escapes into the bloodstream. Circulating hemoglobin passes freely into the kidney tubules, causing cell death and kidney shutdown. If shutdown is complete (acute renal failure), the recipient may die.

Transfusion reactions can also cause fever, chills, low blood pressure, rapid heartbeat, nausea, vomiting, and general toxicity, but in the absence of kidney shutdown, these reactions are rarely lethal. Treatment of transfusion reactions focuses on preventing kidney damage by administering fluid and diuretics to increase urine output, diluting and washing out the hemoglobin.

As indicated in Table 17.4, group O red blood cells bear neither the A nor the B antigen, so theoretically group O is the **universal donor**. Indeed, some laboratories are developing methods to enzymatically clip off the sugar molecules that specifiy A or B blood type, converting the blood to type O. Since group AB plasma is devoid of antibodies to both A and B antigens, group AB people are theoretically **universal recipients** and can receive blood transfusions from any of the ABO groups. However, these classifications are misleading, because they do not take into account the other agglutinogens in blood that can trigger transfusion reactions.

The risk of transfusion reactions and transmission of life-threatening infections (particularly with HIV) from pooled blood transfusions has increased public interest in **autologous transfusions** (*auto* = self). In autologous transfusions, the patient *predonates* his or her own blood, and it is stored and immediately available if needed during surgery.

Blood Typing

It is crucial to determine the blood group of both the donor and the recipient *before* blood is transfused. **Figure 17.17** briefly outlines the general procedure for determining ABO blood type. Because it is so critical that blood groups be compatible, cross matching is also done. *Cross matching* tests whether the recipient's serum will agglutinate the donor's RBCs or the donor's serum will agglutinate the recipient's

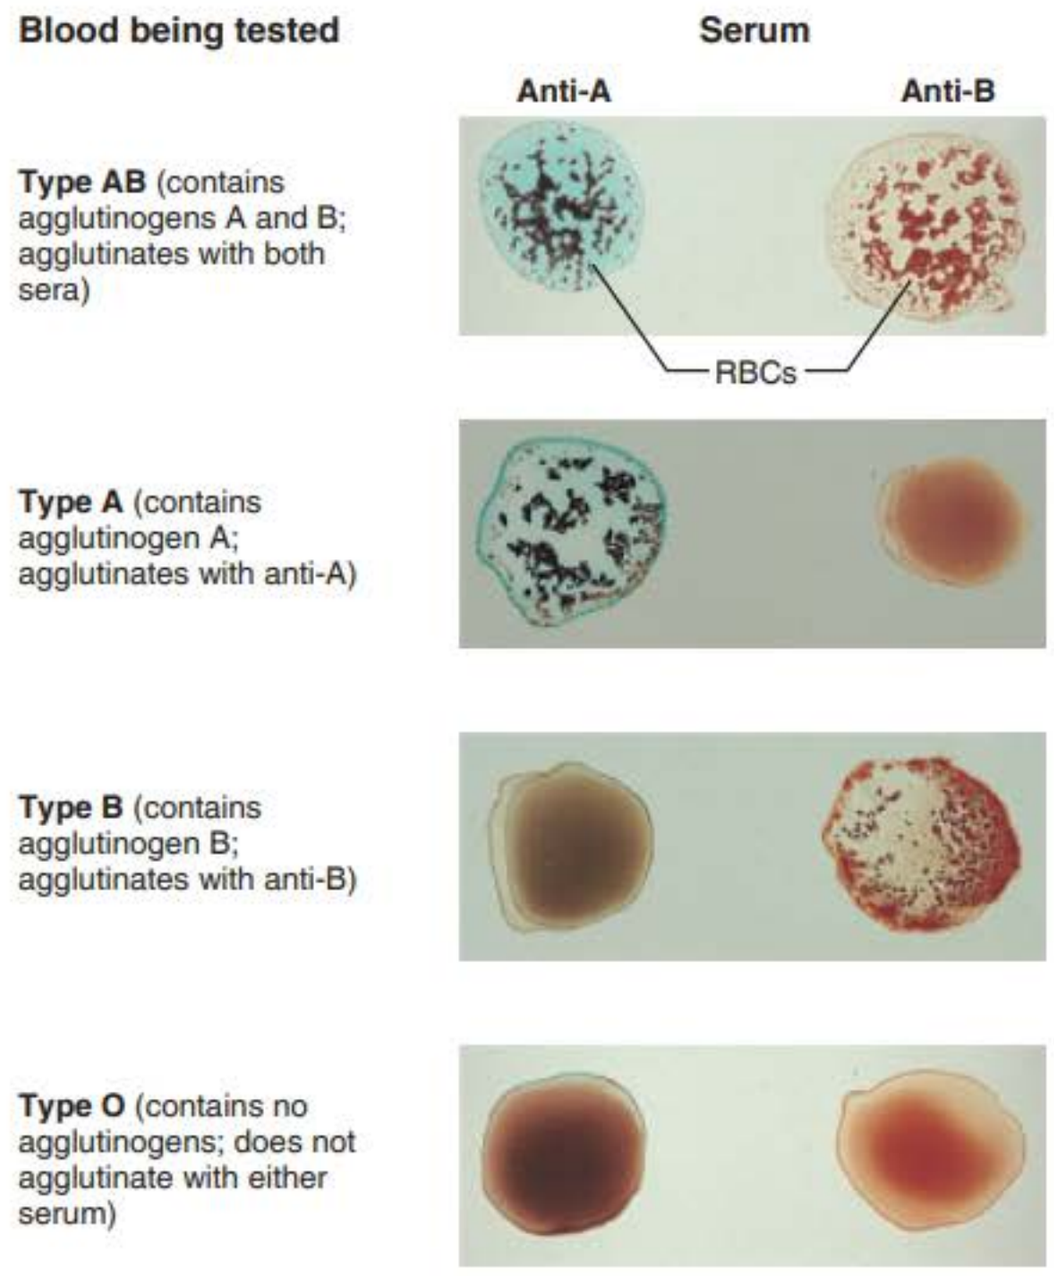

Figure 17.17 Blood typing of ABO blood types. When serum containing anti-A or anti-B agglutinins is added to a blood sample diluted with saline, agglutination will occur between the agglutinin and the corresponding agglutinogen (A or B).

RBCs. Typing for Rh factors is done in the same manner as ABO blood typing.

Check Your Understanding

13. Nigel is told he has type A blood. Which ABO antibodies does he have in his plasma? Which agglutinogens are on his RBCs? Could he donate blood to an AB recipient? Could he receive blood from an AB donor? Explain.

14. DRAW Draw a red blood cell. Show and label the location of the antigens (agglutinogens) that must be present in a person with type B^+ blood. Also show the type of antibodies (agglutinins) that would be present in the plasma.

For answers, see Answers Appendix.

17.8 Blood tests give insights into a patient's health

Learning Outcome

▶ **Explain the diagnostic importance of blood testing.**

A laboratory examination of blood yields information that can be used to evaluate a person's health. For example, in some anemias, the blood is pale and has a low hematocrit. A high fat content (*lipidemia*) gives blood plasma a yellowish hue and forecasts problems in those with heart disease. Blood glucose tests indicate how well a diabetic is controlling diet and blood sugar levels. Leukocytosis signals infections; severe infections yield larger-than-normal buffy coats in the hematocrit.

Microscopic studies of blood can reveal variations in the size and shape of erythrocytes that indicate iron deficiency or pernicious anemia. A **differential white blood cell count**, which determines the relative proportions of individual leukocyte types, is a valuable diagnostic tool. For example, a high eosinophil count may indicate a parasitic infection or an allergic response somewhere in the body.

A number of tests provide information on the status of the hemostasis system. For example, clinicians determine the **prothrombin time** to assess the ability of blood to clot, or do a **platelet count** when thrombocytopenia is suspected.

Two batteries of tests—a **CMP (comprehensive metabolic panel)** and a **complete blood count (CBC)**—are routinely ordered during physical examinations and before hospital admissions. CMP is a blood *chemistry* profile that measures various electrolytes, glucose, and markers of liver and kidney disorders. The CBC includes counts of the different types of formed elements, the hematocrit, measurements of hemoglobin content, and size of RBCs. Together these tests provide a comprehensive picture of a person's general health in relation to normal blood values.

Appendix F lists normal values for selected blood tests.

Check Your Understanding

15. PREDICT Emily Wong, 17, is brought to the ER with a fever, headache, and stiff neck. You suspect bacterial meningitis. Would you expect to see an elevated neutrophil count in a differential WBC count? Explain.

For answers, see Answers Appendix.

Developmental Aspects of Blood

Early in fetal development, blood cells form at many sites—the fetal yolk sac, liver, and spleen, among others—but by the seventh month, the red marrow has become the primary hematopoietic area and remains so (barring serious illness) throughout life. If there is a severe need for blood cell production, however, the liver and spleen may resume their fetal blood-forming roles. Additionally, inactive yellow bone marrow regions (essentially fatty tissue) may revert to active red marrow.

Blood cells develop from collections of mesenchymal cells, called *blood islands*, derived from the mesoderm germ layer. The fetus forms a unique hemoglobin, **hemoglobin F**, that has a higher affinity for oxygen than does adult hemoglobin (hemoglobin A) so that the fetus can effectively transfer oxygen from the mother to itself. It contains two alpha and two gamma (γ) polypeptide chains per globin molecule, instead of the paired alpha and beta chains typical of hemoglobin A. After birth, the liver rapidly destroys fetal erythrocytes carrying hemoglobin F, and the baby's erythroblasts begin producing hemoglobin A.

The most common blood diseases that appear during aging are chronic leukemias, anemias, and clotting disorders. However, these and most other age-related blood disorders are usually precipitated by disorders of the heart, blood vessels, or immune system. For example, the increased incidence of leukemias in old age is believed to result from the waning efficiency of the immune system, and abnormal thrombus and embolus formation reflects atherosclerosis, which roughens the blood vessel walls.

RELATED CLINICAL TERMS

Blood chemistry tests Chemical analysis of substances in the blood, e.g., glucose, iron, calcium, protein, bilirubin, and pH.

Blood fraction Any one of the components of whole blood that has been separated out from the other blood components, such as platelets or clotting factors.

Bone marrow biopsy A sample of red bone marrow is obtained by needle aspiration (typically from the anterior or posterior iliac crest) and examined to diagnose disorders of blood-cell formation, leukemia, various marrow infections, and anemias resulting from damage to or failure of the marrow.

Exchange transfusion A technique of removing the patient's blood and infusing donor blood until a large fraction of the patient's blood has been replaced; used to treat fetal blood incompatibilities and poisoning victims.

Hematology (hem″ah-tol′o-je) Study of blood.

Hematoma (hem″ah-to′mah) Accumulated, clotted blood in the tissues usually resulting from injury; visible as "black and blue" marks or bruises; eventually absorbed naturally unless infections develop.

Hemochromatosis (he″mo-kro″mah-to′sis) An inherited disorder of iron overload in which the intestine absorbs too much iron from the diet. The iron builds up in body tissues, where it oxidizes to form compounds that poison those organs (especially joints, liver, and pancreas).

Myeloproliferative disorder All-inclusive term for a group of proliferative disorders (disorders in which normal cell division controls are lost) including leukoerythroblastic anemia involving fibrosis of the bone marrow, polycythemia vera, and leukemia.

Plasmapheresis (plaz″mah-fĕ-re′sis) A process in which blood is removed, its plasma is separated from formed elements, and the formed elements are returned to the patient or donor. The most important application is removal of antibodies or immune complexes from the blood of individuals with autoimmune disorders (multiple sclerosis, myasthenia gravis, and others). Also used by blood banks to collect plasma for burn victims and to obtain plasma components for therapeutic use.

Septicemia (sep″tĭ-se′me-ah; *septos* = rotten) Excessive and harmful levels of bacteria or their toxins in the blood. Also called blood poisoning.

CHAPTER SUMMARY

17.1 The functions of blood are transport, regulation, and protection (p. 643)

1. Transport functions include delivering oxygen and nutrients to body tissues, removing metabolic wastes, and transporting hormones.
2. Regulation functions include maintaining body temperature, constant blood pH, and adequate fluid volume.
3. Protective functions include hemostasis and prevention of infection.

17.2 Blood consists of plasma and formed elements (pp. 643–645)

1. Blood is composed of formed elements and plasma. The hematocrit is a measure of one formed element, erythrocytes, as a percentage of total blood volume.
2. Blood is a viscous, slightly alkaline fluid representing about 8% of total body weight. Blood volume of a normal adult is about 5 L.
3. Plasma is a straw-colored, viscous fluid and is 90% water. The remaining 10% is solutes, such as nutrients, respiratory gases, electrolytes, hormones, and proteins. Plasma makes up 55% of whole blood.
4. Plasma proteins, most made by the liver, include albumin, globulins, and fibrinogen. Albumin is the most important contributor to the osmotic pressure of blood and carries certain molecules through the blood.
5. Formed elements, accounting for 45% of whole blood, are erythrocytes, leukocytes, and platelets. All formed elements arise from hematopoietic stem cells in red bone marrow.

17.3 Erythrocytes play a crucial role in oxygen and carbon dioxide transport (pp. 645–651)

1. Erythrocytes (red blood cells, RBCs) are small, biconcave cells containing large amounts of hemoglobin. They have no nucleus and few organelles. Spectrin allows the cells to change shape as they pass through tiny capillaries.
2. Oxygen transport is the major function of erythrocytes. In the lungs, oxygen binds to iron atoms in hemoglobin molecules, producing oxyhemoglobin. In body tissues, oxygen dissociates from iron, producing deoxyhemoglobin.
3. Red blood cells begin as hematopoietic stem cells and, through erythropoiesis, proceed from the proerythroblast (committed cell) stage to the basophilic, polychromatic and orthochromatic erythroblast, and reticulocyte stages. During this process, hemoglobin accumulates and the organelles and nucleus are extruded. Differentiation of reticulocytes is completed in the bloodstream.
4. Erythropoietin and testosterone enhance erythropoiesis.
5. Iron, vitamin B_{12}, and folic acid are essential for production of hemoglobin.
6. Red blood cells have a life span of approximately 120 days. Macrophages of the spleen and liver remove old and damaged erythrocytes from the circulation. Released iron from hemoglobin is stored as ferritin or hemosiderin to be reused. The balance of the heme group is degraded to bilirubin and secreted in bile. Amino acids of globin are metabolized or recycled.
7. Erythrocyte disorders include anemia and polycythemia.

17.4 Leukocytes defend the body (pp. 651–656)

1. Leukocytes are white blood cells (WBCs). All are nucleated, and all have crucial roles in defending against disease. Two main categories exist: granulocytes and agranulocytes.
2. Granulocytes include neutrophils, eosinophils, and basophils. Neutrophils are active phagocytes. Eosinophils attack parasitic worms, and their numbers increase during allergic reactions. Basophils contain histamine, which promotes vasodilation and enhances migration of leukocytes to inflammatory sites.
3. Agranulocytes have crucial roles in immunity. They include lymphocytes—the "immune cells"—and monocytes, which differentiate into macrophages.
4. Leukopoiesis is directed by colony-stimulating factors and interleukins released by supporting cells of the red bone marrow and mature WBCs.
5. Leukocyte disorders include leukemias and infectious mononucleosis.

17.5 Platelets are cell fragments that help stop bleeding (p. 657)

1. Platelets are fragments of large megakaryocytes formed in red marrow. When a blood vessel is damaged, platelets form a plug to help prevent blood loss and play a central role in the clotting cascade.

17.6 Hemostasis prevents blood loss (pp. 657–663)

1. Hemostasis is prevention of blood loss. The three major steps of hemostasis are vascular spasm, platelet plug formation, and blood coagulation.
2. Spasms of smooth muscle in blood vessel walls and accumulation of platelets (platelet plug) at the site of vessel injury stop or slow down blood loss temporarily until coagulation occurs.
3. Coagulation of blood may be initiated by either the intrinsic or the extrinsic pathway. Platelet phospholipid membranes are crucial to both pathways. Tissue factor (factor III) exposed by tissue injury allows the extrinsic pathway to bypass many steps

of the intrinsic pathway. A series of activated clotting factors oversees the intermediate steps of each cascade. The pathways converge as prothrombin is converted to thrombin.

4. After a clot is formed, clot retraction occurs. Serum is squeezed out and the ruptured vessel edges are drawn together. Smooth muscle, connective tissue, and endothelial cell proliferation and migration repair the injured blood vessel.
5. When healing is complete, clot digestion (fibrinolysis) occurs.
6. Abnormal expansion of clots is prevented by removal of coagulation factors in contact with rapidly flowing blood and by inhibition of activated blood factors. Prostacyclin (PGI_2) and nitric oxide secreted by the endothelial cells help prevent undesirable (unnecessary) clotting.
7. Thromboembolic disorders involve undesirable clot formation, which can block vessels.
8. Thrombocytopenia, a deficit of platelets, causes spontaneous bleeding from small blood vessels. Hemophilia is caused by a genetic deficiency of certain coagulation factors. Liver disease can also cause bleeding disorders because many coagulation proteins are formed by the liver.
9. Disseminated intravascular coagulation (DIC) is a condition of bodywide clotting in undamaged blood vessels and subsequent hemorrhages.

17.7 Transfusion can replace lost blood (pp. 663–666)

1. Plasma volume can be replaced with balanced electrolyte solutions.
2. Whole blood transfusions are sometimes given to replace severe and rapid blood loss. Packed RBCs are given to replace lost O_2-carrying capacity.
3. Blood group is based on agglutinogens (antigens) present on red blood cell membranes.
4. When mismatched blood is transfused, the recipient's agglutinins (plasma antibodies) clump the foreign RBCs. The clumped RBCs may block blood vessels temporarily and then are lysed. Released hemoglobin may cause kidney shutdown.
5. Before whole blood can be transfused, it must be typed and cross matched to prevent transfusion reactions. The most important blood groups for which blood must be typed are the ABO and Rh groups.

17.8 Blood tests give insights into a patient's health (p. 666)

1. Diagnostic blood tests can provide valuable information about the current status of the blood and of the body as a whole.

Developmental Aspects of Blood (p. 666)

1. Fetal hematopoietic sites include the yolk sac, liver, and spleen. By the seventh month of development, the red bone marrow is the primary blood-forming site.
2. Blood cells develop from blood islands derived from mesoderm. Fetal blood contains hemoglobin F. After birth, hemoglobin A is formed.
3. The major blood-related problems associated with aging are leukemia, anemia, and thromboembolic disease.

REVIEW QUESTIONS

To access additional practice questions using your smartphone, tablet, or computer: MasteringA&P® > Study Area > Practice Tests & Quizzes

Level 1 Remember/Understand

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. The blood volume in an adult averages approximately **(a)** 1 L, **(b)** 3 L, **(c)** 5 L, **(d)** 7 L.
2. The hormonal stimulus that prompts red blood cell formation is **(a)** serotonin, **(b)** heparin, **(c)** erythropoietin, **(d)** thrombopoietin.
3. All of the following are true of RBCs except **(a)** biconcave disc shape, **(b)** life span of approximately 120 days, **(c)** contain hemoglobin, **(d)** contain nuclei.
4. The most numerous WBC is the **(a)** eosinophil, **(b)** neutrophil, **(c)** monocyte, **(d)** lymphocyte.
5. Blood proteins play an important part in **(a)** blood clotting, **(b)** immunity, **(c)** maintenance of blood volume, **(d)** all of the above.
6. The white blood cell that releases histamine and other inflammatory chemicals is the **(a)** basophil, **(b)** neutrophil, **(c)** monocyte, **(d)** eosinophil.
7. The blood cell that can become an antibody-secreting cell is the **(a)** lymphocyte, **(b)** megakaryocyte, **(c)** neutrophil, **(d)** basophil.
8. Which of the following does not promote multiple steps in the clotting pathway? **(a)** platelet phospholipids, **(b)** factor XI, **(c)** thrombin, **(d)** Ca^{2+}.
9. The normal pH of the blood is about **(a)** 8.4, **(b)** 7.8, **(c)** 7.4, **(d)** 4.7.
10. Suppose your blood is AB positive. This means that **(a)** agglutinogens A and B are present on your red blood cells, **(b)** there are no anti-A or anti-B antibodies in your plasma, **(c)** your blood is Rh^+, **(d)** all of the above.
11. **(a)** List the three major categories of formed elements. **(b)** Which is least numerous? **(c)** Which comprise(s) the buffy coat in a hematocrit tube?
12. **(a)** What is a transfusion reaction and why does it happen? **(b)** What are its possible consequences?

Level 2 Apply/Analyze

13. If you had a high hematocrit, would you expect your hemoglobin determination to be low or high? Why?
14. **(a)** Describe the process of erythropoiesis. **(b)** What name is given to the immature cell type released to the circulation? **(c)** How does it differ from a mature erythrocyte?
15. Besides the ability to move by amoeboid motion, what other physiological attributes contribute to the function of white blood cells in the body?
16. **(a)** If you had a severe infection, would you expect your WBC count to be closest to 5000, 10,000, or 15,000/μl? **(b)** What is this condition called?
17. **(a)** Describe the appearance of platelets and state their major function. **(b)** Why should platelets not be called "cells"?
18. **(a)** Define fibrinolysis. **(b)** What is the importance of this process?
19. **(a)** How is clot overgrowth usually prevented? **(b)** List two conditions that may lead to unnecessary (and undesirable) clot formation.
20. How can poor nutrition lead to anemia?
21. Alan Forsythe, a middle-aged college professor from Boston, is in the Swiss Alps studying astronomy during his sabbatical leave. He has been there for two days and plans to stay the entire year. However, he notices that he is short of breath when he walks up steps and tires easily with any physical activity. His symptoms gradually disappear, and he feels fine after less than a month. Upon returning to the United States, he has a complete physical exam and is told that his erythrocyte count is higher than normal.

(a) Attempt to explain this finding. (b) Will his RBC count remain at this higher-than-normal level? Why or why not?

Level 3 Evaluate/Synthesize

22. Discuss hemoglobin relative to its chemical structure, its function, and the color changes it undergoes during loading and unloading of oxygen.
23. (a) Define hemostasis. (b) List the three major phases of coagulation. Explain what initiates each phase and what the phase accomplishes. (c) In what general way do the intrinsic and extrinsic mechanisms of clotting differ? (d) Which ion is essential to virtually all stages of coagulation?
24. Cancer patients being treated with chemotherapeutic drugs designed to destroy rapidly dividing cells are monitored closely for changes in their red and white blood counts. Why so?
25. Amanda Healy, a young woman with severe vaginal bleeding, is admitted to the emergency room. She is three months pregnant, and the physician is concerned about the volume of blood she is losing. (a) What type of transfusion will probably be given to this patient? (b) Which blood tests will be performed before starting the transfusion?
26. A reticulocyte count indicated that 5% of Tyler's red blood cells were reticulocytes. His blood test also indicated he had polycythemia and a hematocrit of 65%. Explain the connection between these three facts.
27. Mr. Chu has been scheduled for surgery to have his arthritic hip replaced. His surgeon tells him he must switch from aspirin to acetaminophen for pain control before his surgery. Why?

CLINICAL CASE STUDY

20-Year-Old-Male with Abdominal Trauma

Richard Watkins, 20, fell off his roof while replacing some shingles. Upon arrival at the scene, paramedics make the following observations:

- Abdominal pain, right upper quadrant
- Cyanotic, cool & clammy skin
- Falling blood pressure, 100/60 mm Hg; rapid pulse, 100 beats/min

Paramedics start an IV to rapidly infuse a 0.9% sodium chloride solution (normal saline). They transport him to a small rural hospital where Mr. Watkins's blood pressure continues to fall and his cyanosis worsens. The local physician begins infusing O negative packed red blood cells (PRBCs) and arranges transport by helicopter to a trauma center. She sends additional PRBC units in the helicopter for transfusion en route. After arrival at the trauma center, the following notes were added to Mr. Watkins's chart:

- Abdomen firm and distended
- Blood drawn for typing and cross matching; packed A positive blood cells infused
- Emergency FAST (focused assessment with sonography for trauma) ultrasound is positive for intraperitoneal fluid

A positive FAST scan indicates intra-abdominal bleeding. Mr. Watkins's condition continues to deteriorate, so he is prepared for surgery. The operation reveals a lacerated liver, which is repaired. Mr. Watkins's vital signs stabilize.

1. Mr. Watkins was going into shock because of blood loss, so paramedics infused a saline solution. Why would this help?
2. + NCLEX-STYLE Why was Mr. Watkins given PRBCs in addition to normal saline solution? What problem does the infusion of PRBCs address that the saline solution could not?
   a. PRBCs help restore blood ion composition to normal.
   b. PRBCs increase blood osmotic pressure, making the infused fluid stay in the vessels rather than move into the cells.
   c. PRBCs enhance clotting, sealing off the injured vessels.
   d. PRBCs contain hemoglobin, so they are able to carry oxygen to the tissues.
3. Why was the physician able to use O negative blood before the results of the blood type tests were obtained?
4. + NCLEX-STYLE Mr. Watkins's blood type was determined to be A positive. Which of the following types of blood can he receive?
   a. A positive, A negative, O positive, and O negative
   b. A positive, O positive, and AB positive
   c. A positive but not A negative
   d. Only A positive and O negative
5. What would happen if doctors had infused type B PRBCs into Mr. Watkins's circulation?

18 The Cardiovascular System: The Heart

Our ceaselessly beating heart has intrigued people for centuries. The ancient Greeks believed the heart was the seat of intelligence. Others thought it was the source of emotions. While these ideas have proved false, we do know that emotions affect heart rate. When your heart pounds or skips a beat, you become acutely aware of how much you depend on this dynamic organ for your very life.

Despite its vital importance, the heart does not work alone. Indeed, it is only part of the cardiovascular system, which includes the miles of blood vessels that run through your body. Day and night, tissue cells take in nutrients and oxygen and excrete wastes. Cells can make such exchanges only with their immediate environment, so some means of changing and renewing that environment is necessary to ensure a continual supply of nutrients and prevent a buildup of wastes. The cardiovascular system provides the transport system "hardware" that keeps blood continuously circulating to fulfill this critical homeostatic need.

18.1 The heart has four chambers and pumps blood through the pulmonary and systemic circuits

Learning Outcomes

- **Describe the size, shape, location, and orientation of the heart in the thorax.**
- **Name the coverings of the heart.**
- **Describe the structure and function of each of the three layers of the heart wall.**
- **Describe the structure and functions of the four heart chambers. Name each chamber and provide the name and general route of its associated great vessel(s).**

The Pulmonary and Systemic Circuits

Stripped of its romantic cloak, the **heart** is no more than the transport system pump, and the blood vessels are the delivery routes. In fact, the heart is actually two pumps side by side (**Figure 18.1**).

- The *right side* of the heart receives oxygen-poor blood from body tissues and then pumps this blood to the lungs to pick up oxygen and dispel carbon dioxide. The blood vessels that carry blood to and from the lungs form the **pulmonary circuit** (*pulmo* = lung).
- The *left side* of the heart receives the oxygenated blood returning from the lungs and pumps this blood throughout the body to supply oxygen and nutrients to body tissues. The blood vessels that carry blood to and from all body tissues form the **systemic circuit**.

The heart has two receiving chambers:

- The *right atrium* receives blood returning from the systemic circuit.

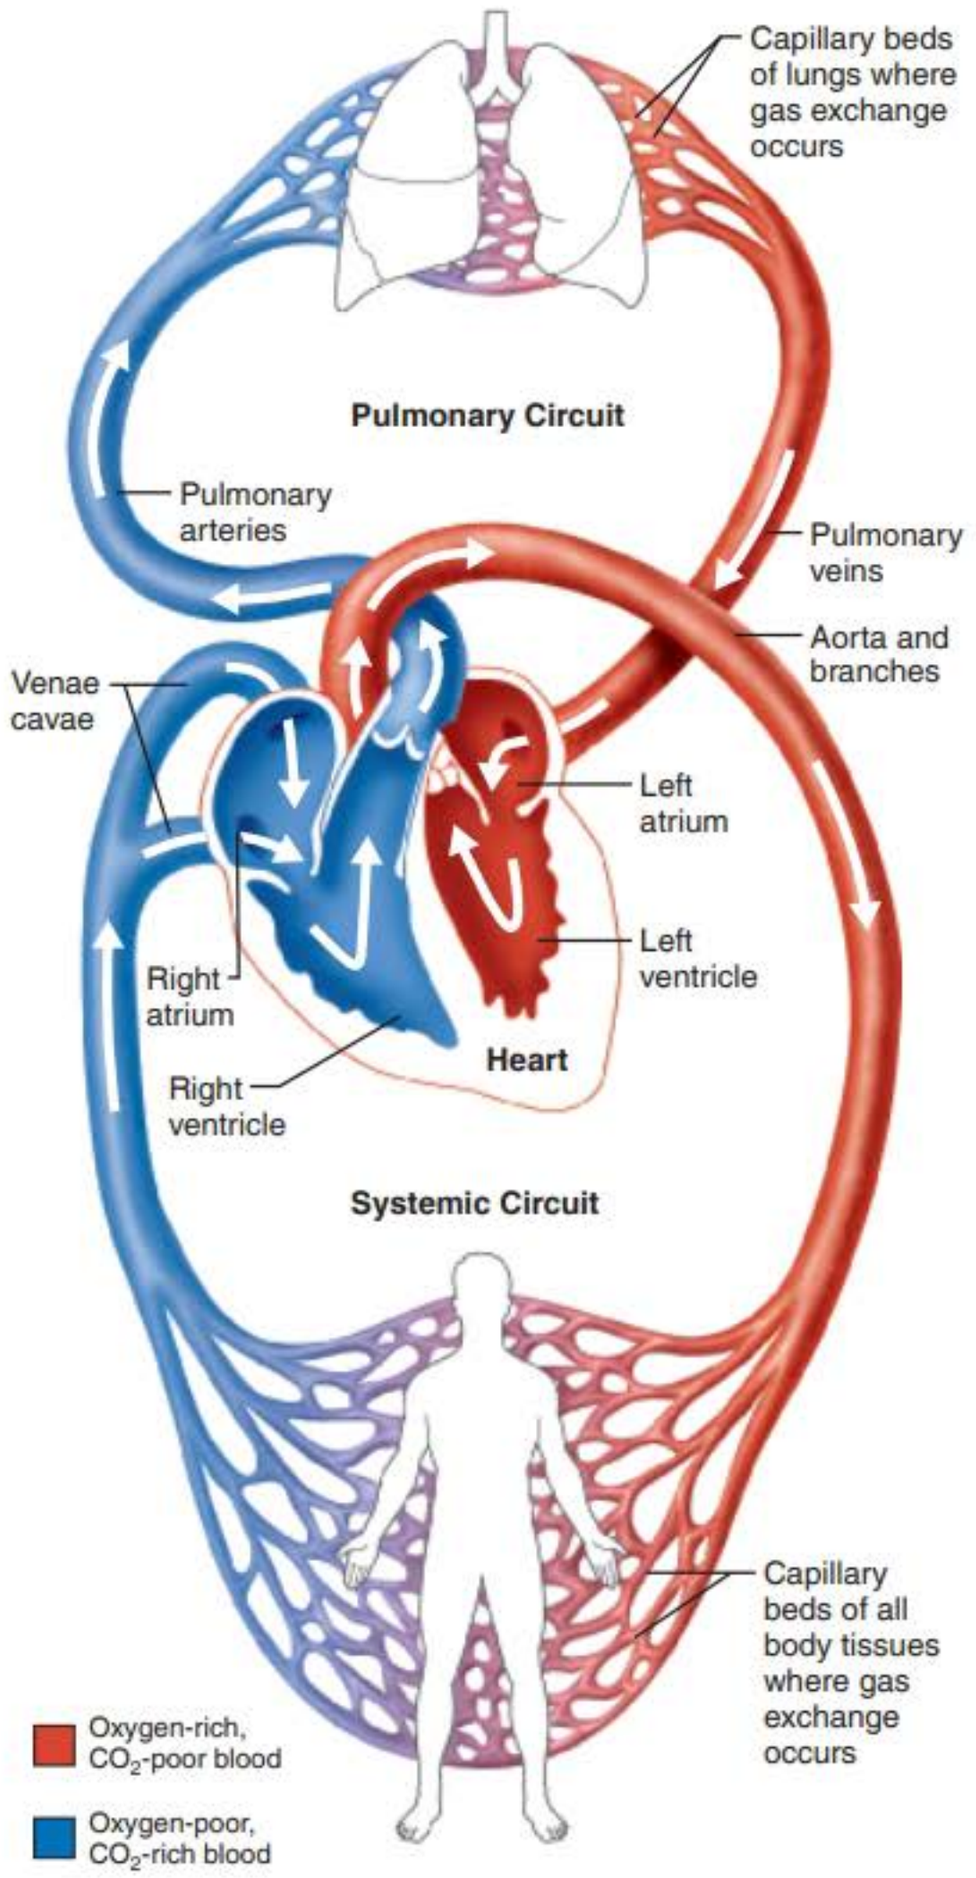

Figure 18.1 The systemic and pulmonary circuits. The right side of the heart pumps blood through the pulmonary circuit and the left side of the heart pumps blood through the systemic circuit. The arrows indicate the direction of blood flow. For simplicity, the actual number of two pulmonary arteries and four pulmonary veins has been reduced to one each.

- The *left atrium* receives blood returning from the pulmonary circuit.

The heart also has two main pumping chambers:

- The *right ventricle* pumps blood into the pulmonary circuit.
- The *left ventricle* pumps blood into the systemic circuit.

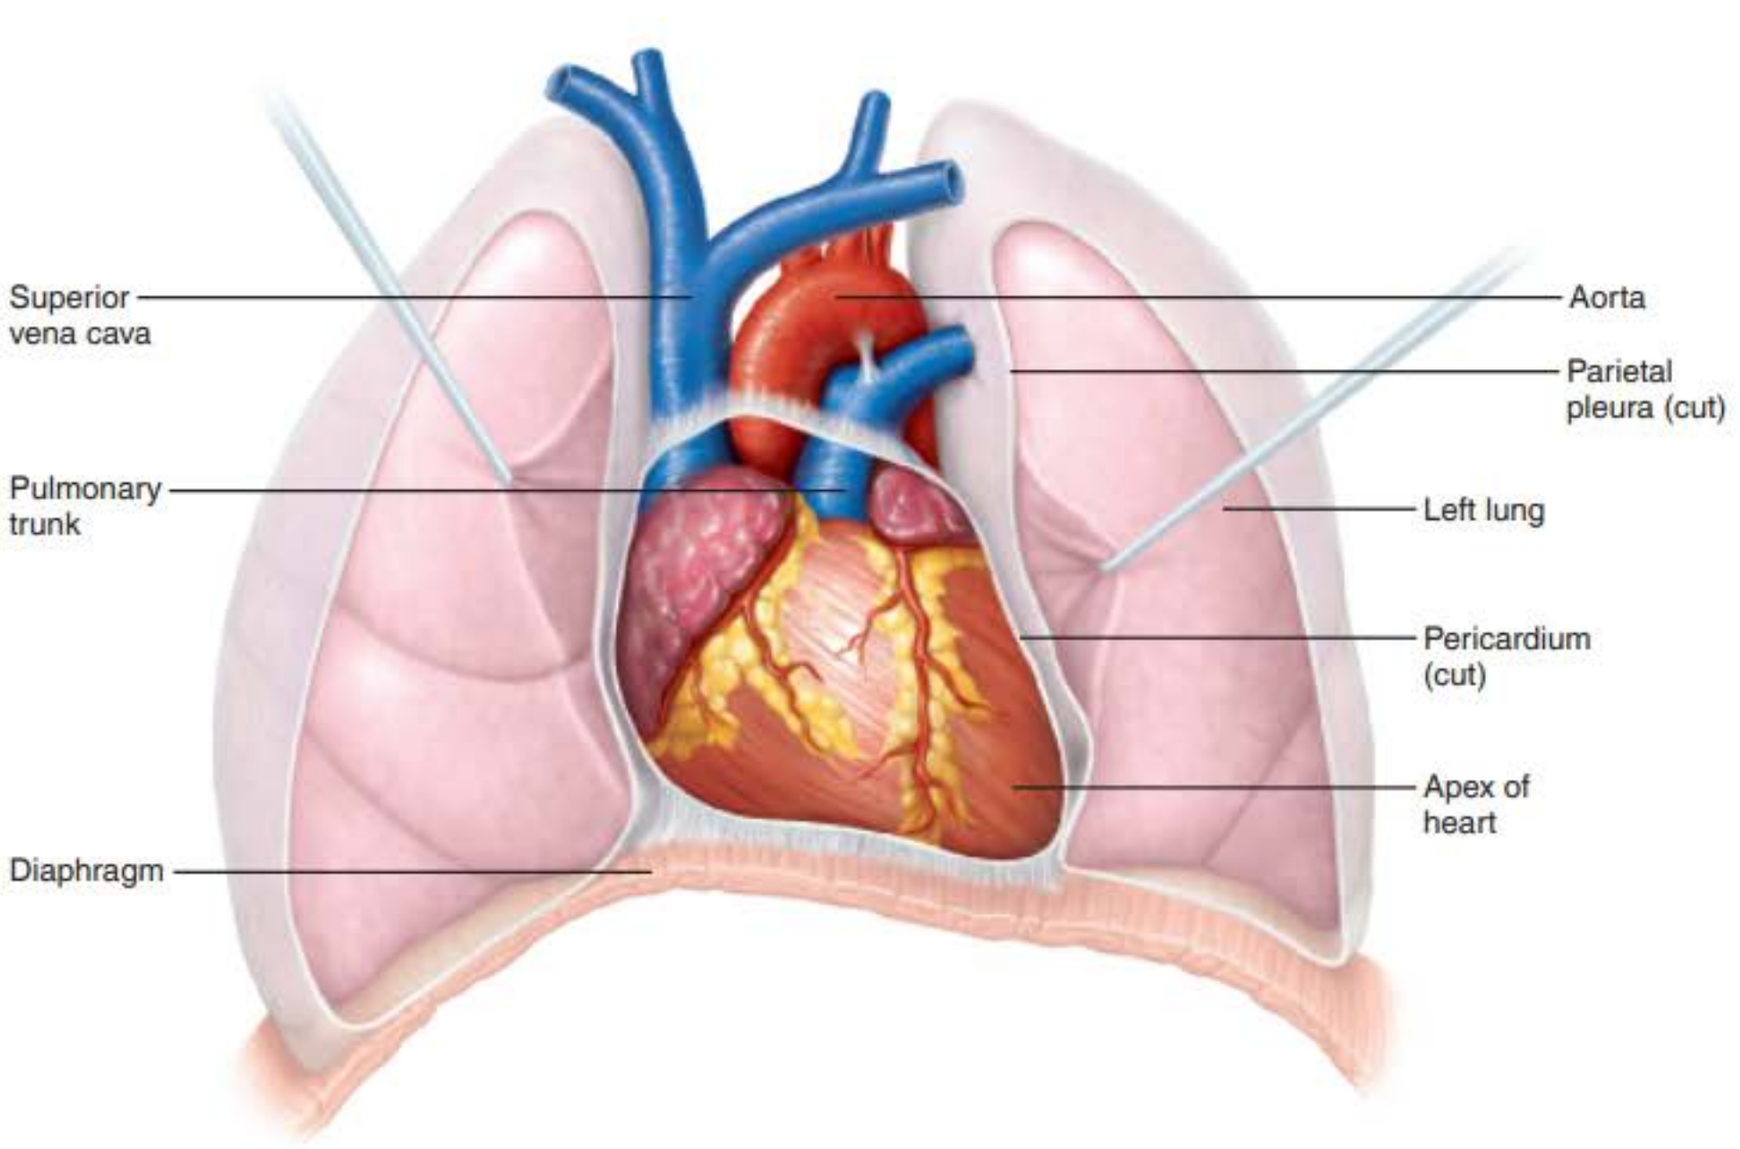
(b)



(c)

Figure 18.2 Location of the heart in the mediastinum. (a) Relationship of the heart to the sternum, ribs, and diaphragm in a person who is lying down (the heart is slightly inferior to this position in a standing person). **(b)** Inferior view of a cross section showing the heart's relative position in the thorax. **(c)** Relationship of the heart and great vessels to the lungs.

Size, Location, and Orientation of the Heart

The modest size and weight of the heart belie its incredible strength and endurance. About the size of a fist, the hollow, cone-shaped heart has a mass of 250 to 350 grams—less than a pound (**Figure 18.2**).

Snugly enclosed within the **mediastinum** (me″de-ah-sti′num), the medial cavity of the thorax, the heart extends obliquely for 12 to 14 cm (about 5 inches) from the second rib to the fifth intercostal space (Figure 18.2a). As it rests on the superior surface of the diaphragm, the heart lies anterior to the vertebral column and posterior to the sternum. Approximately two-thirds of its mass lies to the left of the midsternal line; the balance projects to the right. The lungs flank the heart laterally and partially obscure it (Figure 18.2b, c).

The broad, flat **base**, or posterior surface, of the heart is about 9 cm (3.5 in) wide and directed toward the right shoulder. Its **apex** points inferiorly toward the left hip. If you press your fingers between the fifth and sixth ribs just below the left nipple, you can easily feel the **apical impulse** caused by your beating heart's apex where it touches the chest wall.

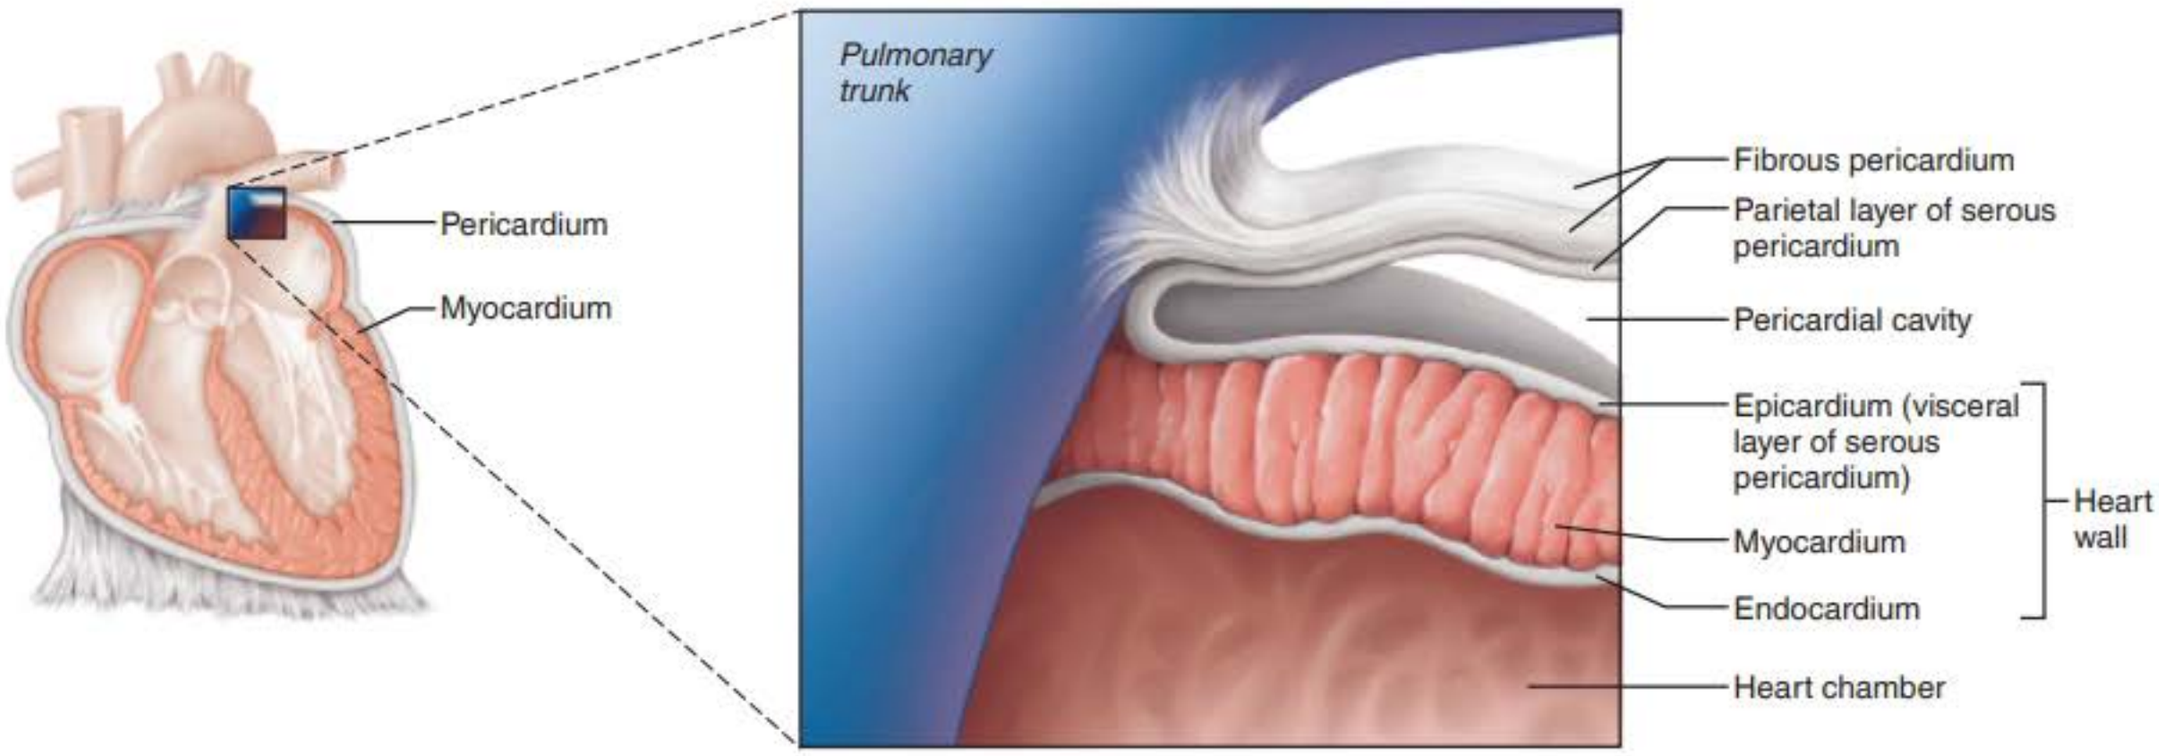


Figure 18.3 The layers of the pericardium and of the heart wall.

Coverings of the Heart

The heart is enclosed in a double-walled sac called the **pericardium** (per″ĭ-kar′de-um; *peri* = around, *cardi* = heart) (**Figure 18.3**). The loosely fitting superficial part of this sac is the **fibrous pericardium**. This tough, dense connective tissue layer (1) protects the heart, (2) anchors it to surrounding structures, and (3) prevents overfilling of the heart with blood.

Deep to the fibrous pericardium is the **serous pericardium**, a thin, slippery, two-layer serous membrane that forms a closed sac around the heart (◀ Figure 1.11, p. 19). Its **parietal layer** lines the internal surface of the fibrous pericardium. At the superior margin of the heart, the parietal layer attaches to the large arteries exiting the heart, and then turns inferiorly and continues over the external heart surface as the **visceral layer**, also called the *epicardium* ("upon the heart"), which is an integral part of the heart wall.

Between the parietal and visceral layers is the slitlike **pericardial cavity**, which contains a film of serous fluid. The serous membranes, lubricated by the fluid, glide smoothly past one another, allowing the mobile heart to work in a relatively friction-free environment.

HOMEOSTATIC IMBALANCE 18.1 CLINICAL

Pericarditis, inflammation of the pericardium, roughens the serous membrane surfaces. Consequently, as the beating heart rubs against its pericardial sac, it creates a creaking sound (*pericardial friction rub*) that can be heard with a stethoscope. Pericarditis is characterized by pain deep to the sternum. Over time, it may lead to adhesions in which the visceral and parietal pericardia stick together and impede heart activity.

In severe cases, large amounts of inflammatory fluid seep into the pericardial cavity. This excess fluid compresses the heart and limits its ability to pump blood, a condition called *cardiac tamponade* (tam″pŏ-nād′), literally, "heart plug." Physicians treat cardiac tamponade by inserting a syringe into the pericardial cavity and draining off the excess fluid.

Layers of the Heart Wall

The heart wall, richly supplied with blood vessels, is composed of three layers: the epicardium, myocardium, and endocardium (Figure 18.3).

As we have noted, the superficial **epicardium** is the visceral layer of the serous pericardium. It is often infiltrated with fat, especially in older people.

The middle layer, the **myocardium** ("muscle heart"), is composed mainly of cardiac muscle and forms the bulk of the heart. This is the layer that contracts. In the myocardium, the branching cardiac muscle cells are tethered to one another by crisscrossing connective tissue fibers and arranged in spiral or circular *bundles* (**Figure 18.4**). These interlacing bundles effectively link all parts of the heart together.

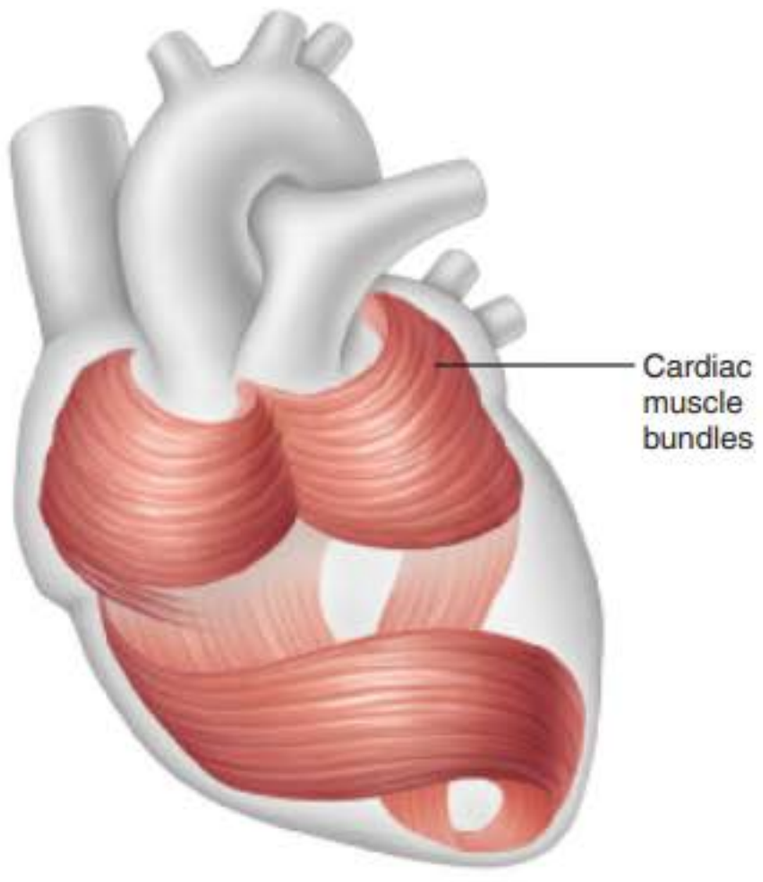

Figure 18.4 The circular and spiral arrangement of cardiac muscle bundles in the myocardium of the heart.

The connective tissue fibers form a dense network, the fibrous **cardiac skeleton**, that reinforces the myocardium internally and anchors the cardiac muscle fibers. This network of collagen and elastic fibers is thicker in some areas than others. For example, it constructs ropelike rings that provide additional support where the great vessels issue from the heart and around the heart valves (see Figure 18.6a, p. 678). Without this support, the vessels and valves might eventually become stretched because of the continuous stress of blood pulsing through them. Additionally, because connective tissue is not electrically excitable, the cardiac skeleton allows action potentials to spread only via specific pathways in the heart.

The third layer of the heart wall, the **endocardium** ("inside the heart"), is a glistening white sheet of endothelium (squamous epithelium; ◀ p. 121) resting on a thin connective tissue layer. Located on the inner myocardial surface, it lines the heart chambers and covers the fibrous skeleton of the valves. The endocardium is continuous with the endothelial linings of the blood vessels leaving and entering the heart.

Chambers and Associated Great Vessels

The heart has four chambers (**Figure 18.5e** on p. 677)—two superior **atria** (a′tre-ah) and two inferior **ventricles** (ven′trĭ-klz). The internal partition that divides the heart longitudinally is called the **interatrial septum** where it separates the atria, and the **interventricular septum** where it separates the ventricles. The right ventricle forms most of the anterior surface of the heart. The left ventricle dominates the inferoposterior aspect of the heart and forms the heart apex.

Two grooves visible on the heart surface indicate the boundaries of its four chambers and carry the blood vessels supplying the myocardium. The **coronary sulcus** (Figure 18.5b, d), or *atrioventricular groove*, encircles the junction of the atria and ventricles like a crown (*corona* = crown). The **anterior interventricular sulcus**, cradling the anterior interventricular artery, marks the anterior position of the septum separating the right and left ventricles. It continues as the **posterior interventricular sulcus**, which provides a similar landmark on the heart's posteroinferior surface.

Atria: The Receiving Chambers

Except for small, wrinkled, protruding appendages called **auricles** (or′ĭ-klz; *auricle* = little ear), which increase the atrial volume somewhat, the right and left atria are remarkably free of distinguishing surface features. Internally, the right atrium has two basic parts (Figure 18.5c): a smooth-walled posterior part and an anterior portion in which bundles of muscle tissue form ridges in the walls. These muscle bundles are called **pectinate muscles** because they look like the teeth of a comb (*pectin* = comb). The posterior and anterior regions of the right atrium are separated by a C-shaped ridge called the *crista terminalis* ("terminal crest").

In contrast, the left atrium is mostly smooth and pectinate muscles are found only in the auricle. The interatrial septum bears a shallow depression, the **fossa ovalis** (o-vă′lis) (Figure 18.5c, e), that marks the spot where an opening, the *foramen ovale*, existed in the fetal heart (see p. 700).

Functionally, the atria are receiving chambers for blood returning to the heart from the circulation (*atrium* = entryway). The atria are relatively small, thin-walled chambers because they need to contract only minimally to push blood "downstairs" into the ventricles. They contribute little to the propulsive pumping activity of the heart.

Blood enters the *right atrium* via three veins (Figure 18.5c–e):

- The **superior vena cava** returns blood from body regions superior to the diaphragm.
- The **inferior vena cava** returns blood from body areas below the diaphragm.
- The **coronary sinus** collects blood draining from the myocardium.

Four **pulmonary veins** enter the *left atrium*, which makes up most of the heart's base. These veins, which transport blood from the lungs back to the heart, are best seen in a posterior view (Figure 18.5d).

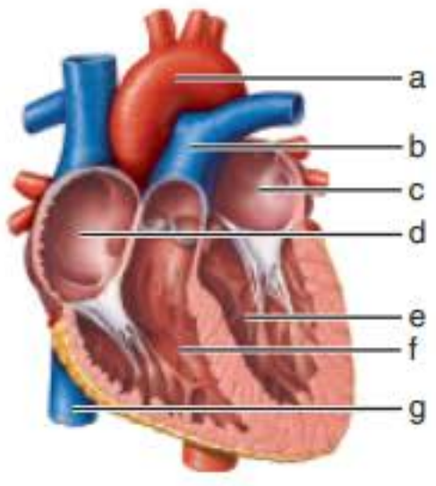
Ventricles: The Discharging Chambers

Together the ventricles (*ventr* = underside) make up most of the volume of the heart. As already mentioned, the right ventricle forms most of the heart's anterior surface and the left ventricle dominates its posteroinferior surface. Irregular ridges of muscle called **trabeculae carneae** (trah-bek′u-le kar′ne-e; "crossbars of flesh") mark the internal walls of the ventricular chambers. Other muscle bundles, the **papillary muscles**, which play a role in valve function, project into the ventricular cavity (Figure 18.5e).

The ventricles are the discharging chambers, the actual pumps of the heart. Their walls are much more massive than the atrial walls, reflecting the difference in function between the atria and ventricles (Figure 18.5e and f). When the ventricles contract, they propel blood out of the heart into the circulation. The right ventricle pumps blood into the **pulmonary trunk**, which routes the blood to the lungs where gas exchange occurs. The left ventricle ejects blood into the **aorta** (a-or′tah), the largest artery in the body.

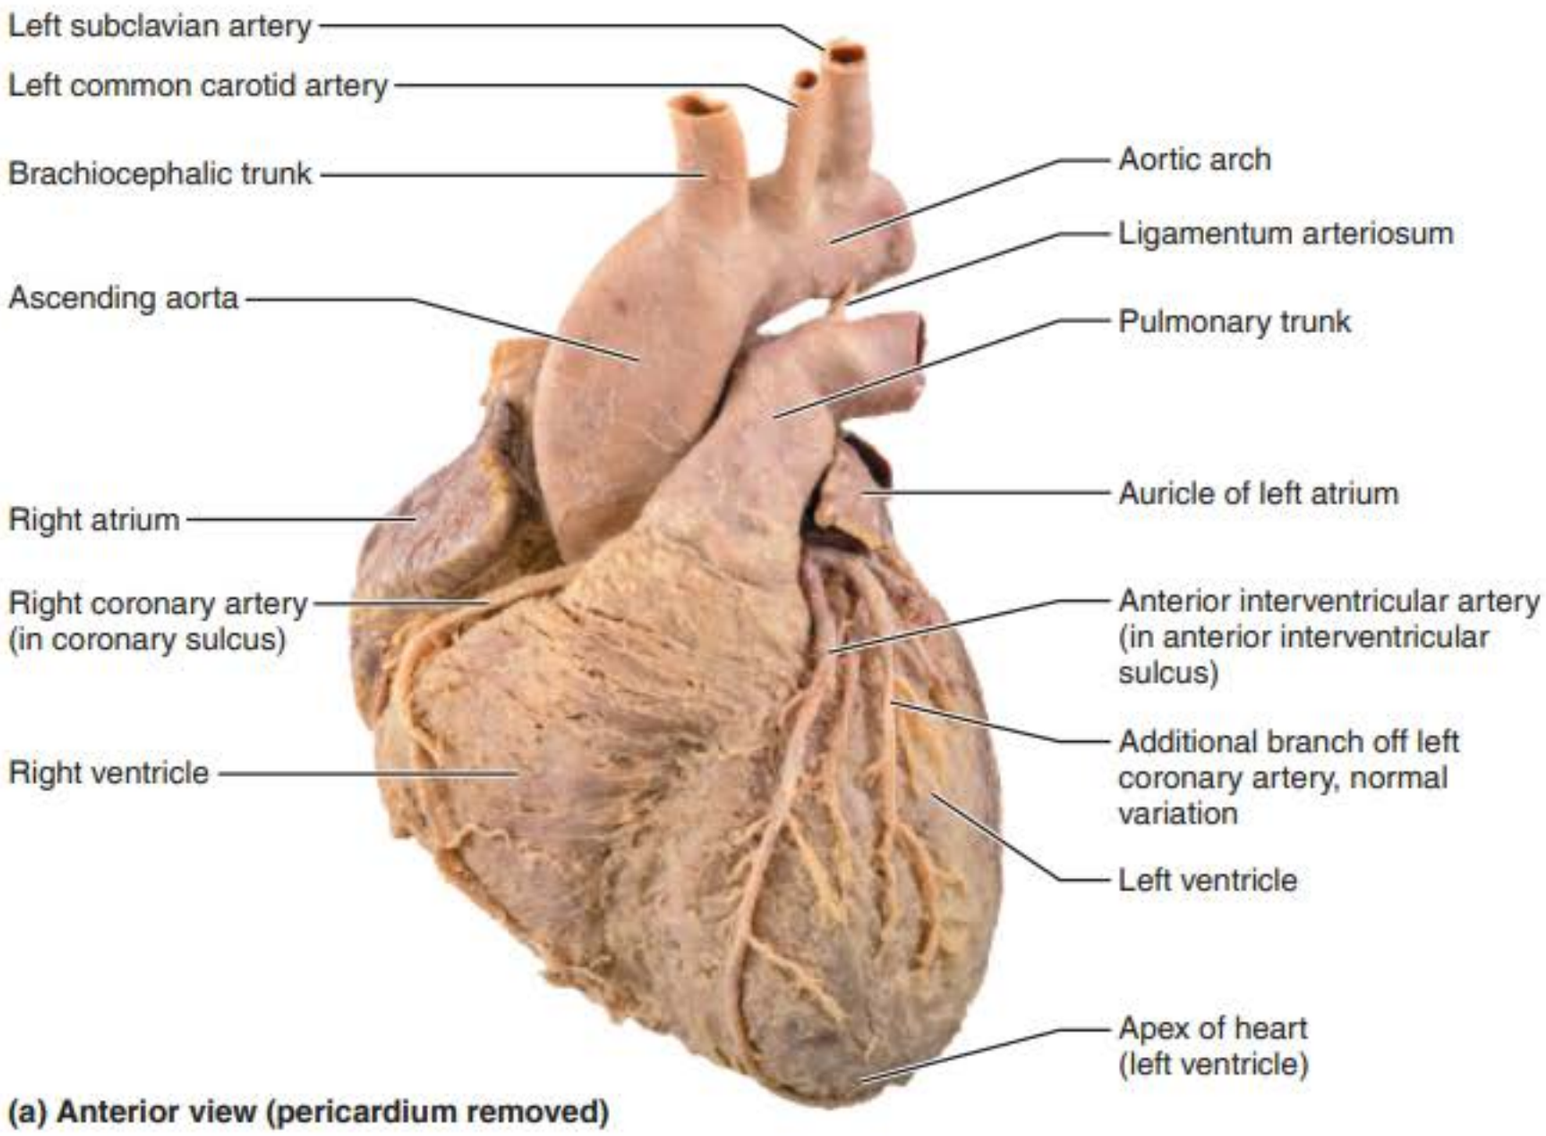
Check Your Understanding

1. The heart is in the mediastinum. Just what is the mediastinum?
2. From inside to outside, list the layers of the heart wall and the coverings of the heart.
3. What is the purpose of the serous fluid inside the pericardial cavity?
4. In the frontal section of the heart at right, name the structures indicated by a–g. Which heart chamber receives oxygen-poor blood from veins? Which chamber pumps blood into the systemic circulation? Which blood vessel transports blood toward the lungs?

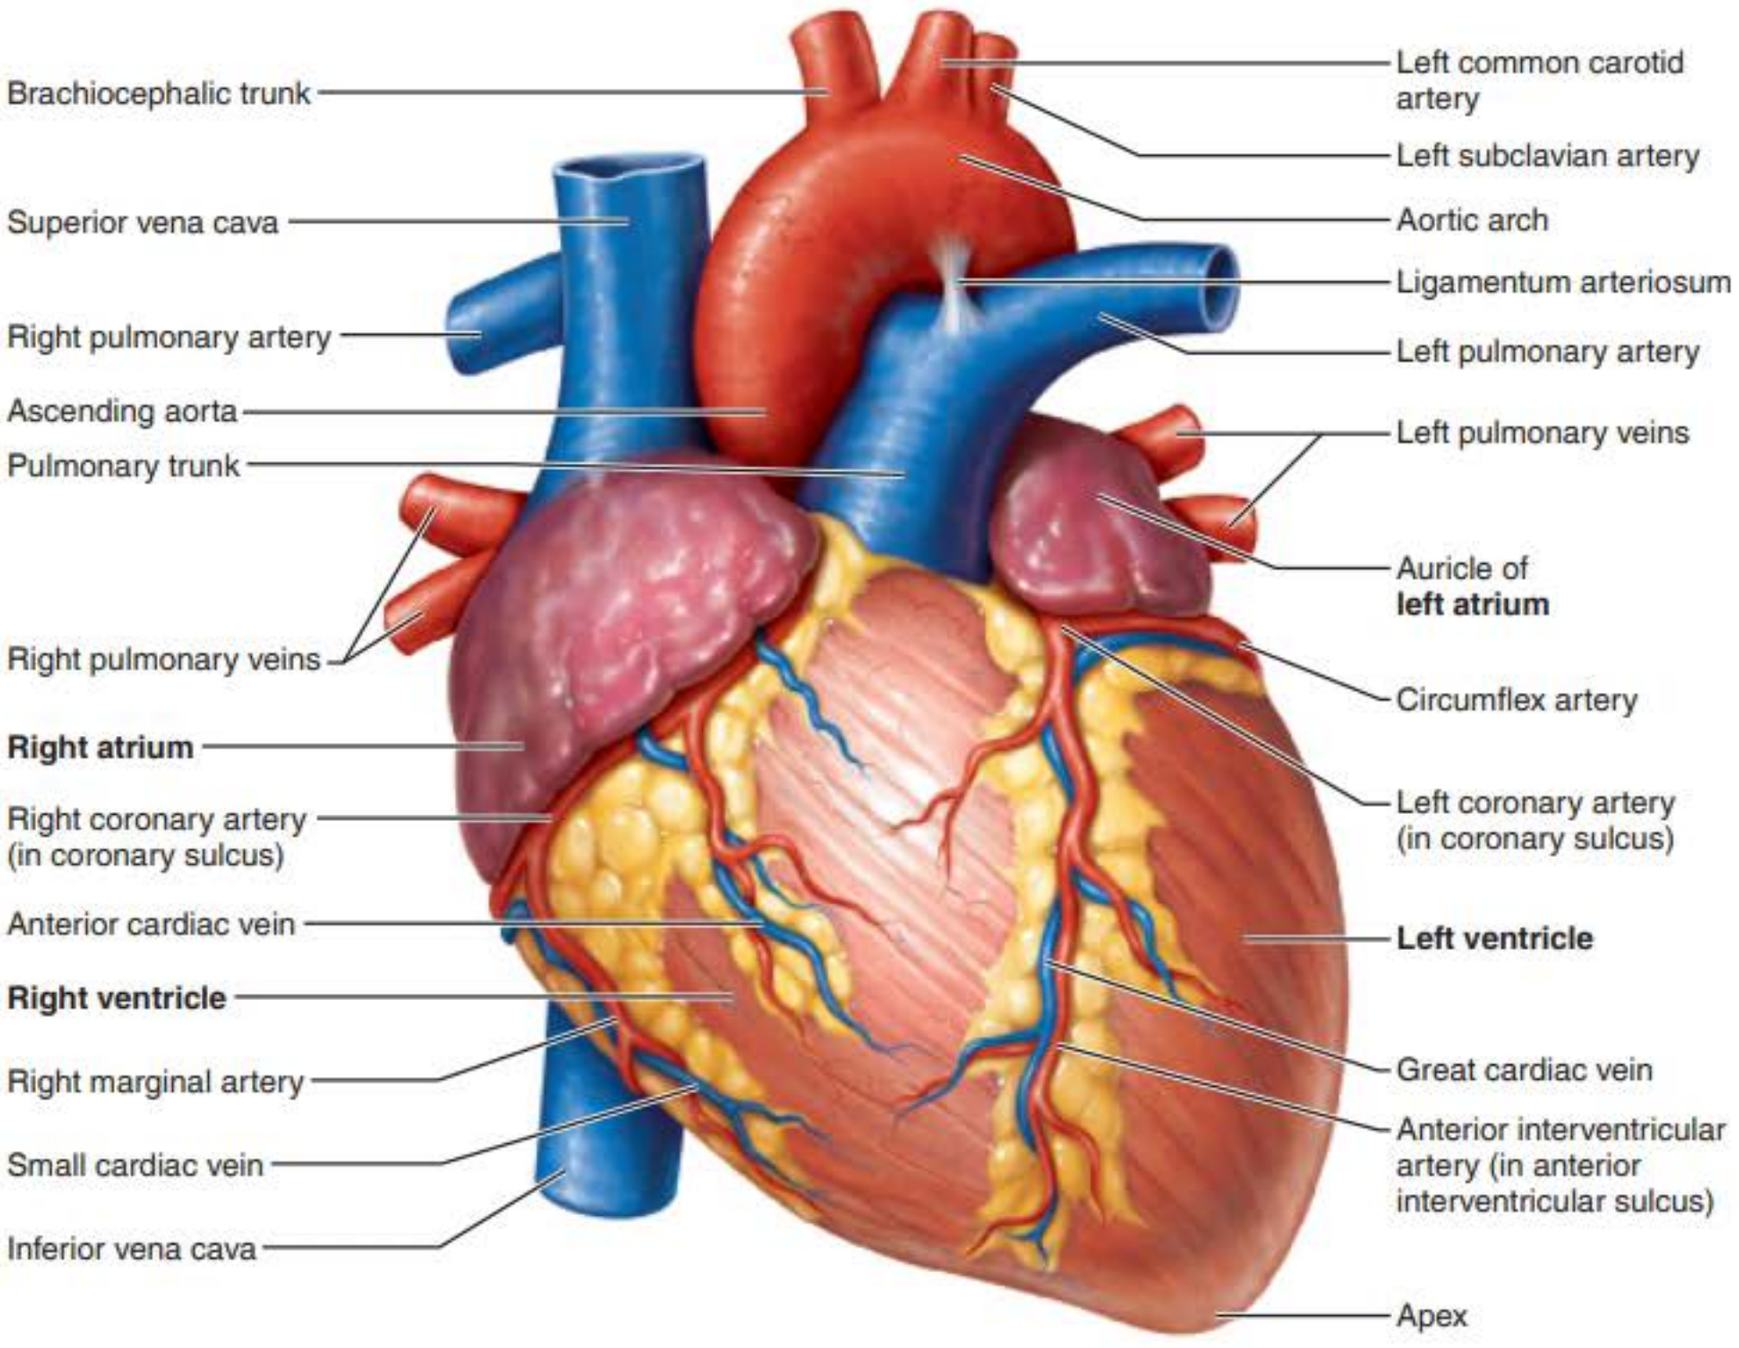


For answers, see Answers Appendix.

(Text continues on p. 679.)



(a) Anterior view (pericardium removed)



(b) Anterior view

Figure 18.5 Gross anatomy of the heart. In diagrammatic views, vessels transporting oxygen-rich blood are red; those transporting oxygen-poor blood are blue.

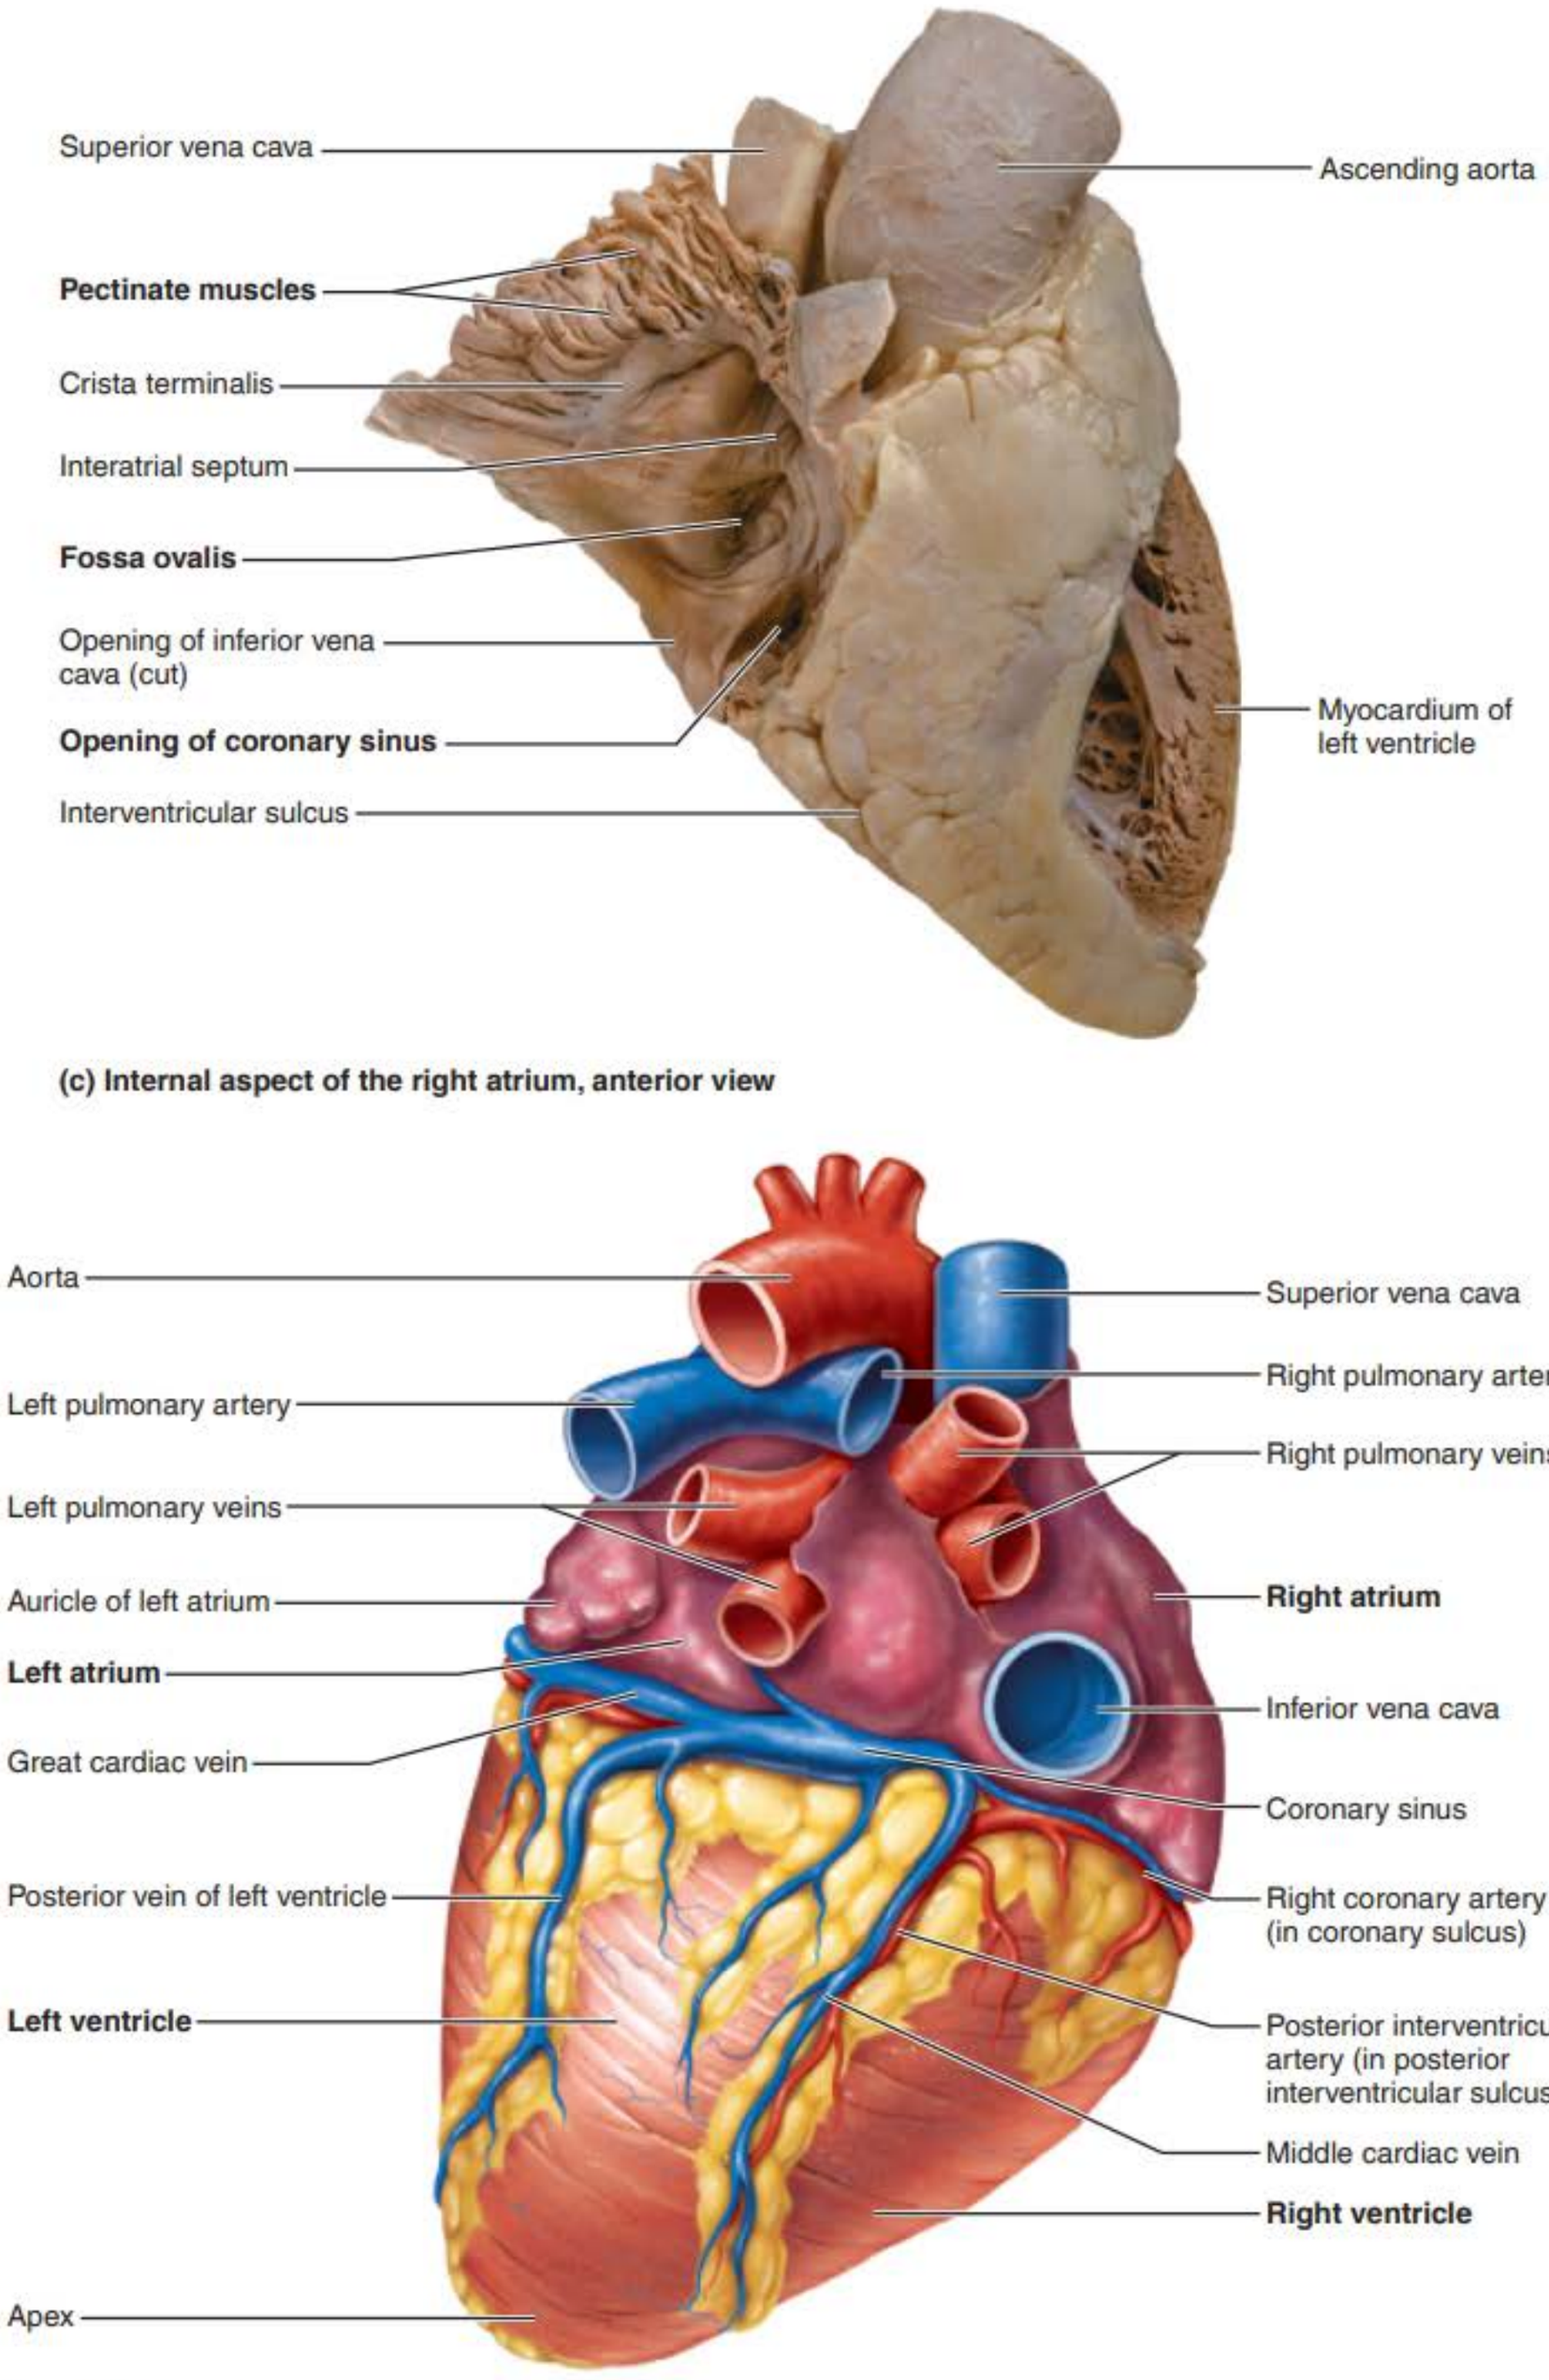


Figure 18.5 *(continued)* **Gross anatomy of the heart.** In (c), the anterior wall of the atrium has been opened and folded superiorly.

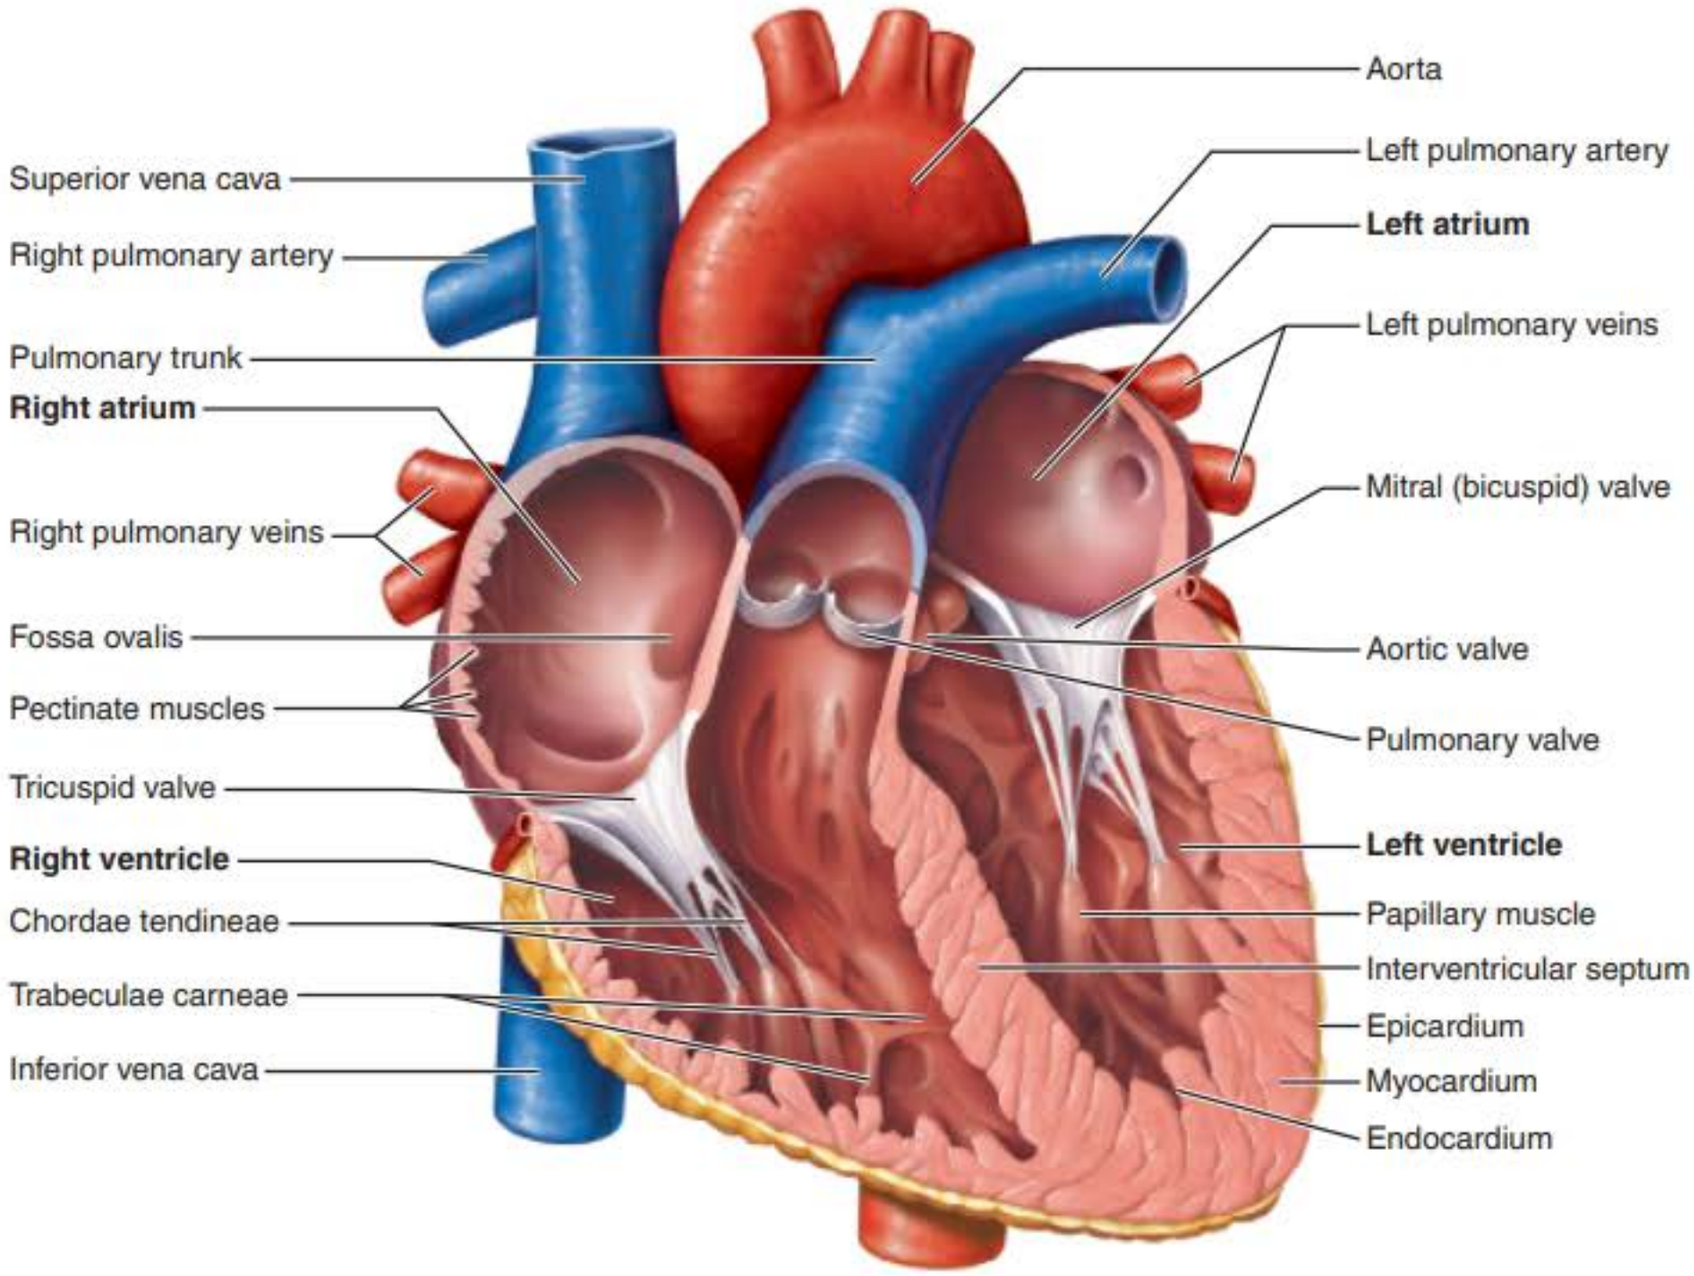
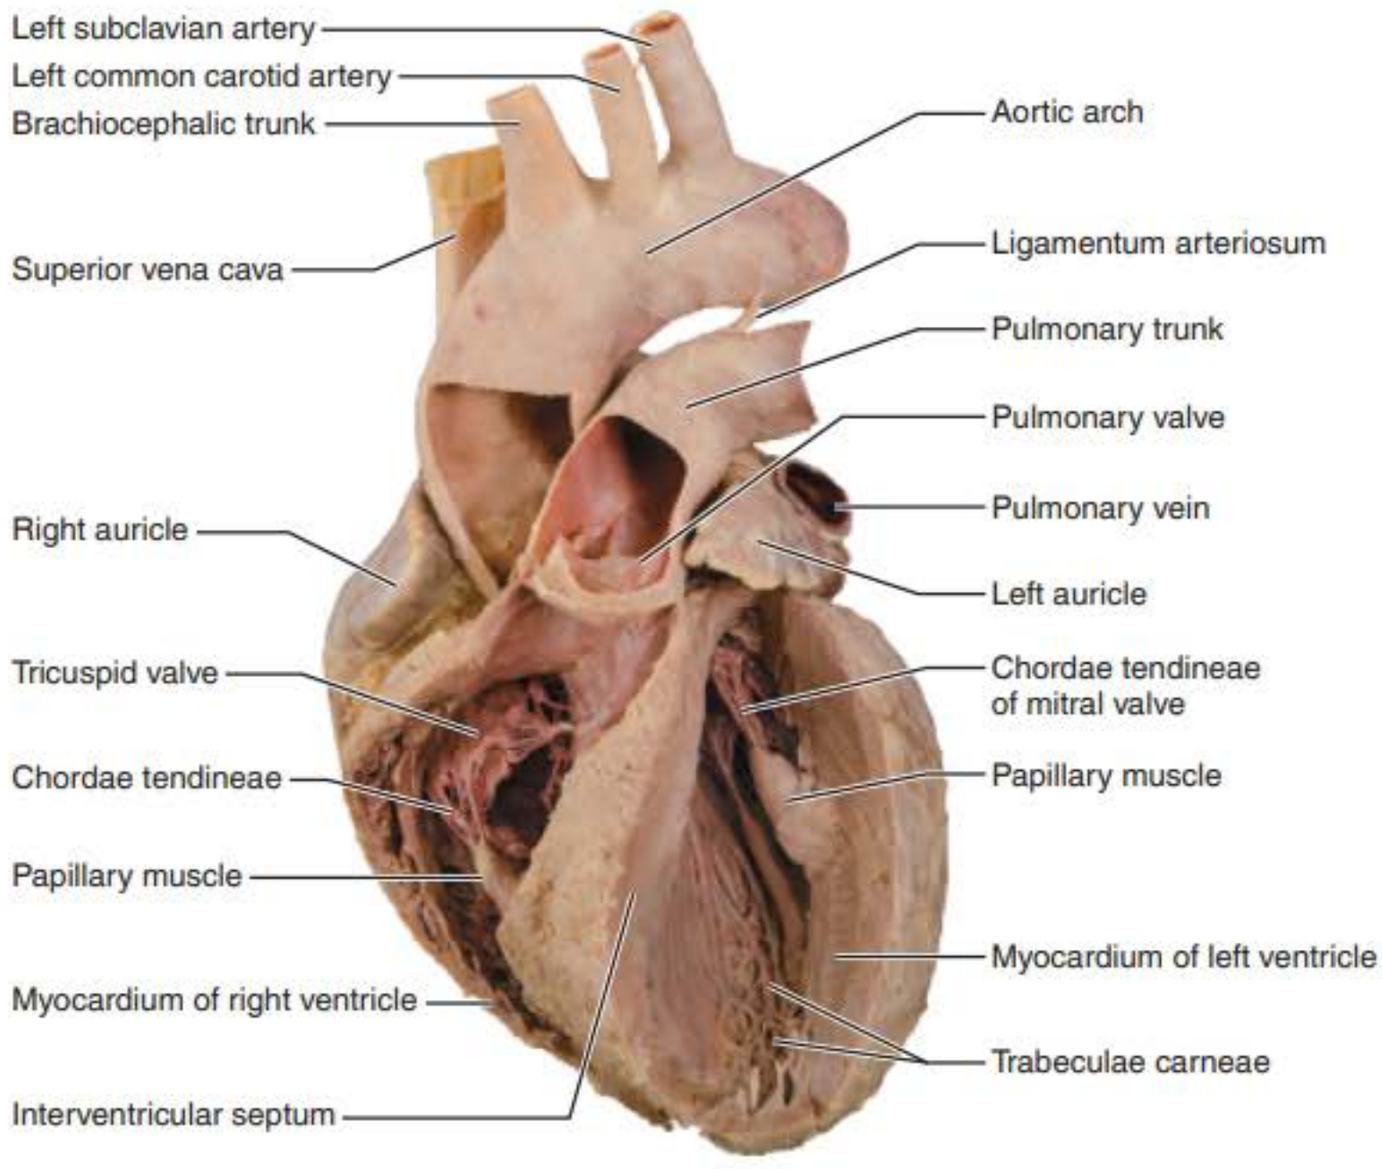
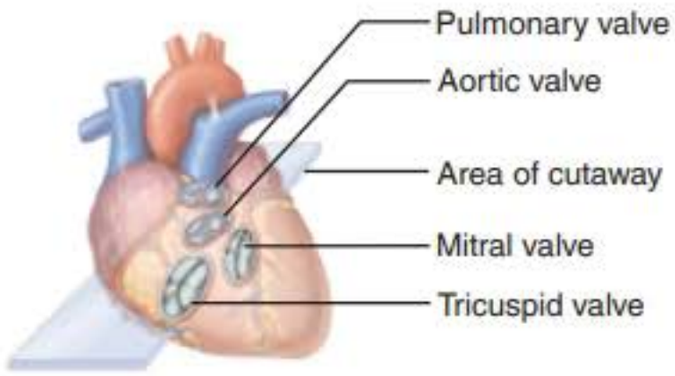


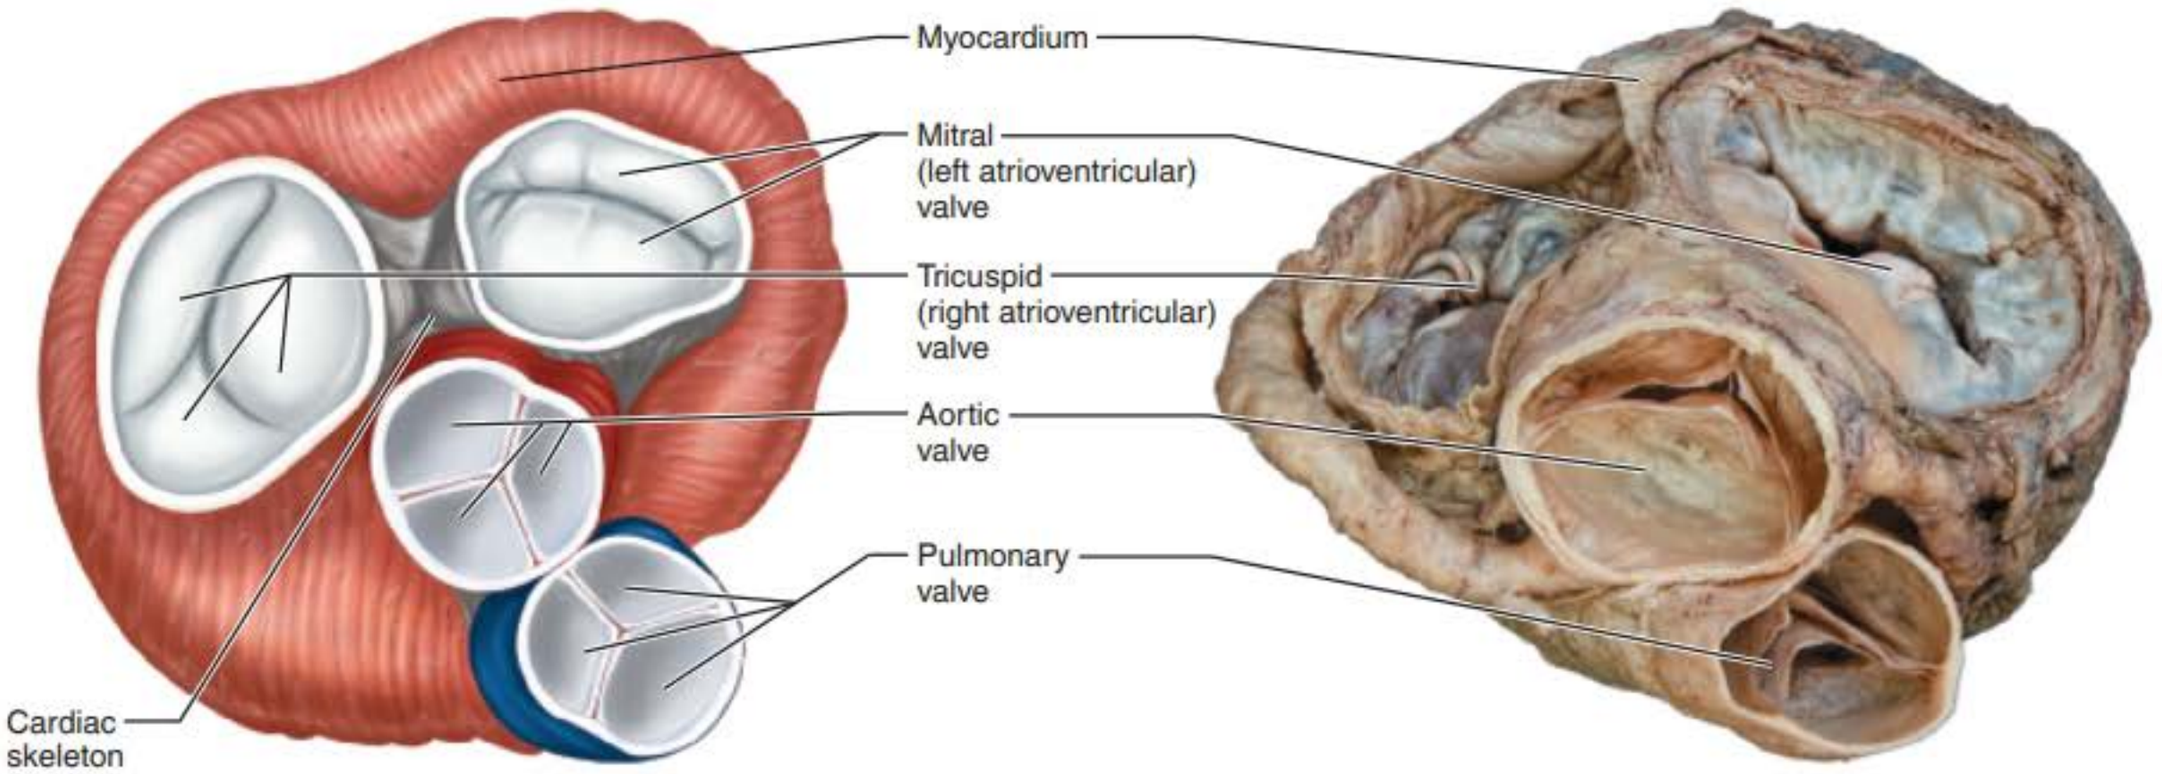
(e) Frontal section

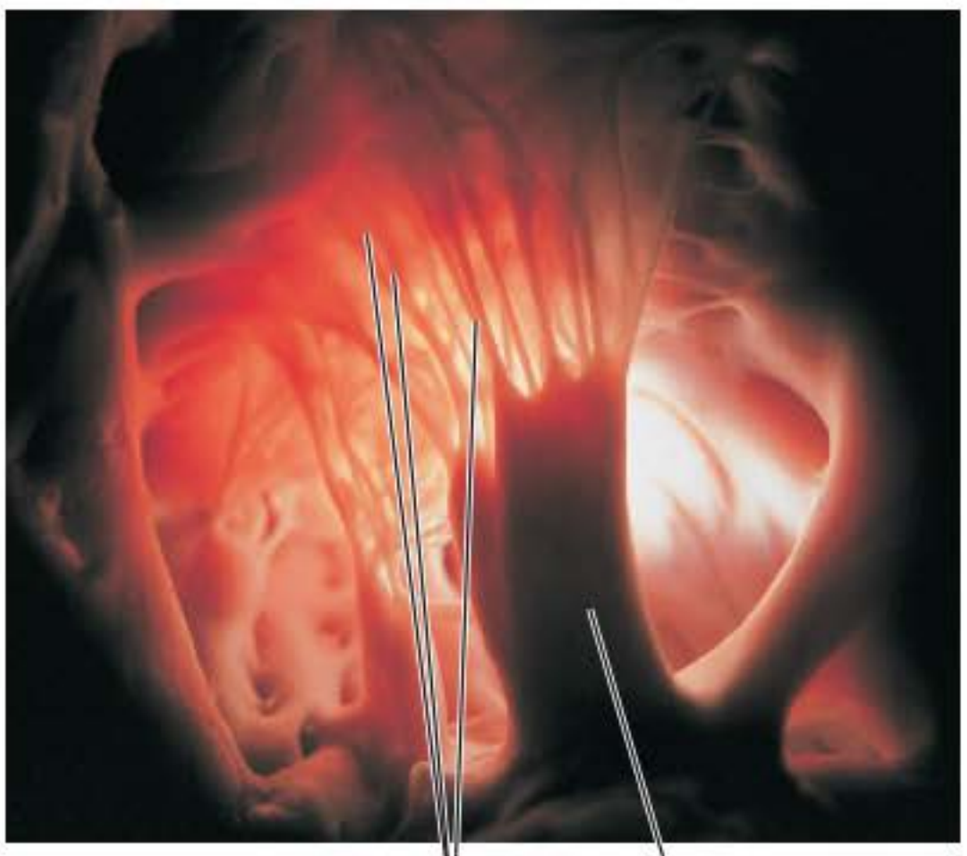


(f) Internal aspect of ventricles; dissection of view similar to (e)

Figure 18.5 *(continued)*







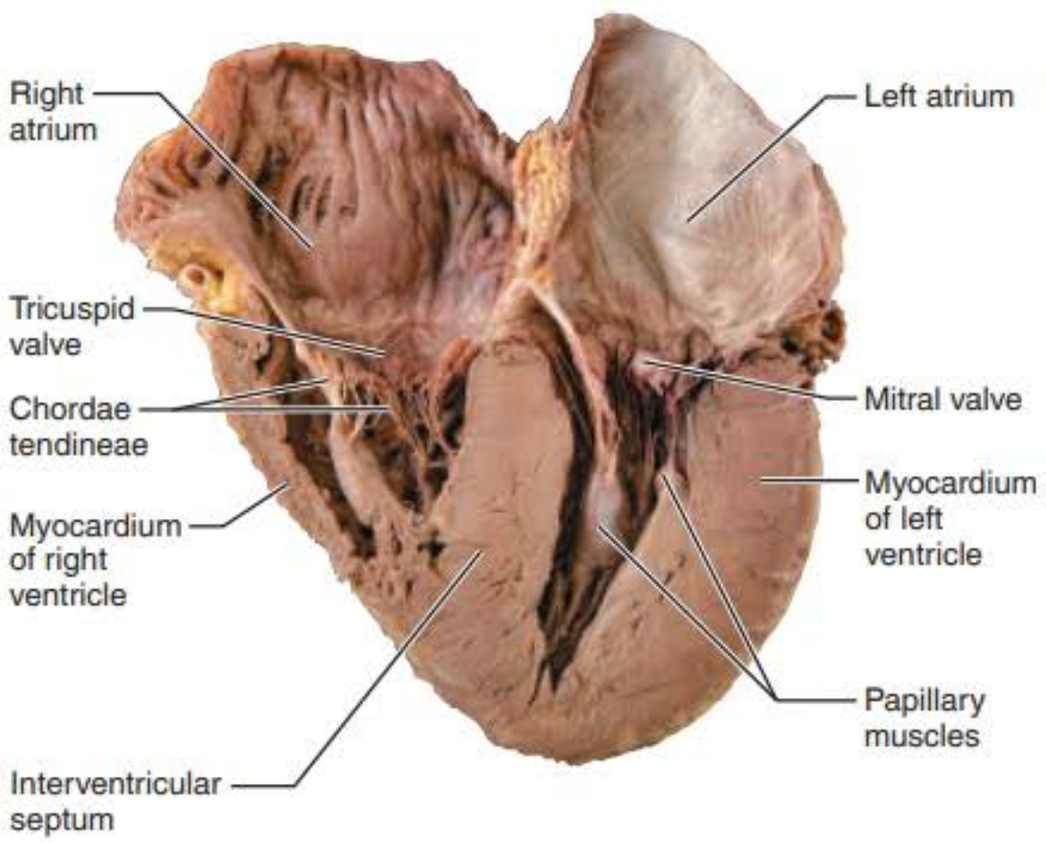


Figure 18.6 Heart valves. (a) Superior view of the two sets of heart valves (atria removed). The paired atrioventricular valves are located between atria and ventricles; the two semilunar valves are located at the junction of the ventricles and the arteries issuing from them. **(b)** Photograph of the heart valves, superior view. **(c)** Photograph of the tricuspid valve. This bottom-to-top view shows the valve as seen from the right ventricle. **(d)** Frontal section of the heart.

Practice Human Cadaver lab questions:
MasteringA&P® > Study Area > Lab Tools > PAL

18.2 Heart valves make blood flow in one direction

Learning Outcome

- **Name the heart valves and describe their location, function, and mechanism of operation.**

Blood flows through the heart in one direction: from atria to ventricles and out the great arteries leaving the superior aspect of the heart. Four valves enforce this one-way traffic (Figure 18.5e and **Figure 18.6**). They open and close in response to differences in blood pressure on their two sides.

Atrioventricular (AV) Valves

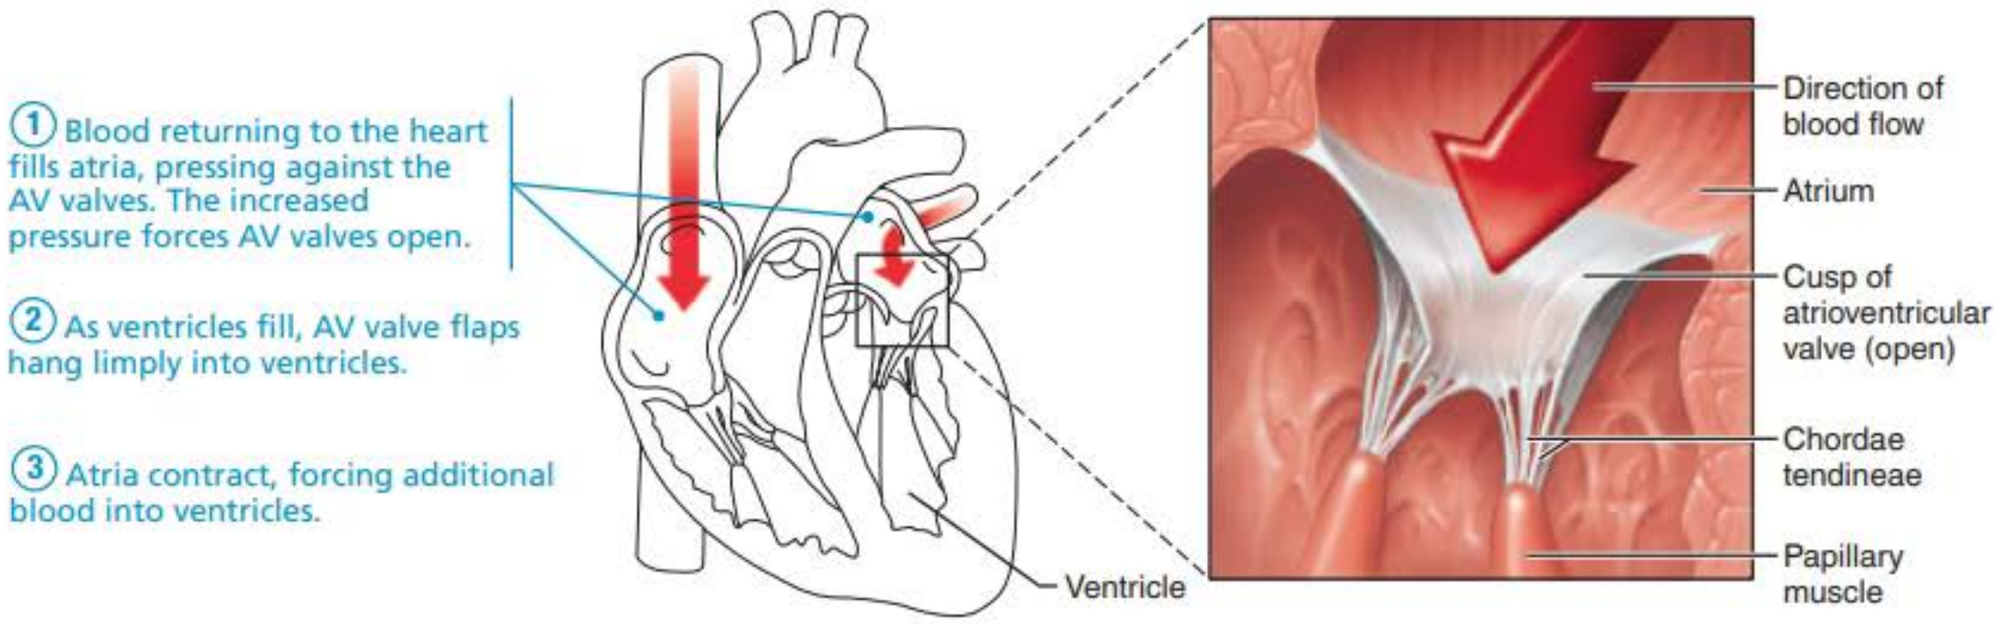
The two **atrioventricular (AV) valves**, one located at each atrial-ventricular junction, prevent backflow into the atria when the ventricles contract.

- The right AV valve, the **tricuspid valve** (tri-kus′pid), has three flexible cusps (flaps of endocardium reinforced by connective tissue cores).
- The left AV valve, with two cusps, is called the **mitral valve** (mi′tral) because it resembles the two-sided bishop's miter (tall, pointed hat). It is sometimes called the *bicuspid valve*.

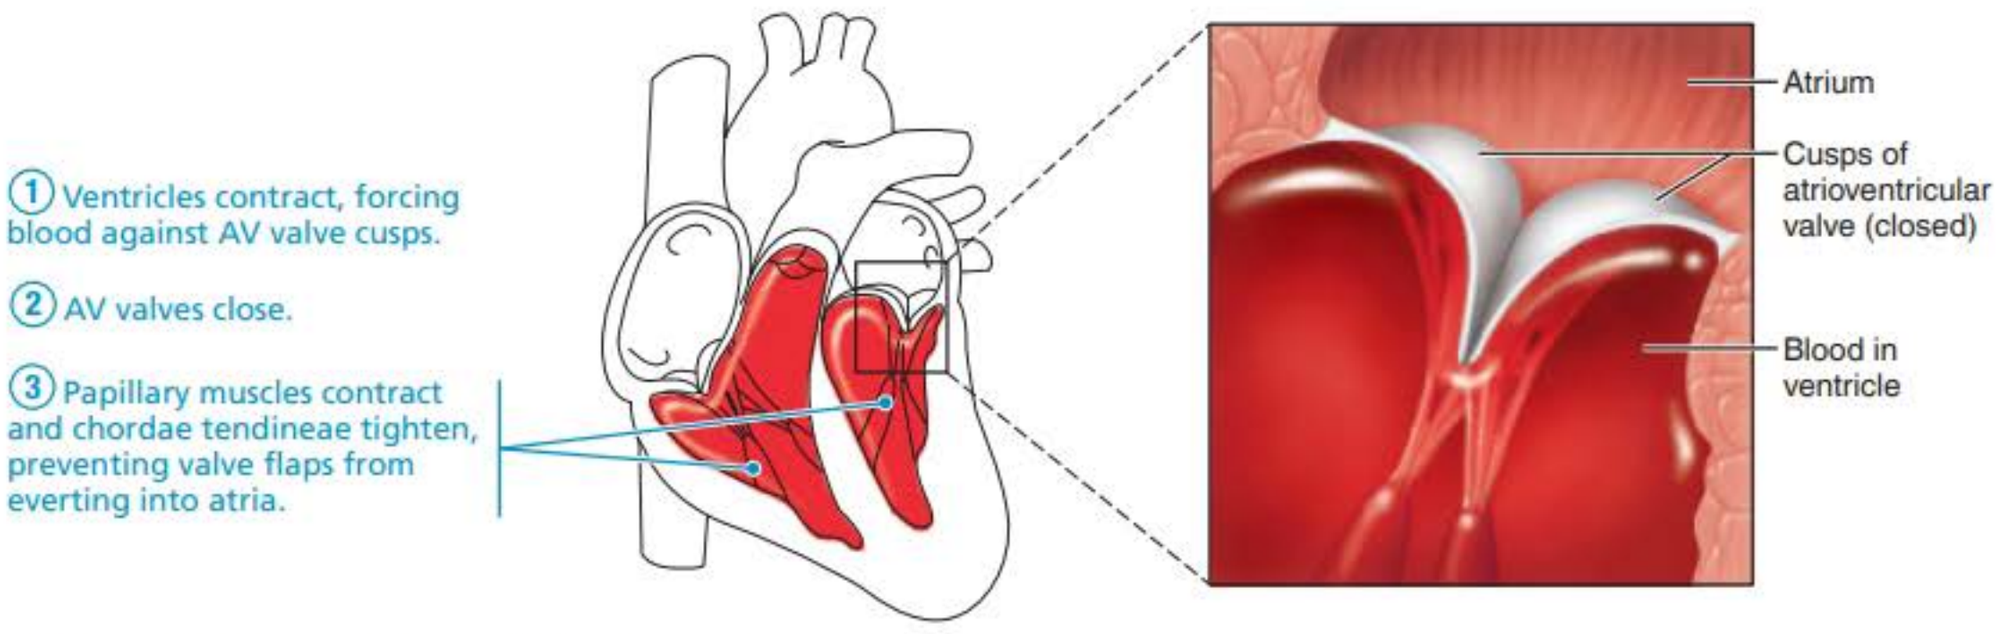
Attached to each AV valve flap are tiny white collagen cords called **chordae tendineae** (kor′de ten″dĭ′ne-e; "tendinous cords"), "heart strings" which anchor the cusps to the papillary muscles protruding from the ventricular walls (Figure 18.6c, d).

When the heart is completely relaxed, the AV valve flaps hang limply into the ventricular chambers below. During this time, blood flows into the atria and then through the open AV valves into the ventricles (**Figure 18.7a**). When the ventricles contract, compressing the blood in their chambers, the intraventricular pressure rises, forcing the blood superiorly against the valve flaps. As a result, the flap edges meet, closing the valve (Figure 18.7b).

The chordae tendineae and the papillary muscles act as tethers that anchor the valve flaps in their *closed* position. If the cusps were not anchored, they would be blown upward (everted) into the atria, in the same way an umbrella is blown inside out by a gusty wind. The papillary muscles contract with the other ventricular musculature so that they take up the slack on the chordae tendineae as the full force of ventricular contraction hurls the blood against the AV valve flaps.



(a) AV valves open; atrial pressure greater than ventricular pressure



(b) AV valves closed; atrial pressure less than ventricular pressure

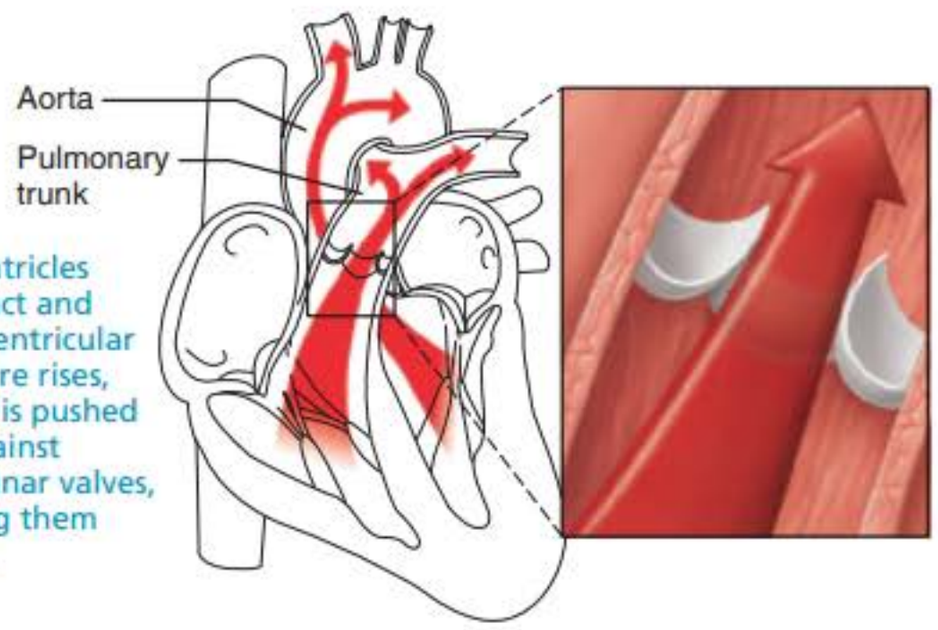
Figure 18.7 The function of the atrioventricular (AV) valves.

Semilunar (SL) Valves

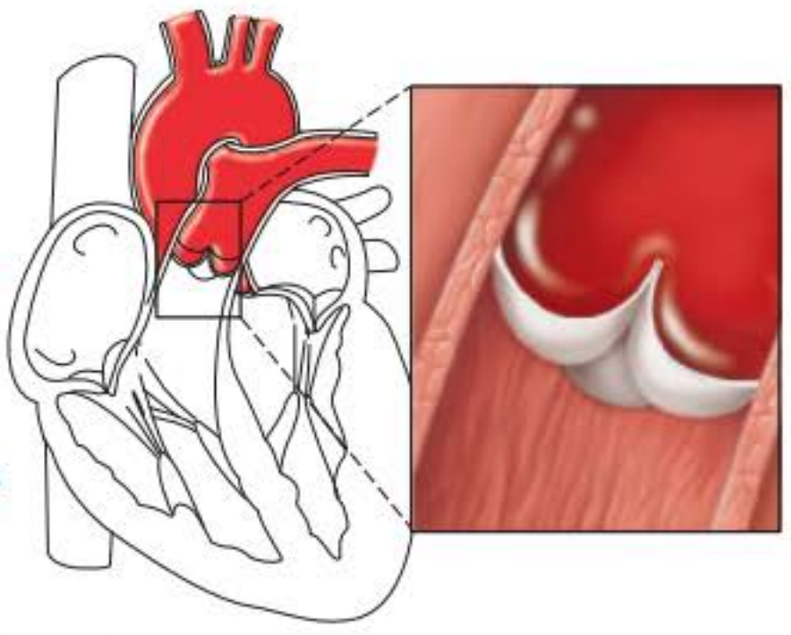
The **aortic** and **pulmonary (semilunar, SL) valves** guard the bases of the large arteries issuing from the ventricles (aorta and pulmonary trunk, respectively) and prevent backflow into the associated ventricles. Each SL valve is fashioned from three pocketlike cusps, each shaped roughly like a crescent moon (*semilunar* = half-moon).

Like the AV valves, the SL valves open and close in response to differences in pressure. When the ventricles contract and intraventricular pressure rises above the pressure in the aorta and pulmonary trunk, the SL valves are forced open and their cusps flatten against the arterial walls as blood rushes past them (**Figure 18.8a**). When the ventricles relax, and the blood flows backward toward the heart, it fills the cusps and closes the valves (Figure 18.8b).

We complete the valve story by noting what seems to be an important omission—there are no valves guarding the entrances of the venae cavae and pulmonary veins into the right and left atria, respectively. Small amounts of blood *do* spurt back into these vessels during atrial contraction, but backflow is minimal because of the inertia of the blood and because as it contracts, the atrial myocardium compresses (and collapses) these venous entry points.



(a) Semilunar valves open



(b) Semilunar valves closed

Figure 18.8 The function of the semilunar (SL) valves.

HOMEOSTATIC IMBALANCE 18.2 — CLINICAL

Heart valves are simple devices, and the heart—like any mechanical pump—can function with "leaky" valves as long as the impairment is not too great. However, severe valve deformities can seriously hamper cardiac function.

An *incompetent*, or *insufficient*, *valve* forces the heart to repump the same blood over and over because the valve does not close properly and blood backflows. In valvular *stenosis* ("narrowing"), the valve flaps become stiff and constrict the opening. [Stenosis is typically due to calcium salt deposits or scar tissue that forms following endocarditis (see Related Clinical Terms, p. 702).] The constricted opening compels the heart to contract more forcibly than normal. Both types of valve problems increase the heart's workload and may weaken the heart severely over time. The mitral and aortic valves are most often affected.

The faulty valve can be replaced with a mechanical valve, a pig or cow heart valve chemically treated to prevent rejection, or cryopreserved valves from human cadavers. Heart valves tissue-engineered from a patient's own cells grown on a biodegradable scaffold are being developed.

Check Your Understanding

5. What is the function of the papillary muscles and chordae tendineae?
6. Name the valve that has just two cusps.

For answers, see Answers Appendix.

18.3 Blood flows from atrium to ventricle, and then to either the lungs or the rest of the body

Learning Outcomes

- **Trace the pathway of blood through the heart.**
- **Name the major branches and describe the distribution of the coronary arteries.**

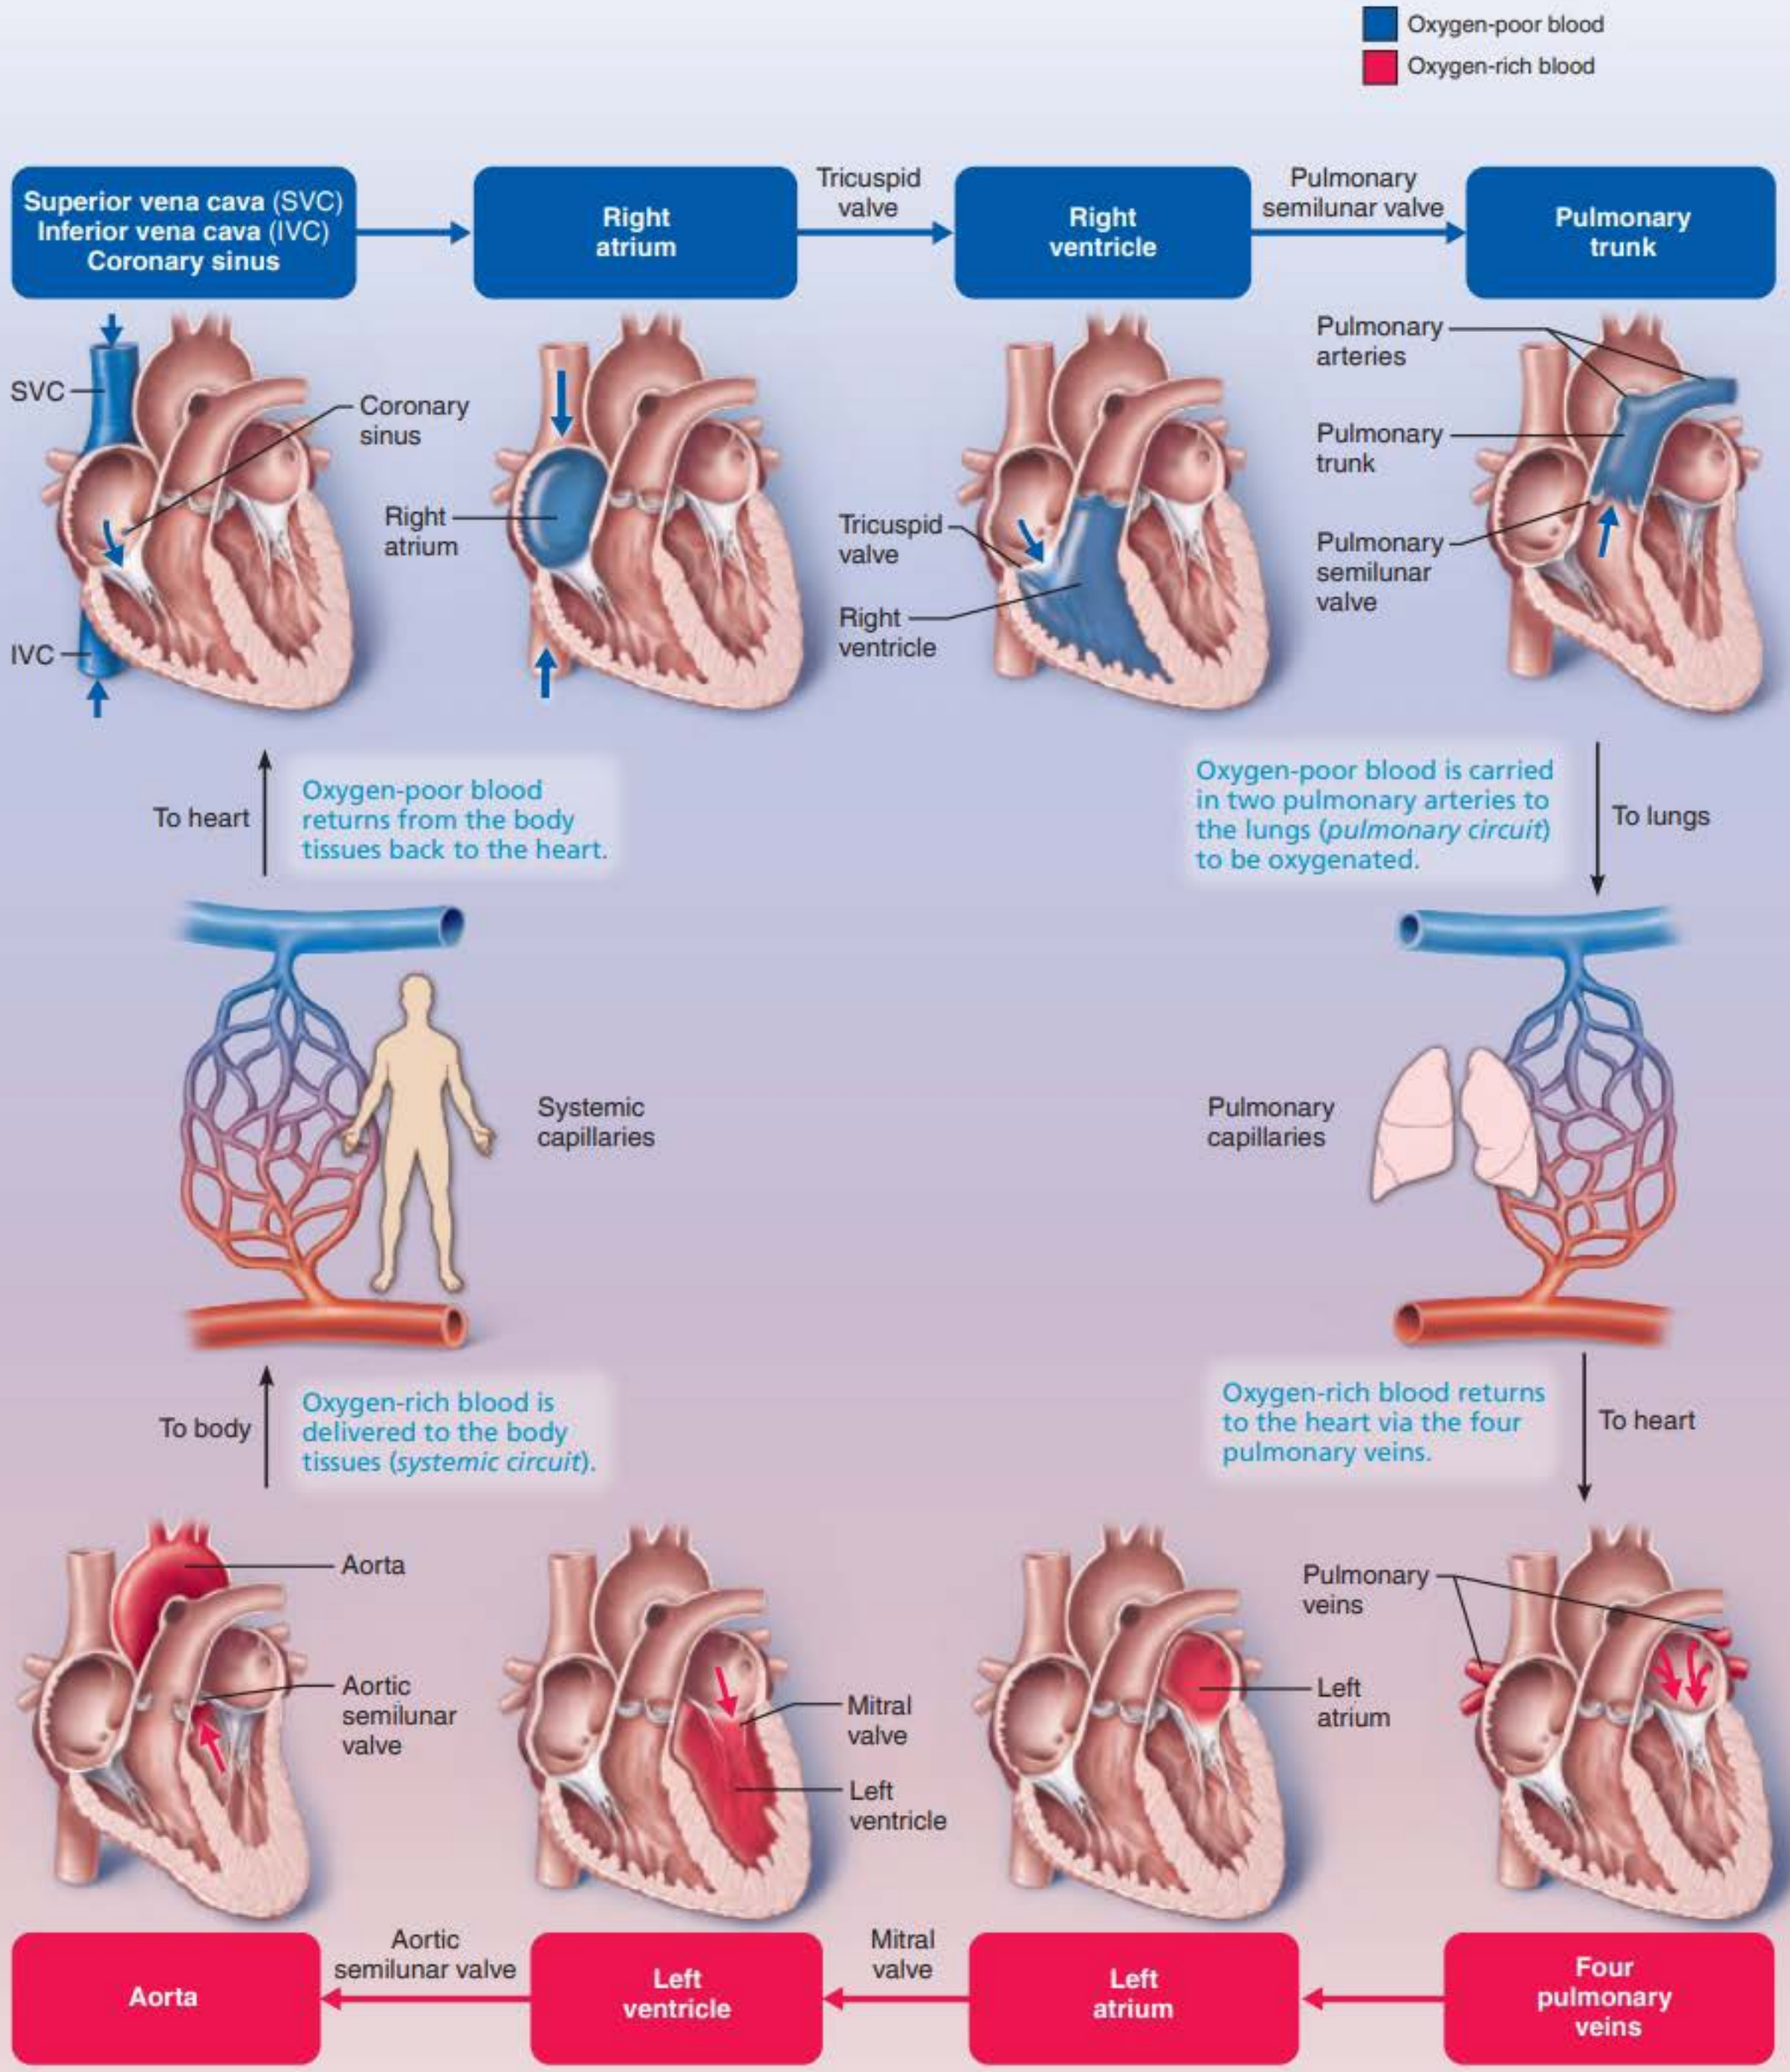
Having covered the basic anatomy of the heart, we can now follow the path that blood takes through the heart and its associated circuits. *Focus on Blood Flow through the Heart* (**Focus Figure 18.1**) follows a single "spurt" of blood as it passes through all four chambers of the heart and both blood circuits in its ever-repeating journey.

As you work your way through this figure, keep in mind that the left side of the heart is the *systemic circuit pump* and the right side is the *pulmonary circuit pump*. Notice how unique the pulmonary circuit is. Elsewhere in the body, veins carry relatively oxygen-poor blood to the heart, and arteries transport oxygen-rich blood from the heart. The opposite oxygenation conditions exist in veins and arteries of the pulmonary circuit.

Equal volumes of blood are pumped to the pulmonary and systemic circuits at any moment, but the two ventricles have very unequal workloads. The pulmonary circuit, served by the right ventricle, is a short, low-pressure circulation. In contrast, the systemic circuit, associated with the left ventricle, takes a

FOCUS FIGURE 18.1 Blood Flow through the Heart

The heart is a double pump, each side supplying its own circuit.



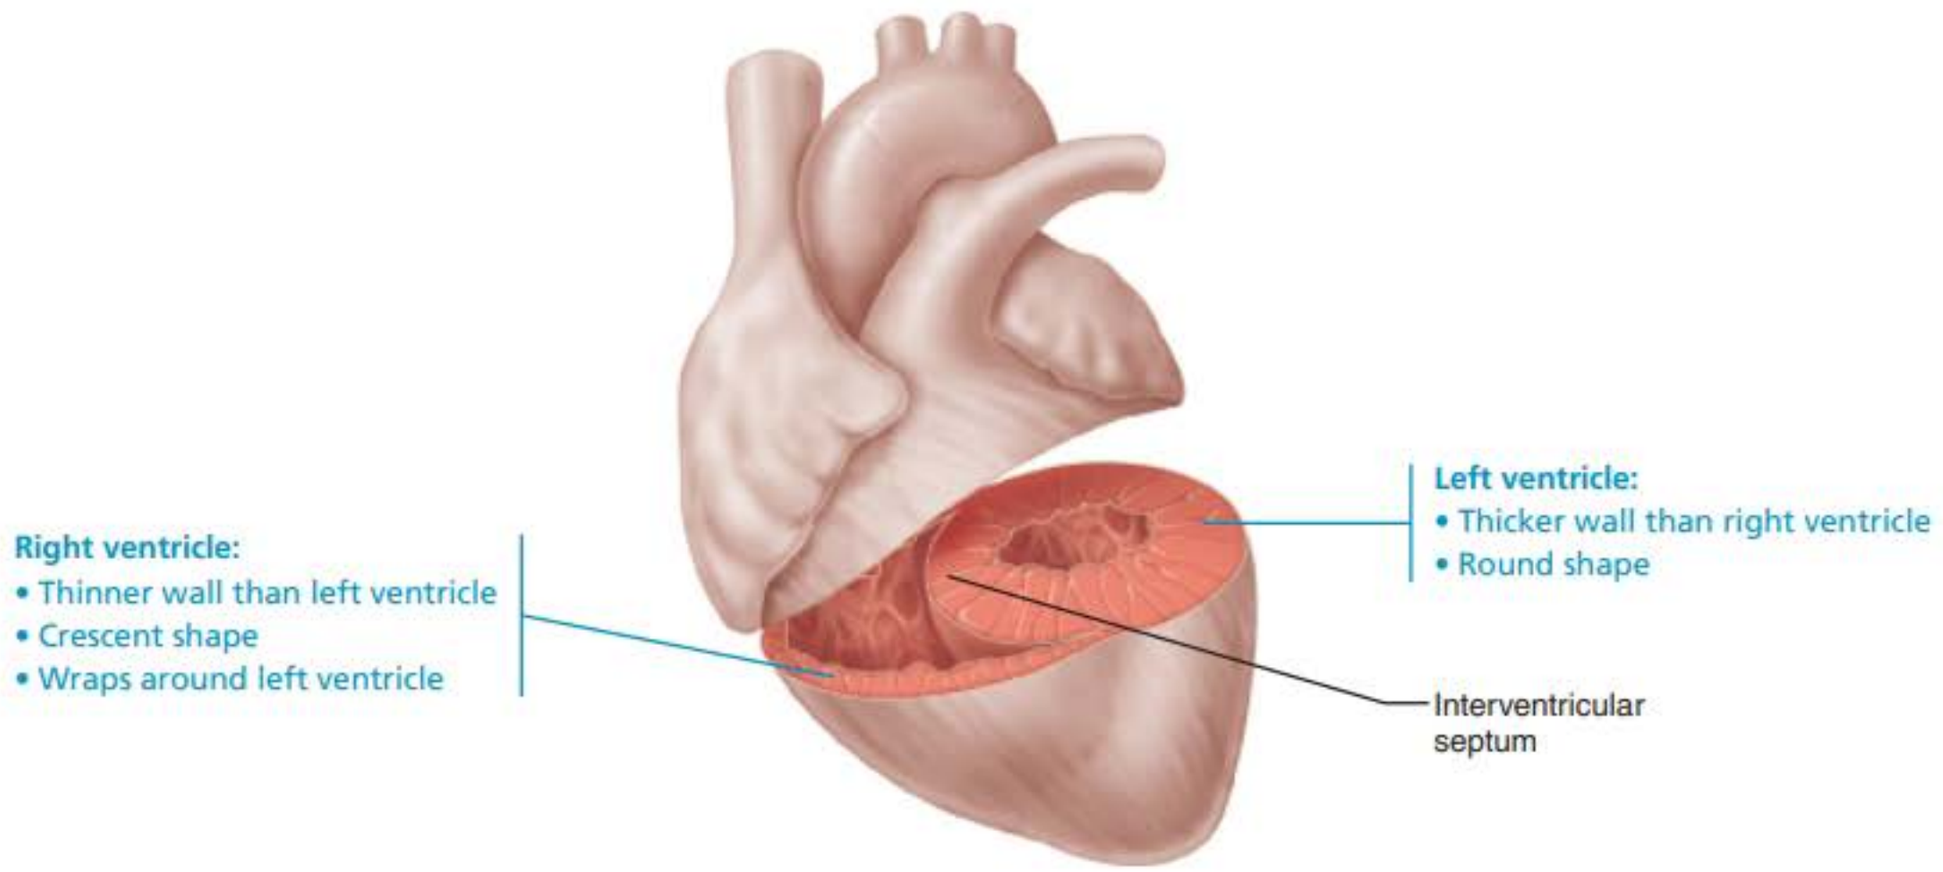


Figure 18.9 **Anatomical differences between the right and left ventricles.**

long pathway through the entire body and encounters about five times as much friction, or resistance to blood flow.

This functional difference is revealed in the anatomy of the two ventricles (Figure 18.5e and **Figure 18.9**):

- The walls of the left ventricle are three times thicker than those of the right ventricle, and its cavity is nearly circular.
- The right ventricular cavity is flattened into a crescent shape that partially encloses the left ventricle, much the way a hand might loosely grasp a clenched fist.

Consequently, the left ventricle can generate much more pressure than the right and is a far more powerful pump.

Coronary Circulation

Although the heart is continuously filled with various amounts of blood, this blood provides little nourishment to heart tissue. (The myocardium is too thick to make diffusion a practical means of delivering nutrients.) How, then, does the heart get nourishment? It does so through the **coronary circulation**, the functional blood supply of the heart and the shortest circulation in the body.

Coronary Arteries

The *left* and *right coronary arteries* both arise from the base of the aorta and encircle the heart in the coronary sulcus. They provide the arterial supply of the coronary circulation (**Figure 18.10a**).

The **left coronary artery** runs toward the left side of the heart and then divides into two major branches:

- The **anterior interventricular artery** (also known clinically as the *left anterior descending artery*) follows the anterior interventricular sulcus and supplies blood to the interventricular septum and anterior walls of both ventricles.
- The **circumflex artery** supplies the left atrium and the posterior walls of the left ventricle.

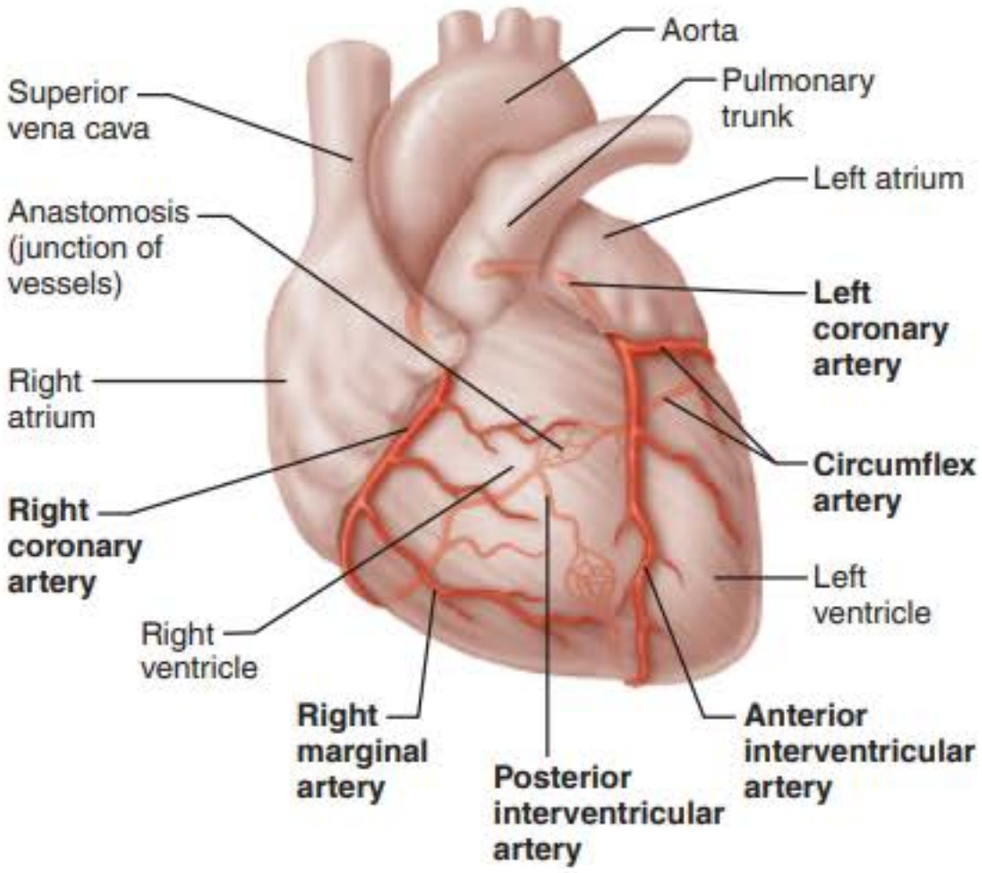
The **right coronary artery** courses to the right side of the heart, where it also gives rise to two branches:

- The **right marginal artery** serves the myocardium of the lateral right side of the heart.
- The **posterior interventricular artery** runs to the heart apex and supplies the posterior ventricular walls. Near the apex of the heart, this artery merges (anastomoses) with the anterior interventricular artery.

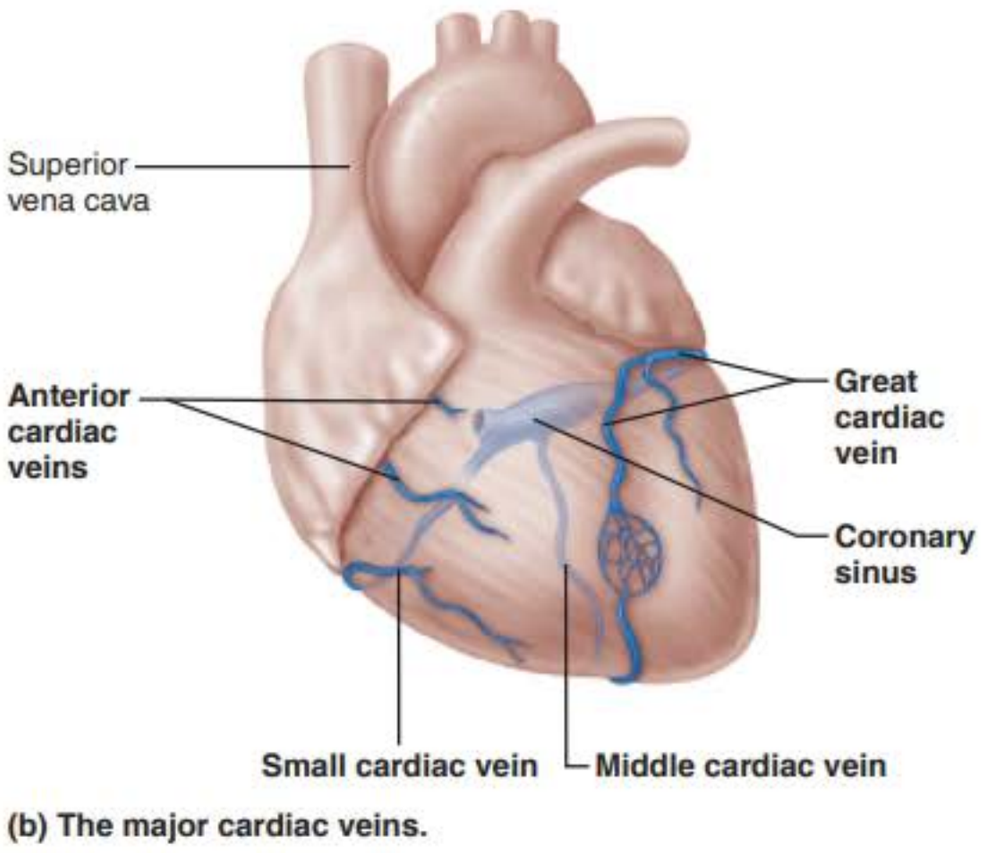
Together the branches of the right coronary artery supply the right atrium and nearly all the right ventricle.

The arterial supply of the heart varies considerably. For example, in 15% of people, the left coronary artery gives rise to *both* interventricular arteries. In about 4% of people, a single coronary artery supplies the whole heart. Additionally, there may be both right and left marginal arteries. There are many anastomoses (junctions) among the coronary arterial branches. These fusing networks provide additional (*collateral*) routes for blood delivery to the heart muscle, but are not robust enough to supply adequate nutrition when a coronary artery is suddenly occluded (blocked). Complete blockage leads to tissue death and heart attack.

The coronary arteries provide an intermittent, pulsating blood flow to the myocardium. These vessels and their main branches lie in the epicardium and send branches inward to nourish the myocardium. They deliver blood when the heart is relaxed, but are fairly ineffective when the ventricles are contracting because they are compressed by the contracting



(a) The major coronary arteries.



(b) The major cardiac veins.

Figure 18.10 Coronary circulation. In both drawings, lighter-tinted vessels are more posterior in the heart.

myocardium. Although the heart represents only about 1/200 of the body's weight, it requires about 1/20 of the body's blood supply. As might be expected, the left ventricle receives the most plentiful blood supply.

Coronary Veins

After passing through the capillary beds of the myocardium, the venous blood is collected by the **cardiac veins**, whose paths roughly follow those of the coronary arteries. These veins join to form an enlarged vessel called the **coronary sinus**, which empties the blood into the right atrium. The coronary sinus is obvious on the posterior aspect of the heart (Figure 18.10b).

The sinus has three large tributaries: the **great cardiac vein** in the anterior interventricular sulcus; the **middle cardiac vein** in the posterior interventricular sulcus; and the **small cardiac vein**, running along the heart's right inferior margin. Additionally, several **anterior cardiac veins** empty directly into the right atrium anteriorly.

HOMEOSTATIC IMBALANCE 18.3 CLINICAL

Blockage of the coronary arterial circulation can be serious and sometimes fatal. **Angina pectoris** (an-ji′nah pek′tor-is; "choked chest") is thoracic pain caused by a fleeting deficiency in blood delivery to the myocardium. It may result from stress-induced spasms of the coronary arteries or from increased physical demands on the heart. The myocardial cells are weakened by the temporary lack of oxygen but do not die.

Prolonged coronary blockage is far more serious because it can lead to a **myocardial infarction (MI)**, commonly called a **heart attack**, in which cells *do* die. Since adult cardiac muscle is essentially amitotic, most of the dead tissue is replaced with noncontractile scar tissue. Whether or not a person survives a myocardial infarction depends on the extent and location of the damage. Damage to the left ventricle—the systemic pump—is most serious.

Check Your Understanding

7. Which side of the heart acts as the pulmonary pump? The systemic pump?
8. Which of the following statements are true? (a) The left ventricle wall is thicker than the right ventricle wall. (b) The left ventricle pumps blood at a higher pressure than the right ventricle. (c) The left ventricle pumps more blood with each beat than the right ventricle. Explain.
9. Name the two main branches of the right coronary artery.

18.4 Intercalated discs connect cardiac muscle fibers into a functional syncytium

Learning Outcomes

- **Describe the structural and functional properties of cardiac muscle, and explain how it differs from skeletal muscle.**
- **Briefly describe the events of excitation-contraction coupling in cardiac muscle cells.**

Although similar to skeletal muscle, cardiac muscle displays some special anatomical features that reflect its unique blood-pumping role.

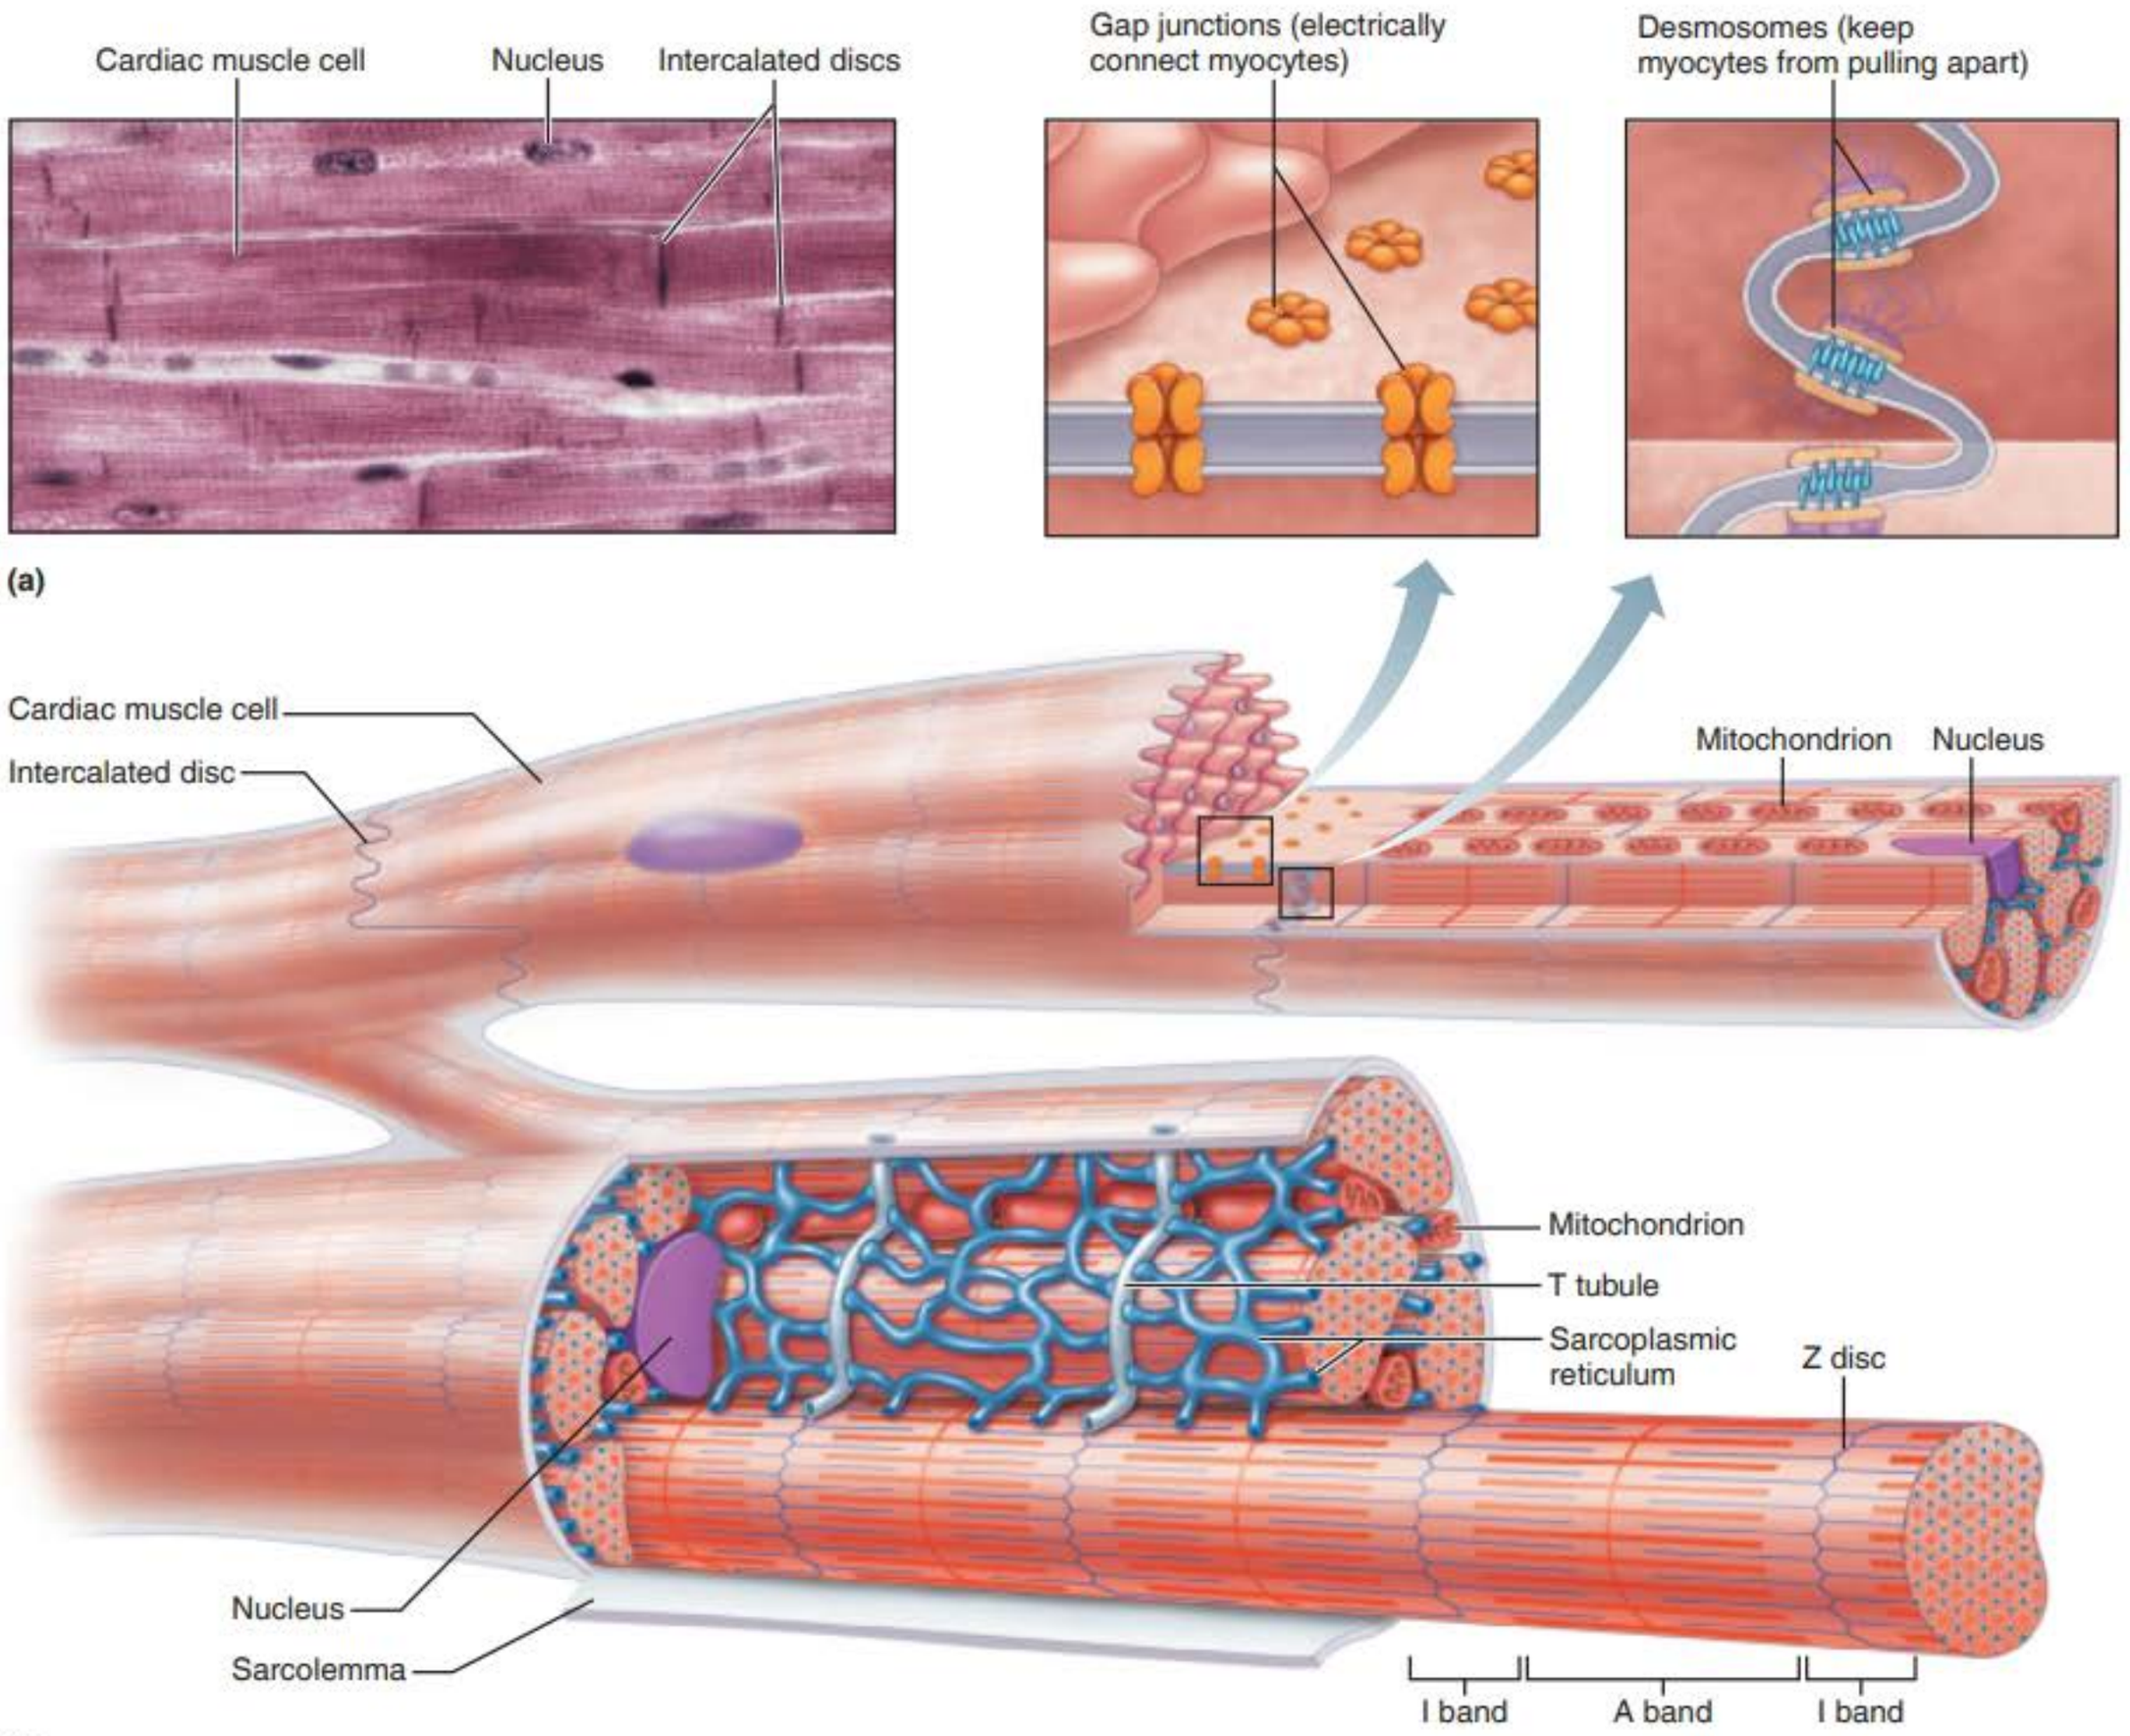

Figure 18.11 Microscopic anatomy of cardiac muscle. (a) Photomicrograph of cardiac muscle (290×). Notice that the cardiac muscle cells are short, branched, and striated. The dark-staining areas are intercalated discs, or junctions, between adjacent cells. **(b)** Components of intercalated discs and cardiac muscle fibers.

Microscopic Anatomy

Like skeletal muscle, **cardiac muscle** is striated and contracts by the sliding filament mechanism. However, in contrast to the long, cylindrical, multinucleate skeletal muscle fibers, cardiac cells are short, fat, branched, and interconnected. Each *cardiac myocyte* (*myo* = muscle, *cyte* = cell) contains one or at most two large, pale, *centrally* located nuclei (**Figure 18.11a**). The intercellular spaces are filled with a loose connective tissue matrix (the *endomysium*) containing numerous capillaries. This delicate matrix is connected to the fibrous cardiac skeleton, which acts both as a tendon and as an insertion, giving the cardiac cells something to pull or exert their force against.

Skeletal muscle fibers are independent of one another both structurally and functionally. In contrast, the plasma membranes of adjacent cardiac cells interlock like the ribs of two sheets of corrugated cardboard at dark-staining junctions called **intercalated discs** (in-ter′kah-la″ted; *intercala* = insert) (Figure 18.11). Intercalated discs contain anchoring *desmosomes* and *gap junctions* (cell junctions discussed in Chapter 3, ◀ pp. 67–68). The desmosomes prevent adjacent cells from separating during contraction, and the gap junctions allow ions to pass from cell to cell, transmitting current across the entire heart. Because gap junctions electrically couple cardiac cells, the myocardium *behaves* as a single coordinated unit, or **functional syncytium** (sin-sit′e-um; *syn* = together, *cyt* = cell).

Large mitochondria account for 25–35% of the volume of cardiac cells (compared with only 2% in skeletal muscle), a characteristic that makes cardiac cells highly resistant to fatigue. Most of the remaining volume is occupied by myofibrils composed of fairly typical sarcomeres. The sarcomeres have Z discs, A bands, and I bands that reflect the arrangement of the thick (myosin) and thin (actin) filaments composing them. However, in contrast to skeletal muscle, the myofibrils of cardiac muscle cells vary greatly in diameter and branch extensively, accommodating the abundant mitochondria between them. This difference produces a banding pattern less dramatic than that seen in skeletal muscle.

The system for delivering Ca^{2+} is less elaborate in cardiac muscle cells. The cardiac sarcoplasmic reticulum is simpler and lacks the large terminal cisterns seen in skeletal muscle. As a result, cardiac muscle fibers do not have *triads*. In addition, the T tubules are wider and fewer than in skeletal muscle. They enter the cells once per sarcomere at the Z discs. (Recall that T tubules are invaginations of the sarcolemma. In skeletal muscle, the T tubules invaginate twice per sarcomere, at the A band–I band junctions; ◀ p. 288.)

How Does the Physiology of Skeletal and Cardiac Muscle Differ?

Both skeletal muscle and cardiac muscle are contractile tissues, and in both types of muscle the contraction is preceded by a depolarization in the form of an action potential (AP). Transmission of the depolarization wave down the T tubules (ultimately) causes the sarcoplasmic reticulum (SR) to release Ca^{2+} into the sarcoplasm. Excitation-contraction coupling occurs as Ca^{2+} provides the signal (via troponin binding) for cross bridge activation. This sequence of events couples the depolarization wave to the sliding of the myofilaments in both skeletal and cardiac muscle cells. However, cardiac muscle fibers differ from skeletal muscle fibers as summarized in **Table 18.1** and ◀ Table 9.3 (pp. 312–313), and as described below.

- **Some cardiac muscle cells are self-excitable.** The heart contains two kinds of myocytes. Almost all of the myocytes are *contractile cardiac muscle cells*, responsible for the heart's pumping activity. However, certain locations in the heart contain special noncontractile cells, called *pacemaker cells*, that spontaneously depolarize. This property is called **automaticity** or **autorhythmicity**. Because heart cells are electrically joined together by gap junctions, these cells can initiate not only their own depolarization, but also that of the rest of the heart. No neural input is required. As demonstrated by transplanted hearts, you can cut all of the nerves to the heart and it still beats. In contrast, each skeletal muscle fiber must be stimulated by a nerve ending to contract, and cutting the nerves results in paralysis.
- **The heart contracts as a unit.** As we just learned, gap junctions tie cardiac muscle cells together to form a functional syncytium. This allows the wave of depolarization to travel from cell to cell across the heart. As a result, either all fibers in the heart contract as a unit or the heart doesn't contract at all. In skeletal muscle, on the other hand, impulses do not spread from cell to cell. Only skeletal muscle fibers that are individually stimulated by nerve fibers contract, and the strength of the contraction increases as more motor units are recruited. Such recruitment cannot happen in the heart because it acts as a single huge motor unit. Contraction of all of the cardiac myocytes ensures effective pumping by the heart—a half-hearted contraction would just not do.
- **The influx of Ca^{2+} from extracellular fluid triggers Ca^{2+} release from the SR.** Recall that in skeletal muscle, the wave of depolarization directly causes release from the SR of all the Ca^{2+} required for contraction. In cardiac muscle, depolarization opens special Ca^{2+} channels in the plasma membrane. These *slow Ca^{2+} channels* allow entry of 10–20% of the Ca^{2+} needed for contraction. Once inside, this influx of Ca^{2+} triggers Ca^{2+}-sensitive channels in the SR to release bursts of Ca^{2+} ("calcium sparks") that account for the other 80–90% of the Ca^{2+} needed for contraction.
- **Tetanic contractions cannot occur in cardiac muscles.** The absolute refractory period is the period during an action potential when another action potential cannot be triggered. In skeletal muscle, the absolute refractory period is much shorter than the contraction, allowing multiple contractions to summate (tetanic contractions). If the heart were to contract tetanically, it would be unable to relax and fill, and so would be useless as a pump. The absolute refractory period in the heart is nearly as long as the contraction itself, which prevents tetanic contractions. We will examine the mechanism

Table 18.1 Key Differences between Skeletal and Cardiac Muscle

	SKELETAL MUSCLE	CARDIAC MUSCLE
Structure	Striated, long, cylindrical, multinucleate	Striated, short, branched, one or two nuclei per cell
Gap junctions between cells	No	Yes
Contracts as a unit	No, motor units must be stimulated individually	Yes, gap junctions create a functional syncytium
T tubules	Abundant	Fewer, wider
Sarcoplasmic reticulum	Elaborate; has terminal cisterns	Less elaborate; no terminal cisterns
Source of Ca^{2+} for contraction	Sarcoplasmic reticulum only	Sarcoplasmic reticulum and extracellular fluid
Ca^{2+} binds to troponin	Yes	Yes
Pacemaker cells present	No	Yes
Tetanus possible	Yes	No
Supply of ATP	Aerobic and anaerobic (fewer mitochondria)	Aerobic only (more mitochondria)

underlying the long refractory period of contractile cardiac myocytes shortly.

- **The heart relies almost exclusively on aerobic respiration.** Cardiac muscle has more mitochondria than skeletal muscle does, reflecting its greater dependence on oxygen for its energy metabolism. The heart relies almost exclusively on aerobic respiration, so cardiac muscle cannot operate effectively for long without oxygen. This is in contrast to skeletal muscle, which can contract for prolonged periods by carrying out anaerobic respiration, and then restore its reserves of oxygen and fuel using excess postexercise oxygen consumption (EPOC).

Both types of muscle tissue use multiple fuel molecules, including glucose and fatty acids. But cardiac muscle is much more adaptable and readily switches metabolic pathways to use whatever nutrients are available, including lactic acid generated by skeletal muscle activity. Consequently, the real danger of an inadequate blood supply to the myocardium is not lack of nutrients, but lack of oxygen.

Check Your Understanding

10. For each of the following, state whether it applies to skeletal muscle, cardiac muscle, or both: (a) refractory period is almost as long as the contraction; (b) source of Ca^{2+} for contraction is only SR; (c) has troponin; (d) has triads.

11. MAKE CONNECTIONS Identify the type of muscle represented by structures a and b below. How can you tell?

For answers, see Answers Appendix.

18.5 Pacemaker cells trigger action potentials throughout the heart

Learning Outcomes

- **Describe and compare action potentials in cardiac pacemaker and contractile cells.**
- **Name the components of the conduction system of the heart, and trace the conduction pathway.**
- **Draw a diagram of a normal electrocardiogram tracing. Name the individual waves and intervals, and indicate what each represents. Name some abnormalities that can be detected on an ECG tracing.**

Although the ability of the heart to depolarize and contract is intrinsic (no nerves required), the healthy heart *is* supplied with autonomic nerve fibers that alter its basic rhythm. In this module, we examine how the basic rhythm is generated and modified.

Setting the Basic Rhythm: The Intrinsic Conduction System

The independent, but coordinated, activity of the heart is a function of (1) the presence of gap junctions, and (2) the activity of the heart's "in-house" conduction system. The **intrinsic cardiac conduction system** consists of noncontractile cardiac cells specialized to initiate and distribute impulses throughout the heart, so that it depolarizes and contracts in an orderly, sequential manner. Let's look at how this system works.

Action Potential Initiation by Pacemaker Cells

Unstimulated contractile cells of the heart (and neurons and skeletal muscle fibers) maintain a stable resting membrane potential. However, about 1% of cardiac fibers are autorhythmic ("self-rhythmic") **cardiac pacemaker cells**, having the special ability to depolarize spontaneously and so pace the heart. Pacemaker cells are a part of the intrinsic conduction system. They have an *unstable resting potential* that continuously depolarizes, drifting slowly toward threshold. These spontaneously changing membrane potentials, called **pacemaker potentials** or **prepotentials**, initiate the action potentials that spread throughout the heart to trigger its rhythmic contractions. Let's look at the three parts of an action potential in typical pacemaker cells as shown in **Figure 18.12**.

1. **Pacemaker potential.** The pacemaker potential is due to the special properties of the ion channels in the sarcolemma. In these cells, hyperpolarization at the end of an action potential both closes K^+ channels and opens slow Na^+ channels. The Na^+ influx alters the balance between K^+ loss and Na^+ entry, and the membrane interior becomes less and less negative (more positive).
2. **Depolarization.** Ultimately, at threshold (approximately −40 mV), **Ca^{2+} channels** open, allowing explosive entry of Ca^{2+} from the extracellular space. As a result, in pacemaker cells, it is the influx of Ca^{2+} (rather than Na^+) that produces the rising phase of the action potential and reverses the membrane potential.
3. **Repolarization.** Ca^{2+} channels inactivate. As in other excitable cells, the falling phase of the action potential and repolarization reflect opening of K^+ channels and K^+ efflux from the cell.

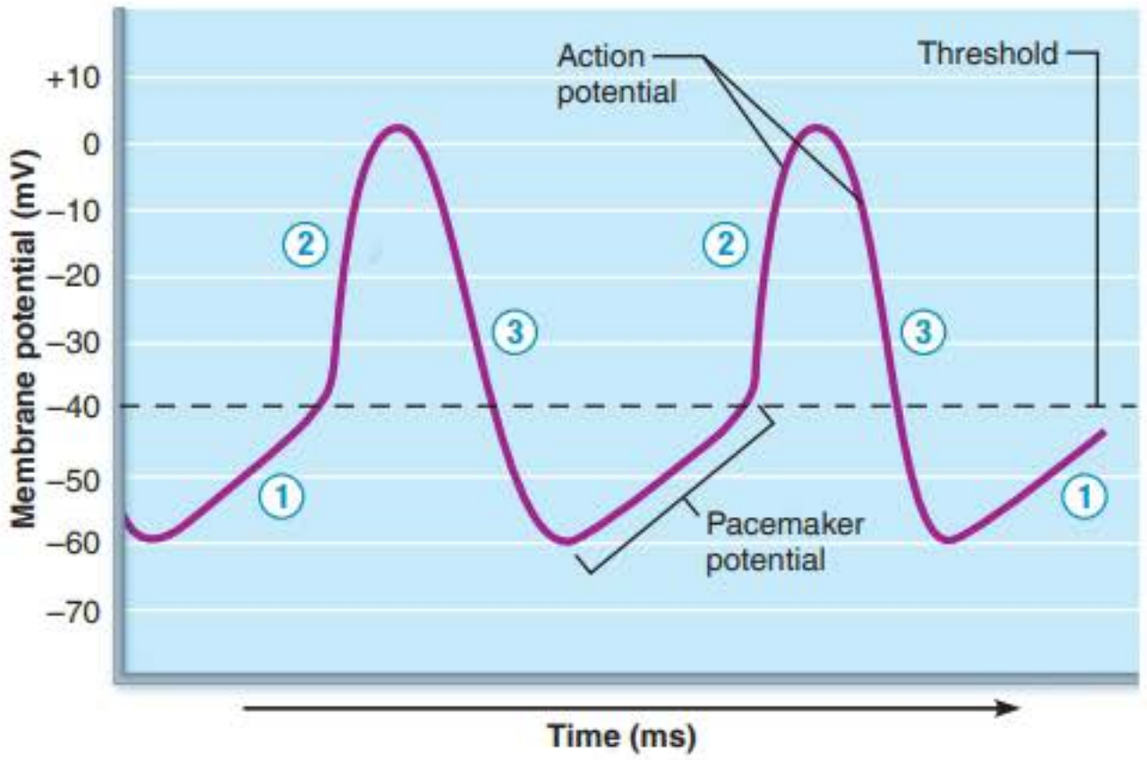
Once repolarization is complete, K^+ channels close, K^+ efflux declines, and the slow depolarization to threshold begins again.

Sequence of Excitation

Typical cardiac pacemaker cells are found in the *sinoatrial* (si″no-a′tre-al) and *atrioventricular nodes* (**Figure 18.13**). In addition, cells of the atrioventricular bundle, right and left bundle branches, and subendocardial conducting network (Purkinje fibers) can sometimes act as pacemakers. Impulses pass across the heart in order from (1) to (5) following the yellow pathway in Figure 18.13a.

Complete an interactive tutorial: MasteringA&P® > Study Area > Interactive Physiology

1. **Sinoatrial (SA) node.** The crescent-shaped **sinoatrial node** is located in the right atrial wall, just inferior to the entrance of the superior vena cava. A minute cell mass with a mammoth job, the SA node typically generates impulses about 75 times every minute. The SA node sets the pace for the



1 **Pacemaker potential** This slow depolarization is due to both opening of Na^+ channels and closing of K^+ channels. Notice that the membrane potential is never a flat line.

2 **Depolarization** The action potential begins when the pacemaker potential reaches threshold. Depolarization is due to Ca^{2+} influx through Ca^{2+} channels.

3 **Repolarization** is due to Ca^{2+} channels inactivating and K^+ channels opening. This allows K^+ efflux, which brings the membrane potential back to its most negative voltage.

Figure 18.12 Pacemaker and action potentials of typical cardiac pacemaker cells.

heart as a whole because no other region of the conduction system or the myocardium has a faster depolarization rate. For this reason, it is the heart's **pacemaker**, and its characteristic rhythm, called **sinus rhythm**, determines heart rate.

② **Atrioventricular (AV) node.** From the SA node, the depolarization wave spreads via gap junctions throughout the atria and via the *internodal pathway* to the **atrioventricular node**, located in the inferior portion of the interatrial septum immediately above the tricuspid valve. At the AV node, the impulse is delayed for about 0.1 second, allowing the atria to respond and complete their contraction before the ventricles contract. This delay reflects the smaller diameter of the fibers here and the fact that they have fewer gap junctions for current flow. Consequently, the AV node conducts impulses more slowly than other parts of the system, just as traffic slows when cars are forced to merge from four lanes into two. Once through the AV node, the signaling impulse passes rapidly through the rest of the system.

③ **Atrioventricular (AV) bundle.** From the AV node, the impulse sweeps to the **atrioventricular bundle** (also called the *bundle of His*) in the superior part of the interventricular septum. Although the atria and ventricles are adjacent to each other, they are *not* connected by gap junctions. The AV bundle is the *only* electrical connection between them. The fibrous cardiac skeleton is nonconducting and insulates the rest of the AV junction.

④ **Right and left bundle branches.** The short AV bundle splits into two pathways—the **right** and **left bundle branches**, which course along the interventricular septum toward the heart apex.

⑤ **Subendocardial conducting network.** Essentially long strands of barrel-shaped cells with few myofibrils, the **subendocardial conducting network**, also called *Purkinje fibers* (pur-kin′je), completes the pathway through the interventricular septum, penetrates into the heart apex, and then turns superiorly into the ventricular walls. The bundle branches excite the cells of the interventricular septum, but the bulk of ventricular depolarization depends on the large

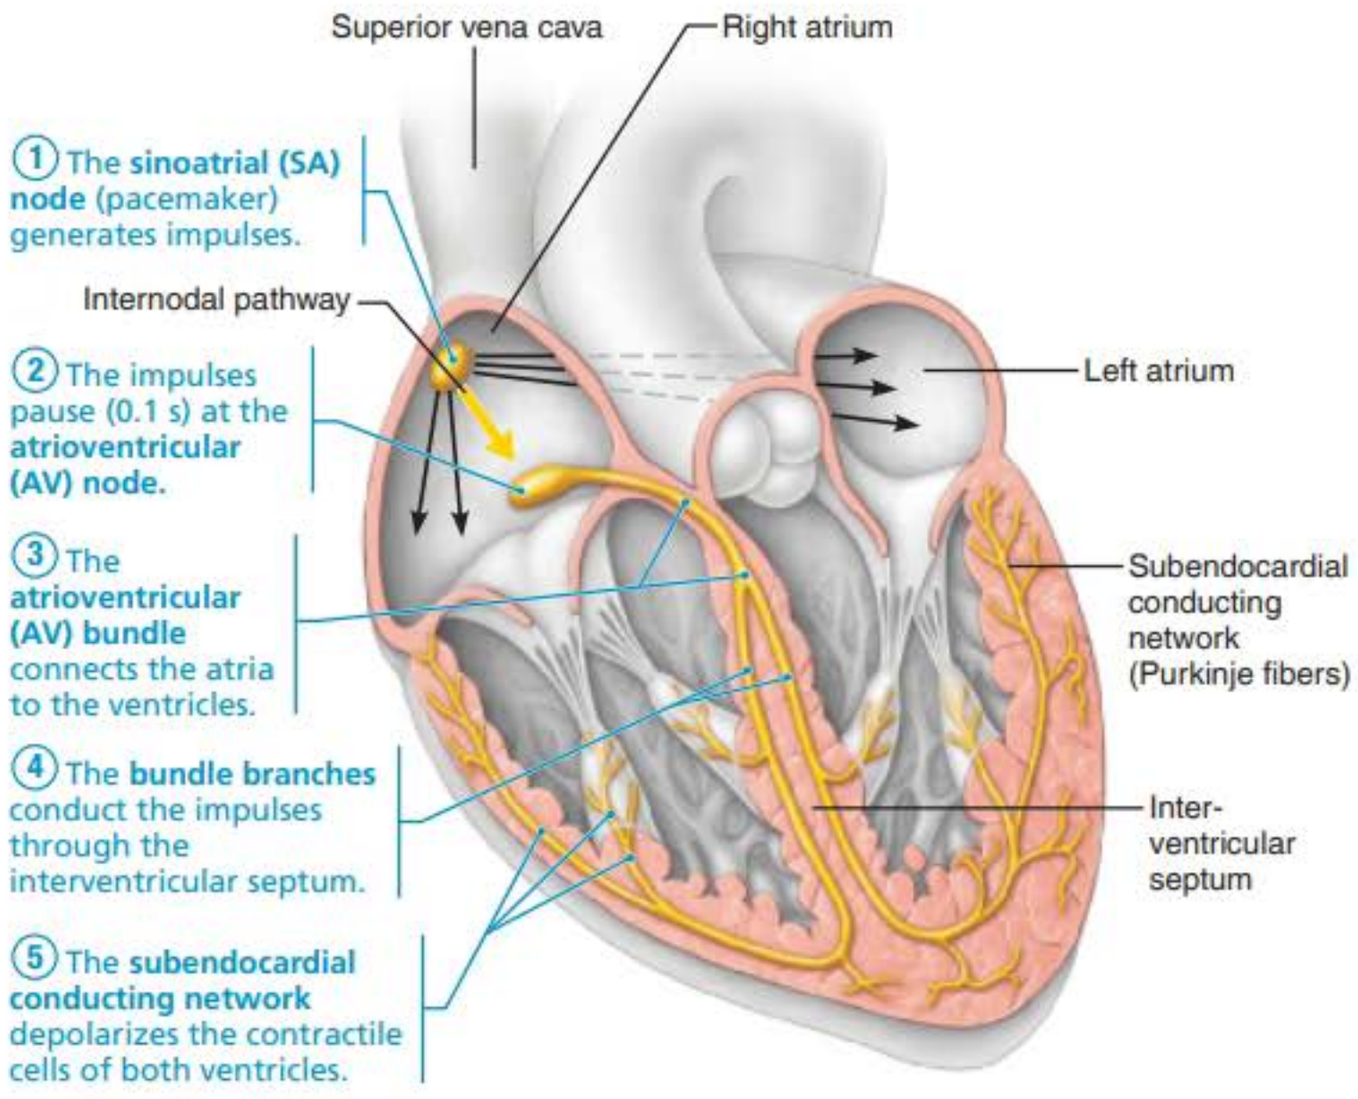


Figure 18.13 The intrinsic cardiac conduction system.

fibers of the conducting network and, ultimately, on cell-to-cell transmission of the impulse via gap junctions between the ventricular muscle cells. Because the left ventricle is much larger than the right, the subendocardial conducting network is more elaborate in that side of the heart.

The total time between initiation of an impulse by the SA node and depolarization of the last of the ventricular muscle cells is approximately 0.22 s (220 ms) in a healthy human heart.

Ventricular contraction almost immediately follows the ventricular depolarization wave. The wringing motion of contraction begins at the heart apex and moves toward the atria, following the direction of the excitation wave through the ventricle walls. This contraction ejects some of the contained blood *superiorly* into the large arteries leaving the ventricles.

The various cardiac pacemaker cells have different rates of spontaneous depolarization. The SA node normally drives the heart at a rate of 75 beats per minute. Without SA node input, the AV node would depolarize only about 50 times per minute. Without input from the AV node, the atypical pacemakers of the AV bundle and the subendocardial conducting network would depolarize only about 30 times per minute. Note that these slower pacemakers cannot dominate the heart unless faster pacemakers stop functioning.

The cardiac conduction system coordinates and synchronizes heart activity. Without it, impulses would travel much more slowly. This slower rate would allow some muscle fibers to contract long before others, reducing pump effectiveness.

HOMEOSTATIC IMBALANCE 18.4 — CLINICAL

Defects in the intrinsic conduction system can cause irregular heart rhythms, or **arrhythmias** (ah-rith′me-ahz). They may also cause uncoordinated atrial and ventricular contractions, or even **fibrillation**, a condition of rapid and irregular or out-of-sync contractions in which control of heart rhythm by the SA node is disrupted by rapid activity in other heart regions. The heart in fibrillation has been compared with a squirming bag of worms. Fibrillating ventricles are useless as pumps; and unless the heart is defibrillated quickly, circulation stops and brain death occurs.

Defibrillation is accomplished by electrically shocking the heart, which interrupts its chaotic twitching by depolarizing the entire myocardium. The hope is that "with the slate wiped clean" the SA node will begin to function normally and sinus rhythm will be reestablished. Implantable cardioverter defibrillators (ICDs) can continually monitor heart rhythms and slow an abnormally fast heart rate or emit an electrical shock if the heart begins to fibrillate.

A defective SA node may have several consequences. An **ectopic focus** (ek-top′ik) (an abnormal pacemaker) may appear and take over the pacing of heart rate, or the AV node may become the pacemaker. The pace set by the AV node (**junctional rhythm**) is 40 to 60 beats per minute, slower than sinus rhythm but still adequate to maintain circulation.

Occasionally, ectopic pacemakers appear even when the SA node is operating normally. A small region of the heart becomes hyperexcitable, sometimes as a result of too much caffeine or nicotine, and generates impulses more quickly than the SA node. This leads to a *premature contraction* or **extrasystole** (ek″strah-sis′to-le) before the SA node initiates the next contraction. Then, because the heart has a longer time to fill, the next (normal) contraction is felt as a thud. While premature *ventricular* contractions (PVCs) may be unsettling, most are harmless. Persistent PVCs require evaluation.

The only route for impulse transmission from atria to ventricles is through the AV node, AV bundle, and bundle branches. Damage to any of these structures interferes with the ability of the ventricles to receive pacing impulses, and may cause **heart block**. In total heart block, no impulses get through and the ventricles beat at their intrinsic rate, which is too slow to maintain adequate circulation. In partial heart block, only some of

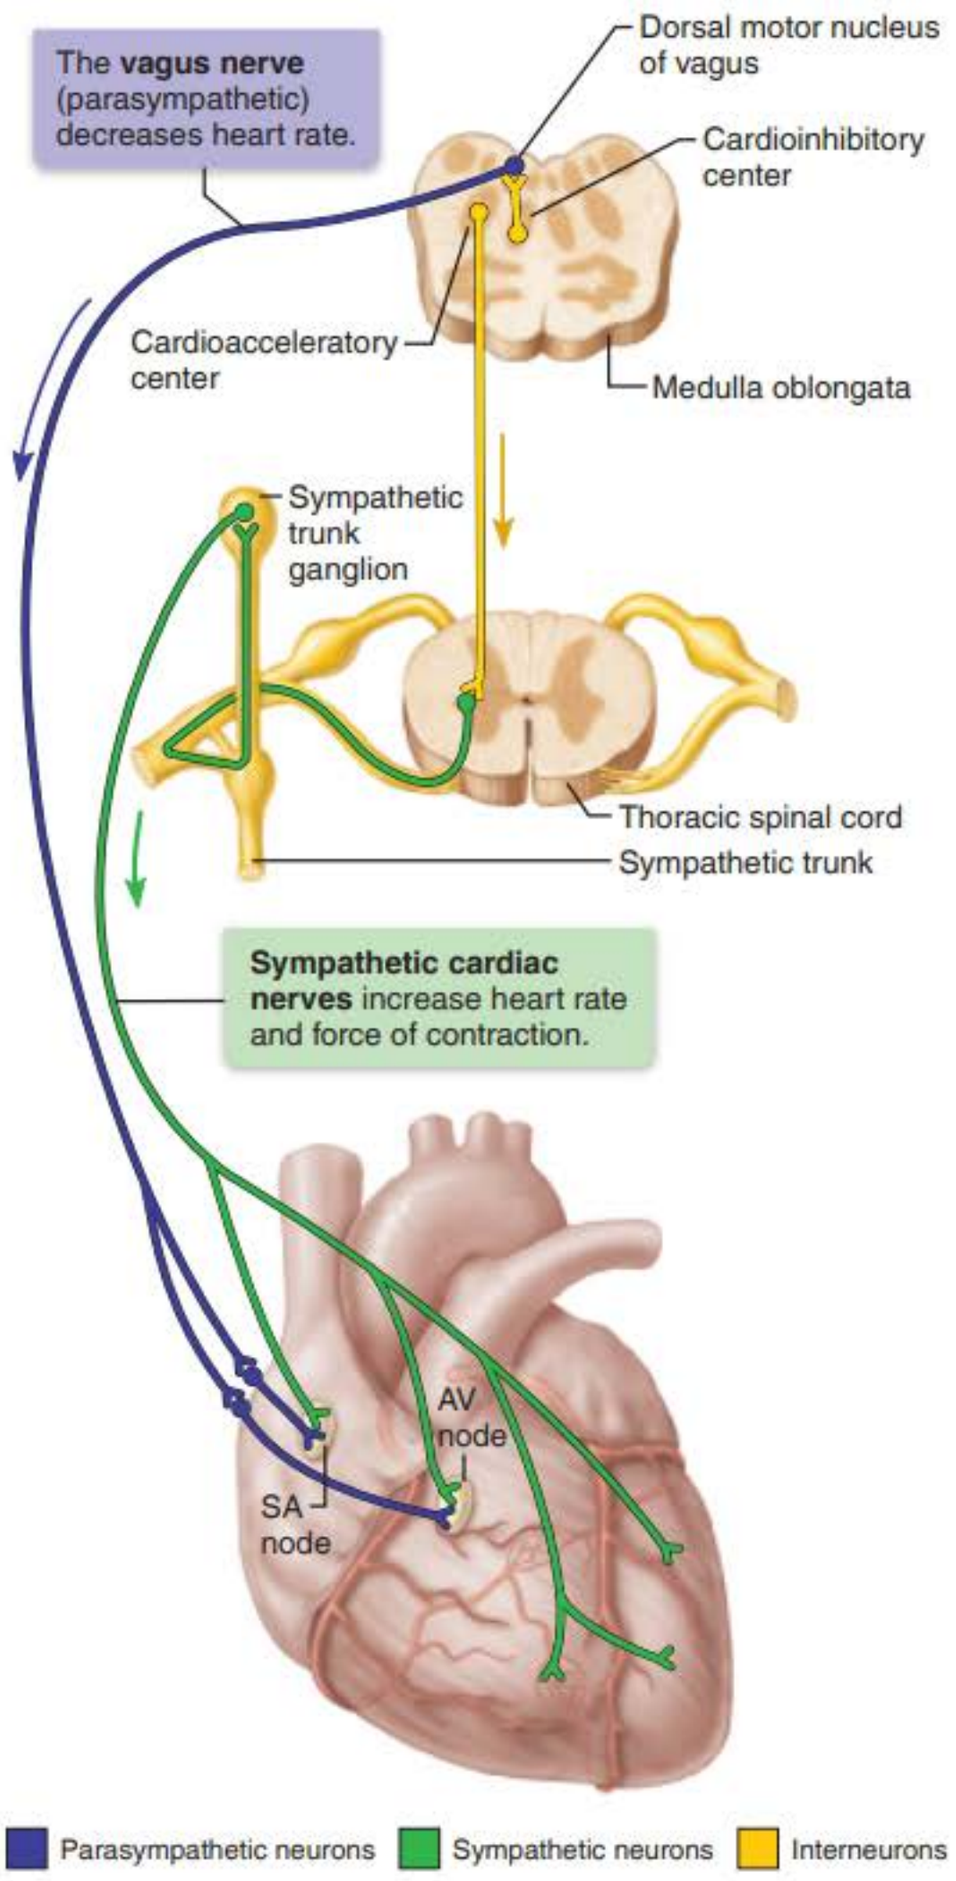

Figure 18.14 Autonomic innervation of the heart.

the atrial impulses reach the ventricles. In both cases, artificial pacemakers are implanted to recouple the atria to the ventricles as necessary. These programmable devices speed up in response to increased physical activity just as a normal heart would, and many can send diagnostic information to the patient's doctor.

Modifying the Basic Rhythm: Extrinsic Innervation of the Heart

Although the intrinsic conduction system sets the basic heart rate, fibers of the autonomic nervous system modify the march-like beat and introduce a subtle variability from one beat to the next. The sympathetic nervous system (the "accelerator") increases both the rate and the force of the heartbeat. Parasympathetic activation (the "brakes") slows the heart. We explain these neural controls later—here we discuss the anatomy of the nerve supply to the heart.

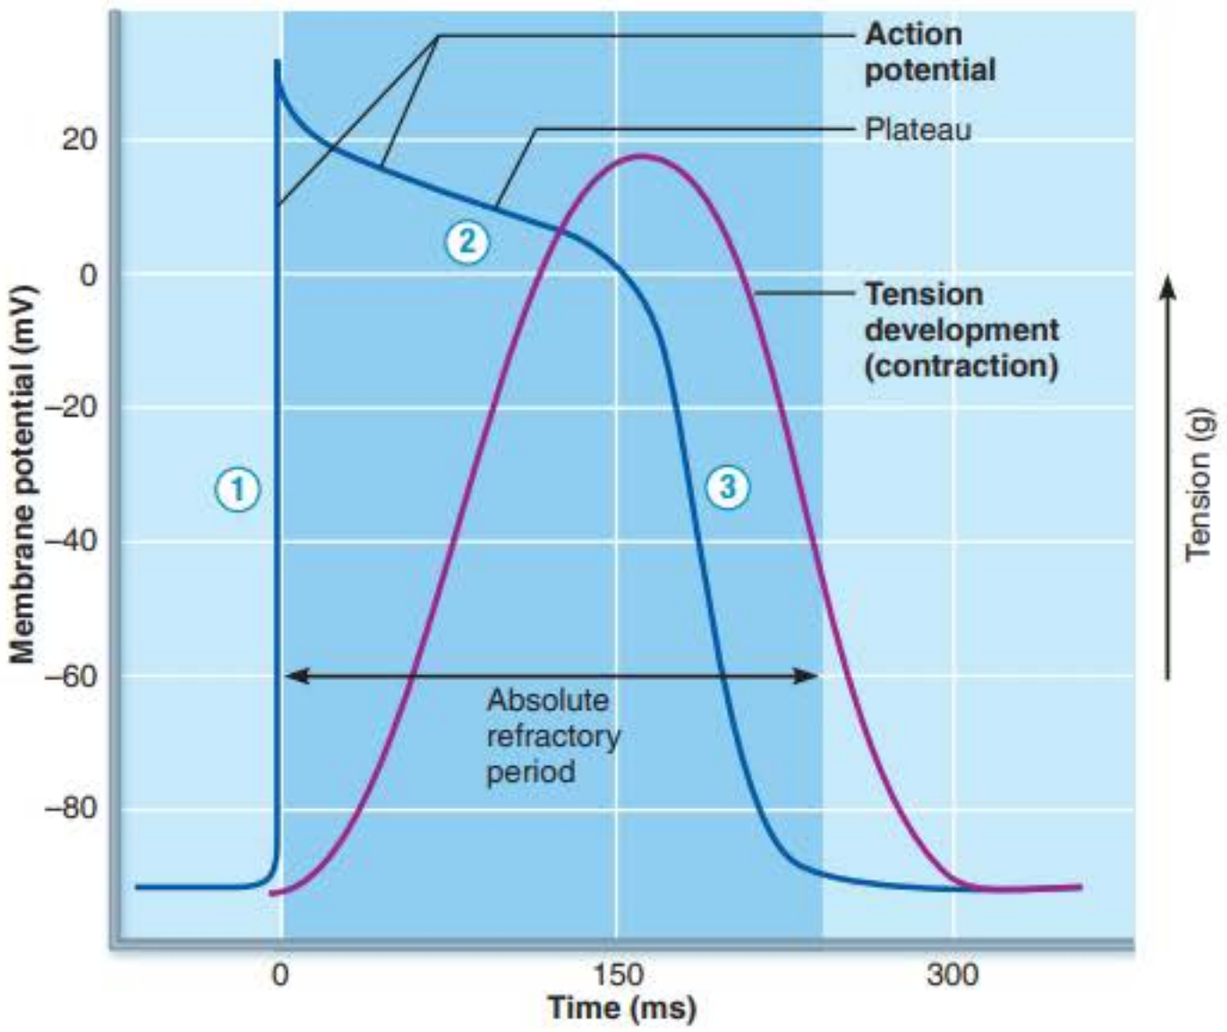
The cardiac centers are located in the medulla oblongata (◀ p. 454). The **cardioacceleratory center** projects to sympathetic neurons in the T_1–T_5 level of the spinal cord. These preganglionic neurons, in turn, synapse with postganglionic neurons in the cervical and upper thoracic sympathetic trunk (**Figure 18.14**). From there, postganglionic fibers run through the cardiac plexus to the heart where they innervate the SA and AV nodes, heart muscle, and coronary arteries.

The **cardioinhibitory center** sends impulses to the parasympathetic dorsal vagus nucleus in the medulla, which in turn sends inhibitory impulses to the heart via branches of the vagus nerves. Most parasympathetic postganglionic motor neurons lie in ganglia in the heart wall and their fibers project most heavily to the SA and AV nodes.

Action Potentials of Contractile Cardiac Muscle Cells

The bulk of heart muscle is composed of *contractile muscle* fibers responsible for the heart's pumping activity. As we have seen, the sequence of events leading to contraction of these cells is similar to that in skeletal muscle fibers. However, the action potential has a characteristic "hump" or *plateau* as shown in **Figure 18.15**.

1. Depolarization opens a few **fast voltage-gated Na^+ channels** in the sarcolemma, allowing extracellular Na^+ to enter. This influx initiates a positive feedback cycle that causes the rising phase of the action potential (and reversal of the membrane potential from –90 mV to nearly +30 mV). The period of Na^+ influx is very brief, because the sodium channels quickly inactivate and the Na^+ influx stops.
2. When Na^+-dependent membrane depolarization occurs, the voltage change also opens channels that allow Ca^{2+} to enter from the extracellular fluid. These channels are called **slow Ca^{2+} channels** because their opening is delayed a bit. The Ca^{2+} surge across the sarcolemma prolongs the depolarization, producing a **plateau** in the action potential tracing. Not many voltage-gated K^+ channels are open yet, so the plateau is prolonged. As long as Ca^{2+} is entering, the cells continue to contract. Notice in Figure 18.15 that muscle tension develops during the plateau, and peaks just after the plateau ends.
3. After about 200 ms, the slope of the action potential tracing falls rapidly. This repolarization results from inactivation of Ca^{2+} channels and opening of voltage-gated K^+ channels. The rapid loss of potassium from the cell through K^+



1 **Depolarization** is due to Na^+ influx through fast voltage-gated Na^+ channels. A positive feedback cycle rapidly opens many Na^+ channels, reversing the membrane potential. Channel inactivation ends this phase.

2 **Plateau phase** is due to Ca^{2+} influx through slow Ca^{2+} channels. This keeps the cell depolarized because most K^+ channels are closed.

3 **Repolarization** is due to Ca^{2+} channels inactivating and K^+ channels opening. This allows K^+ efflux, which brings the membrane potential back to its resting voltage.

Figure 18.15 The action potential of contractile cardiac muscle cells. Relationship between the action potential, period of contraction, and absolute refractory period in a single ventricular cell.

channels restores the resting membrane potential. During repolarization, Ca^{2+} is pumped back into the SR and the extracellular space.

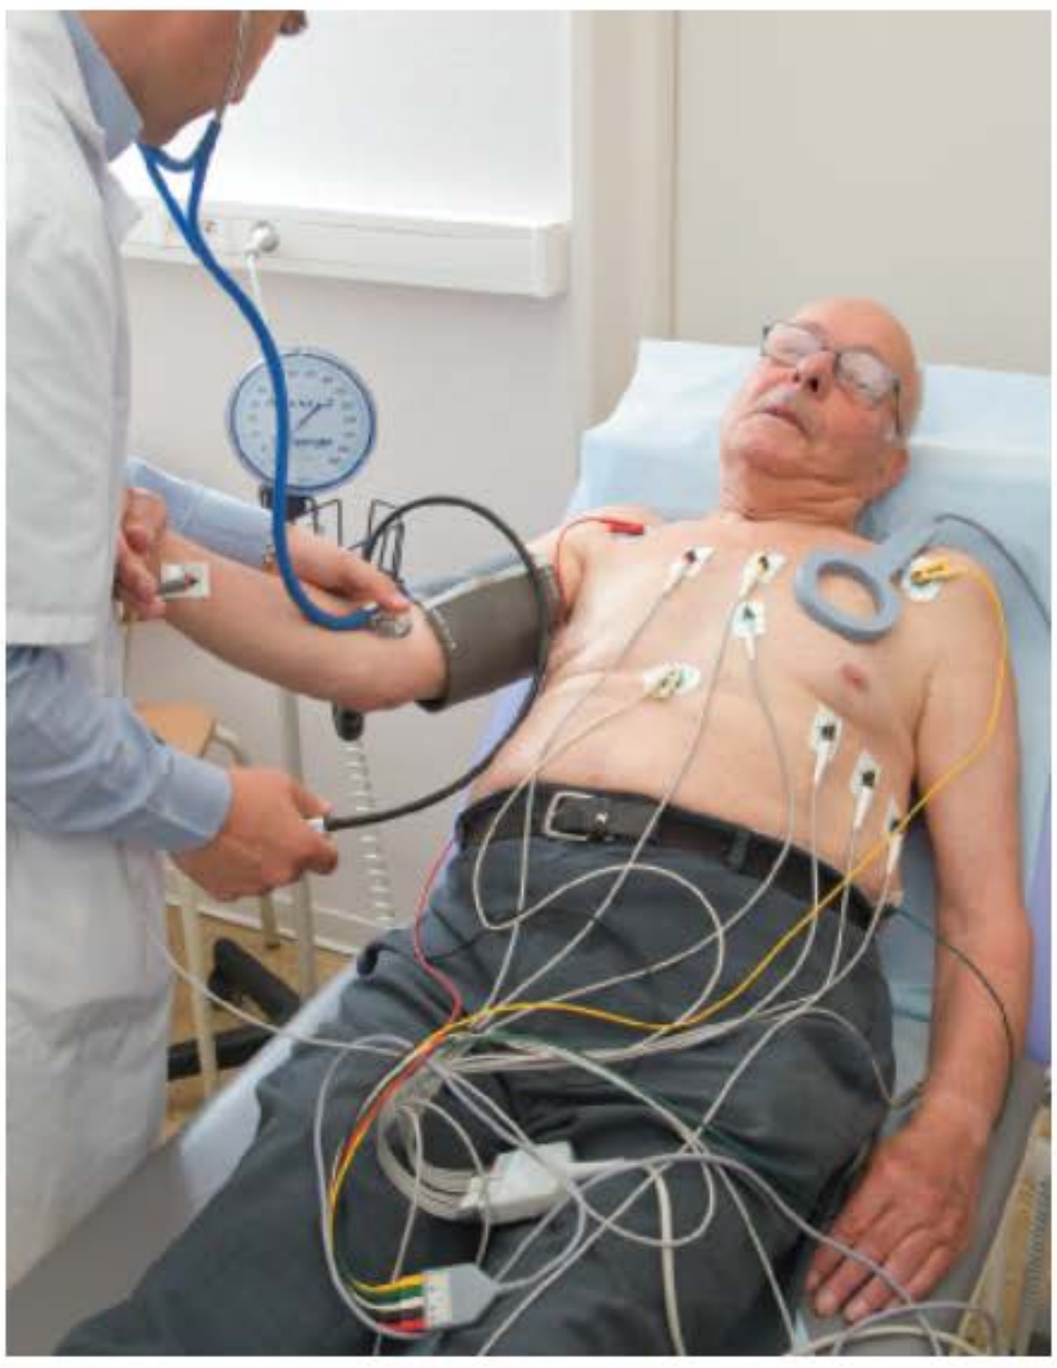
Notice that the action potential and contractile phase lasts much longer in cardiac muscle than in skeletal muscle. In skeletal muscle, the action potential typically lasts 1–2 ms and the contraction (for a single stimulus) 15–100 ms (◀ p. 299). In cardiac muscle, the action potential lasts 200 ms or more (because of the plateau), and tension development persists for 200 ms or more. This long plateau in cardiac muscle has two consequences:

- It ensures that the contraction is sustained so that blood is ejected efficiently from the heart.
- It ensures that there is a long absolute refractory period, so that tetanic contractions cannot occur and the heart can fill again for the next beat.

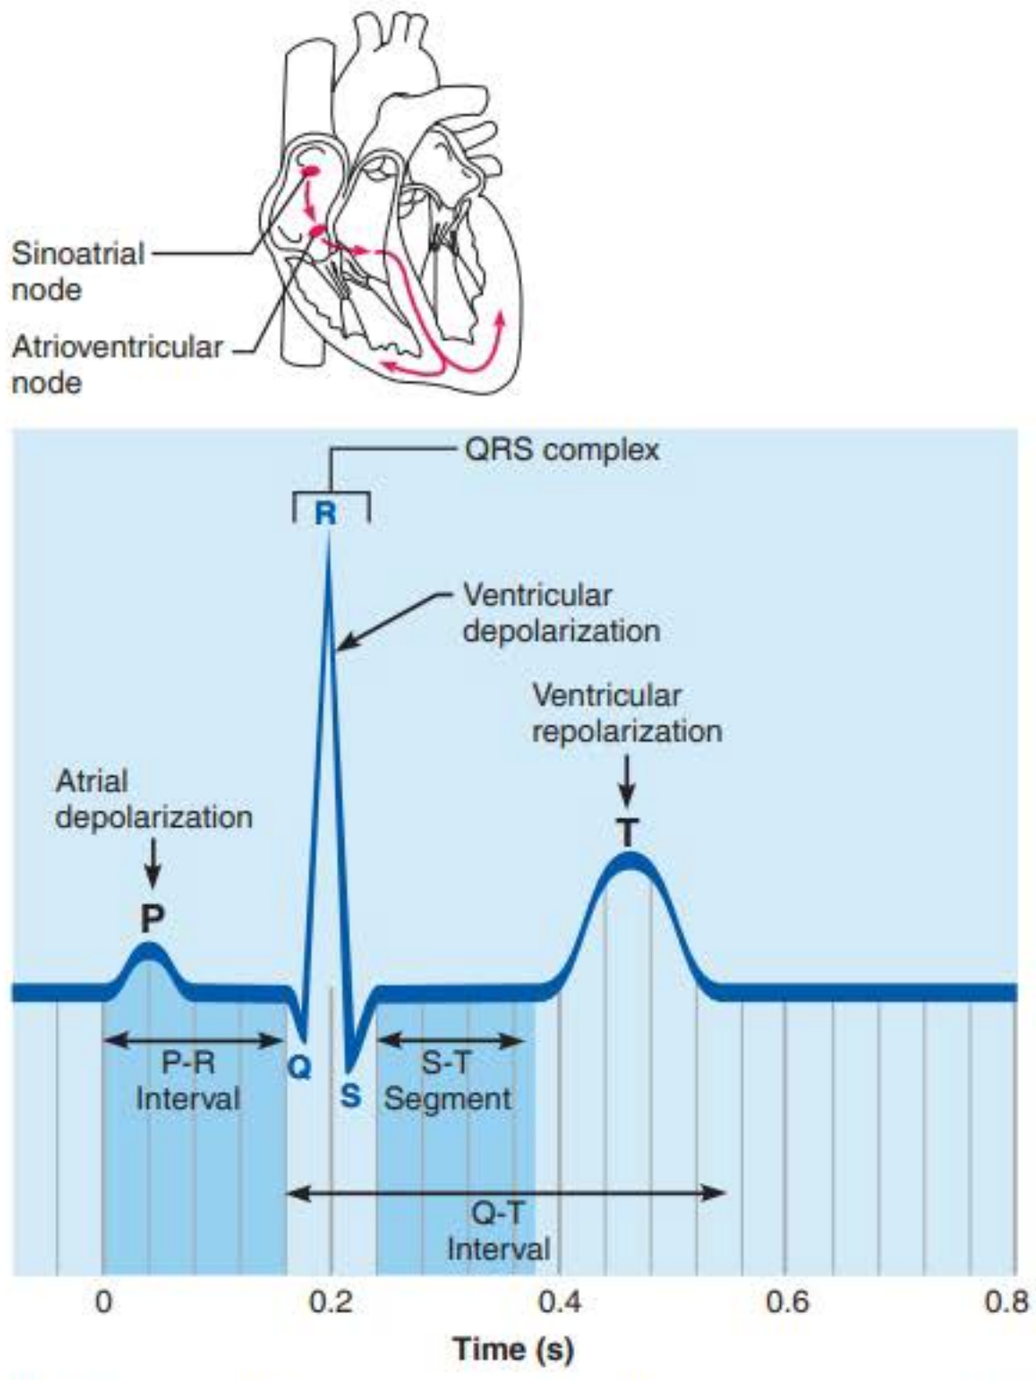
Electrocardiography

The electrical currents generated in and transmitted through the heart spread throughout the body and can be detected with a device called an **electrocardiograph**. An **electrocardiogram (ECG)** is a graphic record of heart activity. An ECG is a composite of all the action potentials generated by nodal and contractile cells at a given time (**Figure 18.16b**)—*not*, as sometimes assumed, a tracing of a single action potential.

To record an ECG, recording electrodes are placed at various sites on the body surface. In a typical 12-lead ECG, three electrodes form bipolar leads that measure the voltage



(a) Skin electrodes are used to record an ECG. (The round antenna near the patient's left shoulder reads his pacemaker data.)



(b) An ECG tracing. The labels identify the three normally recognizable waves and the important intervals.

Figure 18.16 The electrocardiogram (ECG).

difference either between the arms or between an arm and a leg, and nine form unipolar leads (Figure 18.16a). Together the 12 leads provide a comprehensive picture of the heart's electrical activity.

A typical ECG has three almost immediately distinguishable waves or *deflections*: the P wave, the QRS complex, and the T wave (Figure 18.16b).

The P Wave

The first, the small **P wave**, lasts about 0.08 s and results from movement of the depolarization wave from the SA node through the atria. Approximately 0.1 s after the P wave begins, the atria contract.

The QRS Complex

The large **QRS complex** results from ventricular depolarization and precedes ventricular contraction. It has a complicated shape because the paths of the depolarization waves through the ventricular walls change continuously, producing corresponding changes in current direction. Additionally, the time required for each ventricle to depolarize depends on its size relative to the other ventricle. Average duration of the QRS complex is 0.08 s.

The T Wave

The **T wave**, caused by ventricular repolarization, typically lasts about 0.16 s. Repolarization is slower than depolarization, so the T wave is more spread out and has a lower amplitude (height) than the QRS complex. Because atrial repolarization takes place during the period of ventricular excitation, the wave representing atrial repolarization is normally obscured by the large QRS complex being recorded at the same time.

The P-R Interval

The **P-R interval** is the time (about 0.16 s) from the beginning of atrial excitation to the beginning of ventricular excitation. If the Q wave is visible (which is often not the case), it marks the beginning of ventricular excitation, and for this reason this interval is sometimes called the **P-Q interval**. The P-R interval includes atrial depolarization (and contraction) as well as the passage of the depolarization wave through the rest of the conduction system.

The S-T Segment

During the **S-T segment** of the ECG, when the action potentials of the ventricular myocytes are in their plateau phases, the entire ventricular myocardium is depolarized. The **Q-T interval**, lasting about 0.38 s, is the period from the beginning of ventricular depolarization through ventricular repolarization.

Depolarization and Repolarization in the Heart

Figure 18.17 relates the parts of an ECG to the sequence of depolarization and repolarization in the heart. Note that these electrical events always precede the mechanical events of contraction and relaxation that they trigger.

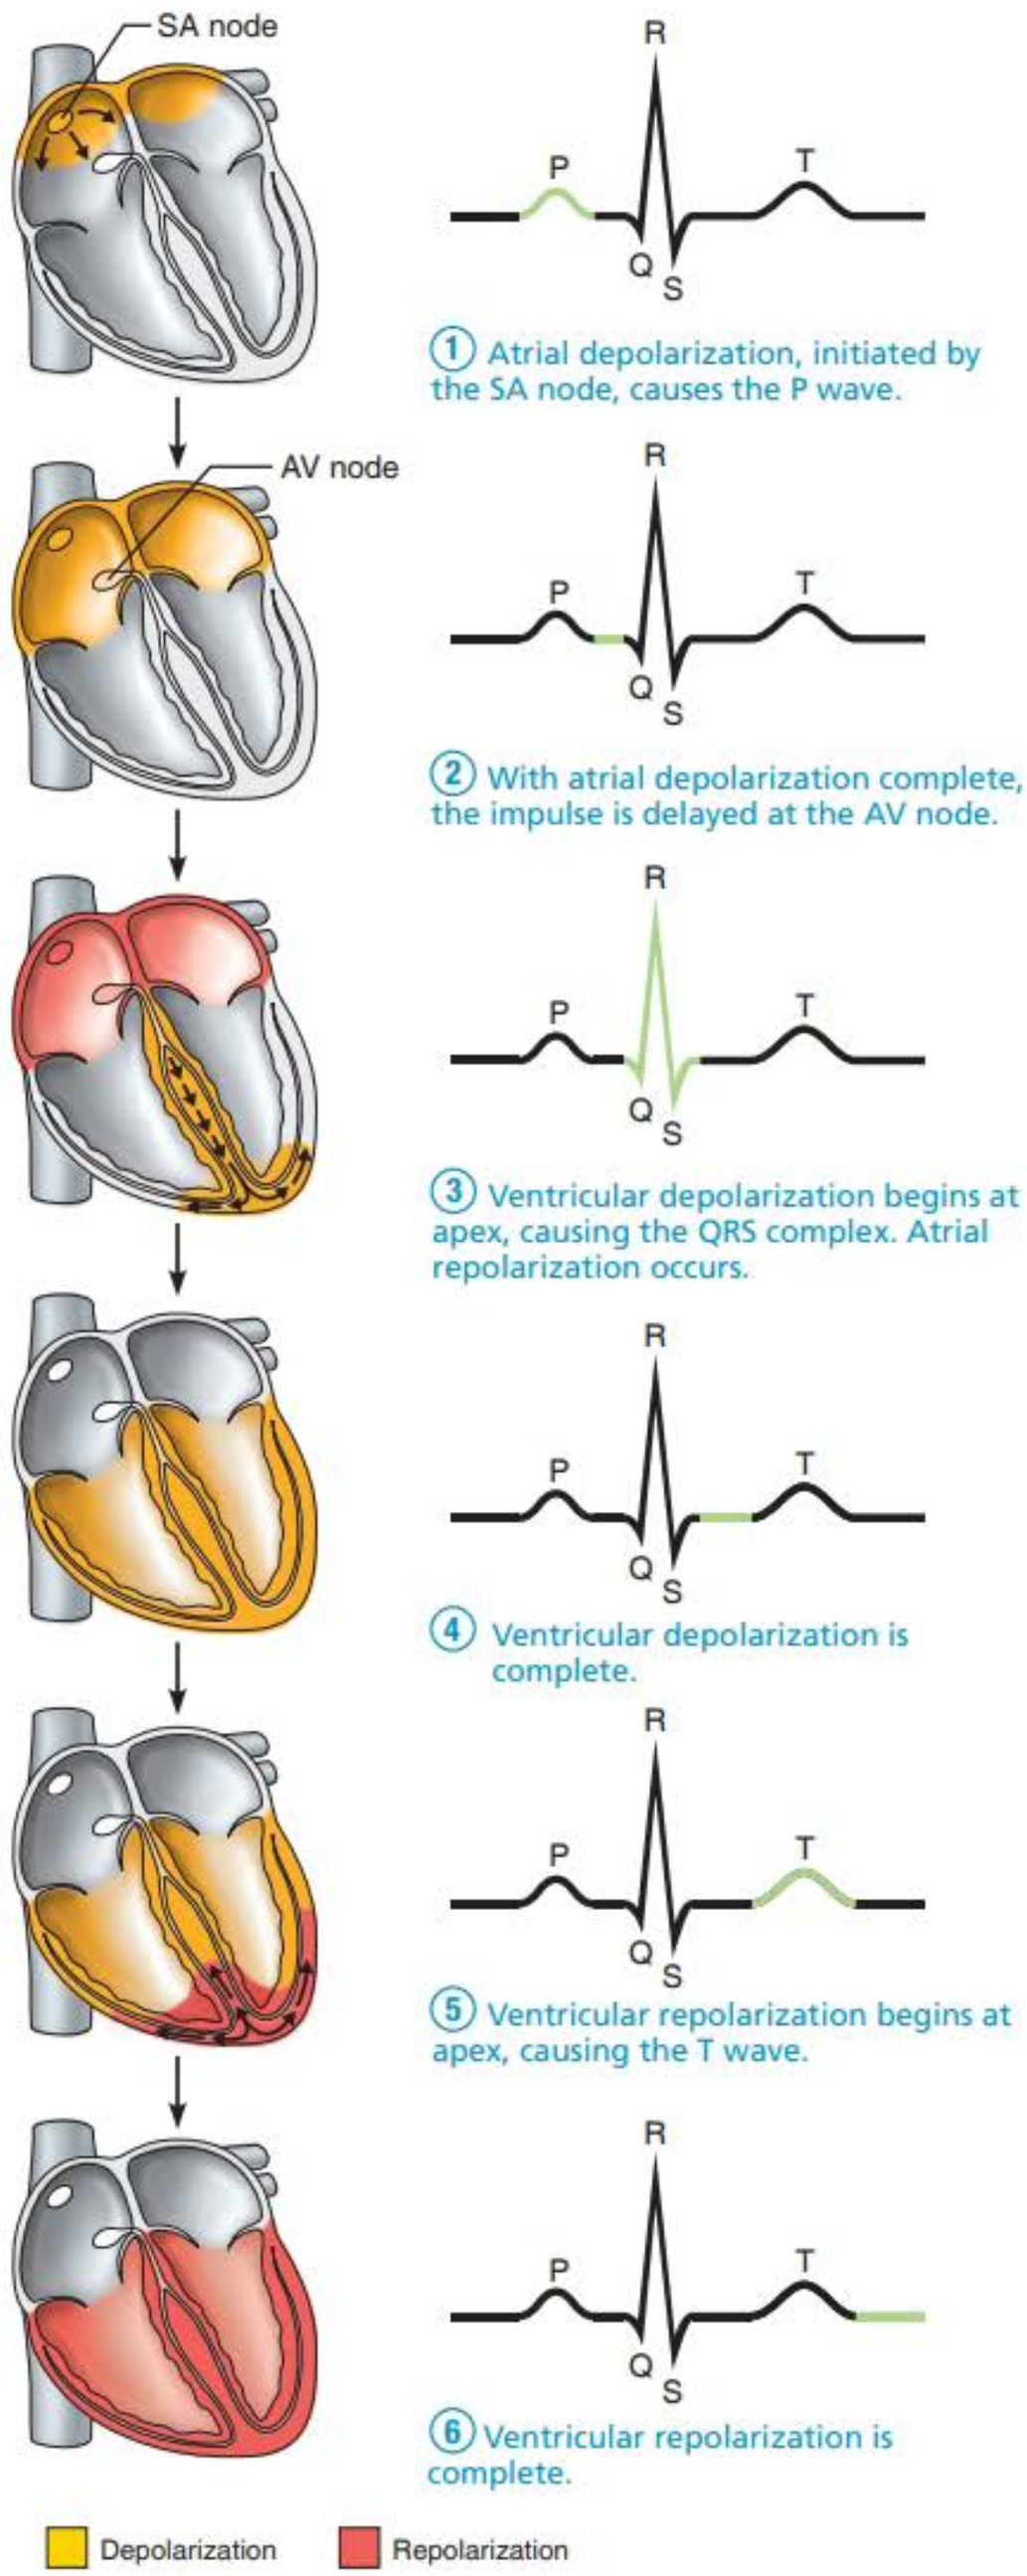


Figure 18.17 The sequence of depolarization and repolarization of the heart related to the ECG waves.

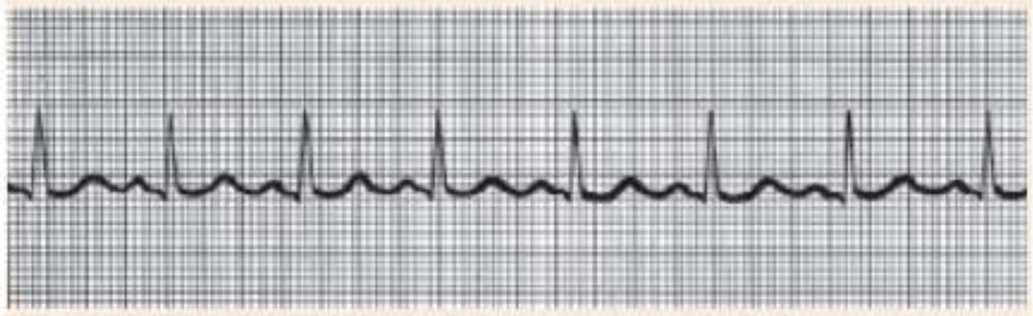
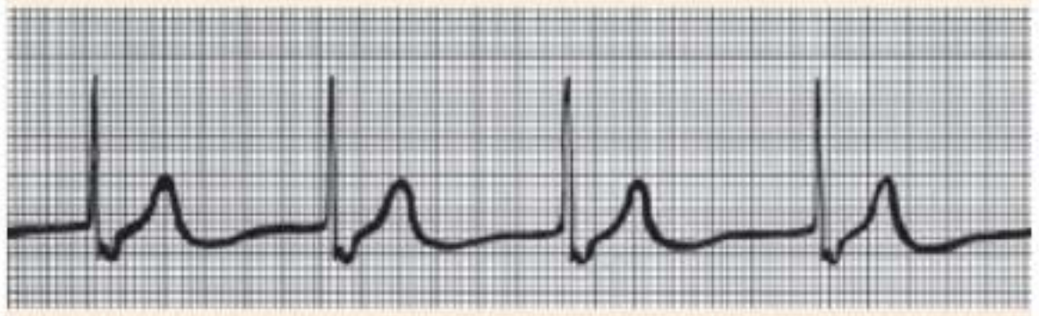
(a) Normal sinus rhythm

Normal ECG trace (sinus rhythm)



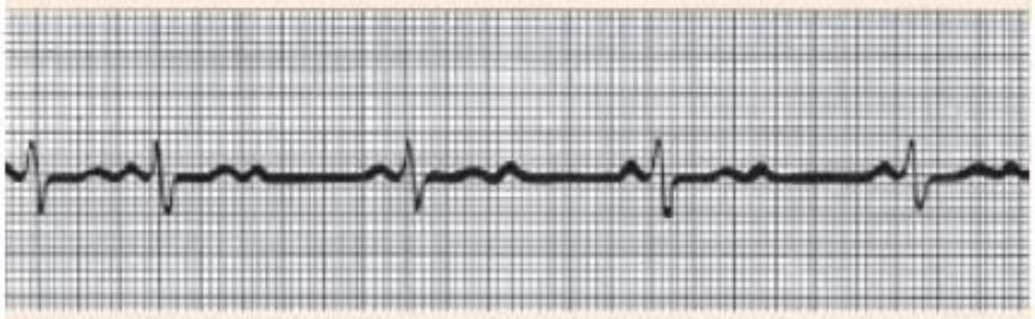
(b) Junctional rhythm

The SA node is nonfunctional. As a result:
- P waves are absent.
- The AV node paces the heart at 40–60 beats per minute.



(c) Second-degree heart block

The AV node fails to conduct some SA node impulses.
- As a result, there are more P waves than QRS waves.
- In this tracing, there are usually two P waves for each QRS wave.



(d) Ventricular fibrillation

Electrical activity is disorganized. Action potentials occur randomly throughout the ventricles.
- Results in chaotic, grossly abnormal ECG deflections.
- Seen in acute heart attack and after an electrical shock.

Figure 18.18 Normal and abnormal ECG tracings.

HOMEOSTATIC IMBALANCE 18.5 CLINICAL

Clinicians look for variations in the pattern or timing of the ECG, which tend to be consistent in a healthy heart. Changes alert them to damage or disease, as well as problems with the conduction system (**Figure 18.18**). For example, an enlarged R wave hints of enlarged ventricles, an S-T segment that is elevated or depressed indicates cardiac ischemia (insufficient blood flow), and a prolonged Q-T interval reveals a repolarization abnormality that increases the risk of ventricular arrhythmias.

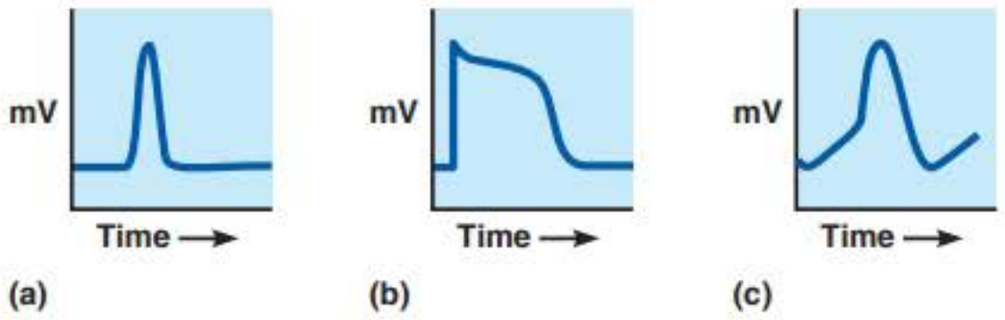
Check Your Understanding

12. Cardiac muscle cannot go into tetany. Why?

13. Describe the electrical event in the heart that occurs during each of the following: (a) the QRS complex of the ECG; (b) the T wave of the ECG; (c) the P-R interval of the ECG.

14. MAKE CONNECTIONS In skeletal muscle, every muscle fiber must be innervated so it can contract. In cardiac muscle, the intrinsic conduction system does not connect to every cardiac myocyte. Why is this not necessary? Which part of the intrinsic conduction system directly excites ventricular myocardial cells? In which direction does the depolarization wave travel across the ventricles?

15. MAKE CONNECTIONS Refer to graphs a–c of action potentials in the next column. Two of these occur in the heart, and one occurs in skeletal muscle (as you learned in Chapter 9).



Which one comes from a contractile cardiac muscle cell? A skeletal muscle cell? A cardiac pacemaker cell? For each one, state which ion is responsible for the depolarization phase and which ion is responsible for the repolarization phase.

For answers, see Answers Appendix.

18.6 The cardiac cycle describes the mechanical events associated with blood flow through the heart

Learning Outcomes

- **Describe the timing and events of the cardiac cycle.**
- **Describe normal heart sounds, and explain how heart murmurs differ.**

The heart undergoes some dramatic writhing movements as it alternately contracts, forcing blood out of its chambers, and then relaxes, allowing its chambers to refill with blood. The

term **systole** (sis′to-le) refers to these periods of contraction, and **diastole** (di-as′to-le) refers to those of relaxation. The **cardiac cycle** includes *all* events associated with the blood flow through the heart during one complete heartbeat—atrial systole and diastole followed by ventricular systole and diastole.

The graphical representation of the cardiac cycle is quite complex and can be daunting to students who see it for the first time. *Focus on the Cardiac Cycle* (**Focus Figure 18.2**, pp. 694–695) will lead you step by step through the cardiac cycle so that you can understand the logical relationships between each of the parts of this cycle. After you work your way through this figure, come back and read the summary of the events that occur during each phase of the cardiac cycle (below).

Complete an interactive tutorial: MasteringA&P® > Study Area > Interactive Physiology

Phases of the Cardiac Cycle

The cardiac cycle is marked by a succession of pressure and blood volume changes in the heart. Because blood circulates continuously, we must choose an arbitrary starting point for one turn of the cardiac cycle. We begin with the heart in total relaxation: Atria and ventricles are quiet, and it is mid-to-late diastole (bottom right of Focus Figure 18.2 on p. 695).

① **Ventricular filling: mid-to-late diastole.** Pressure in the heart is low, blood returning from the circulation is flowing passively through the atria and the open AV valves into the ventricles, and the aortic and pulmonary valves are closed. More than 80% of ventricular filling occurs during this period. (The remaining 20% of the blood is delivered to the ventricles when the atria contract toward the end of this phase.)

Now the stage is set for atrial systole. Following depolarization (P wave of ECG), the atria contract, compressing the blood in their chambers. This causes a sudden slight rise in atrial pressure, which propels residual blood out of the atria into the ventricles. At this point the ventricles are in the last part of their diastole and have the maximum volume of blood they will contain in the cycle, an amount called the *end diastolic volume* (*EDV*). Then the atria relax and the ventricles depolarize (QRS complex). Atrial diastole persists through the rest of the cycle.

② **Isovolumetric contraction.** As the atria relax, the ventricles begin contracting. Their walls close in on the blood in their chambers, and ventricular pressure rises rapidly and sharply, closing the AV valves. The **isovolumetric contraction phase** (i″so-vol″u-met′rik) is the split-second period when the ventricles are completely closed chambers and the blood volume in the chambers remains constant as the ventricles contract.

As ventricular pressure continues to rise, it finally exceeds the pressure in the large arteries issuing from the ventricles. The isovolumetric stage ends as the SL valves are forced open.

③ **Ventricular ejection.** During the ventricular ejection phase, blood rushes from the ventricles into the aorta and pulmonary trunk. The pressure in the aorta normally reaches about 120 mm Hg.

④ **Isovolumetric relaxation: early diastole.** Following the peak of the T wave, the ventricles relax. Because the blood remaining in their chambers, referred to as the *end systolic volume* (*ESV*), is no longer compressed, ventricular pressure drops rapidly and blood in the aorta and pulmonary trunk flows back toward the heart, closing the SL valves. Once again, the ventricles are completely closed chambers, and so this event marks the beginning of the **isovolumetric relaxation phase**. Closure of the aortic valve raises aortic pressure briefly as backflowing blood rebounds off the closed valve cusps, an event beginning at the **dicrotic notch** shown on the pressure graph (p. 694).

All during ventricular systole, the atria have been in diastole. They have been filling with blood and the intra-atrial pressure has been rising. When blood pressure on the atrial side of the AV valves exceeds that in the ventricles, the AV valves are forced open and ventricular filling, phase ①, begins again. Atrial pressure drops to its lowest point and ventricular pressure begins to rise, completing the cycle.

Assuming the average heart beats 75 times each minute, the cardiac cycle lasts about 0.8 s, with atrial systole accounting for 0.1 s and ventricular systole 0.3 s. The remaining 0.4 s is a period of total heart relaxation, the **quiescent period**.

Notice two important points: (1) Blood flow through the heart is controlled entirely by pressure changes, and (2) blood flows down a pressure gradient through any available opening. The pressure changes, in turn, reflect the alternating contraction and relaxation of the myocardium and cause the heart valves to open, which keeps blood flowing in the forward direction.

The situation in the right side of the heart is essentially the same as in the left side *except* for pressure. The pulmonary circulation is a low-pressure circulation as evidenced by the much thinner myocardium of its right ventricle. So, typical systolic and diastolic pressures for the pulmonary artery are 24 and 10 mm Hg, compared to systolic and diastolic pressures of 120 and 80 mm Hg, respectively, for the aorta. However, the two sides of the heart eject the same blood volume with each heartbeat.

Heart Sounds

Auscultating (listening to) the thorax with a stethoscope will reveal two sounds during each heartbeat. These **heart sounds**, often described as lub-dup, are associated with the heart valves closing. (The timing of heart sounds in the cardiac cycle is shown in Focus Figure 18.2 on p. 694.)

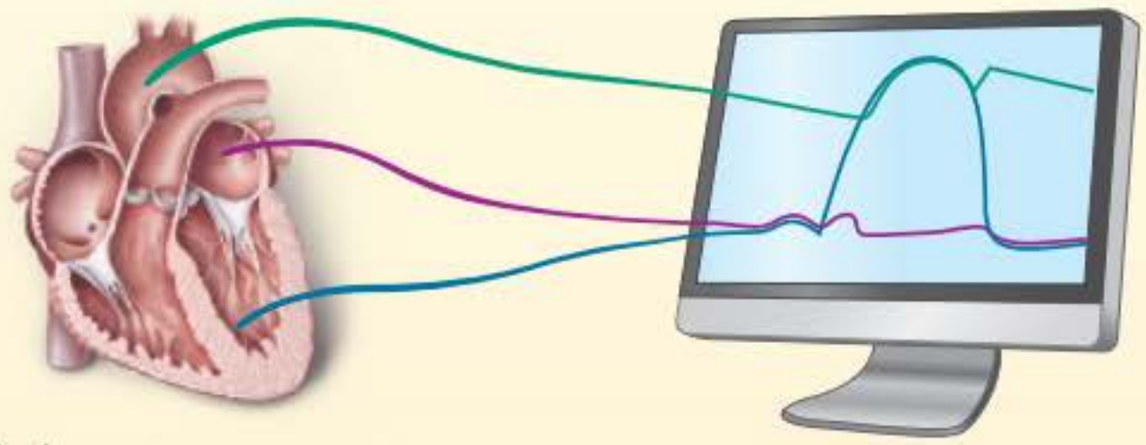
The basic rhythm of the heart sounds is lub-dup, pause, lub-dup, pause, and so on, with the pause indicating the period when the heart is relaxing. The first sound occurs as the AV valves close. It signifies the point when ventricular pressure rises above atrial pressure (the beginning of ventricular systole). The first sound tends to be louder, longer, and more resonant than the second. The second sound occurs as the SL valves snap shut at the beginning of ventricular relaxation (diastole), resulting in a short, sharp sound.

(Text continues on p. 696.)

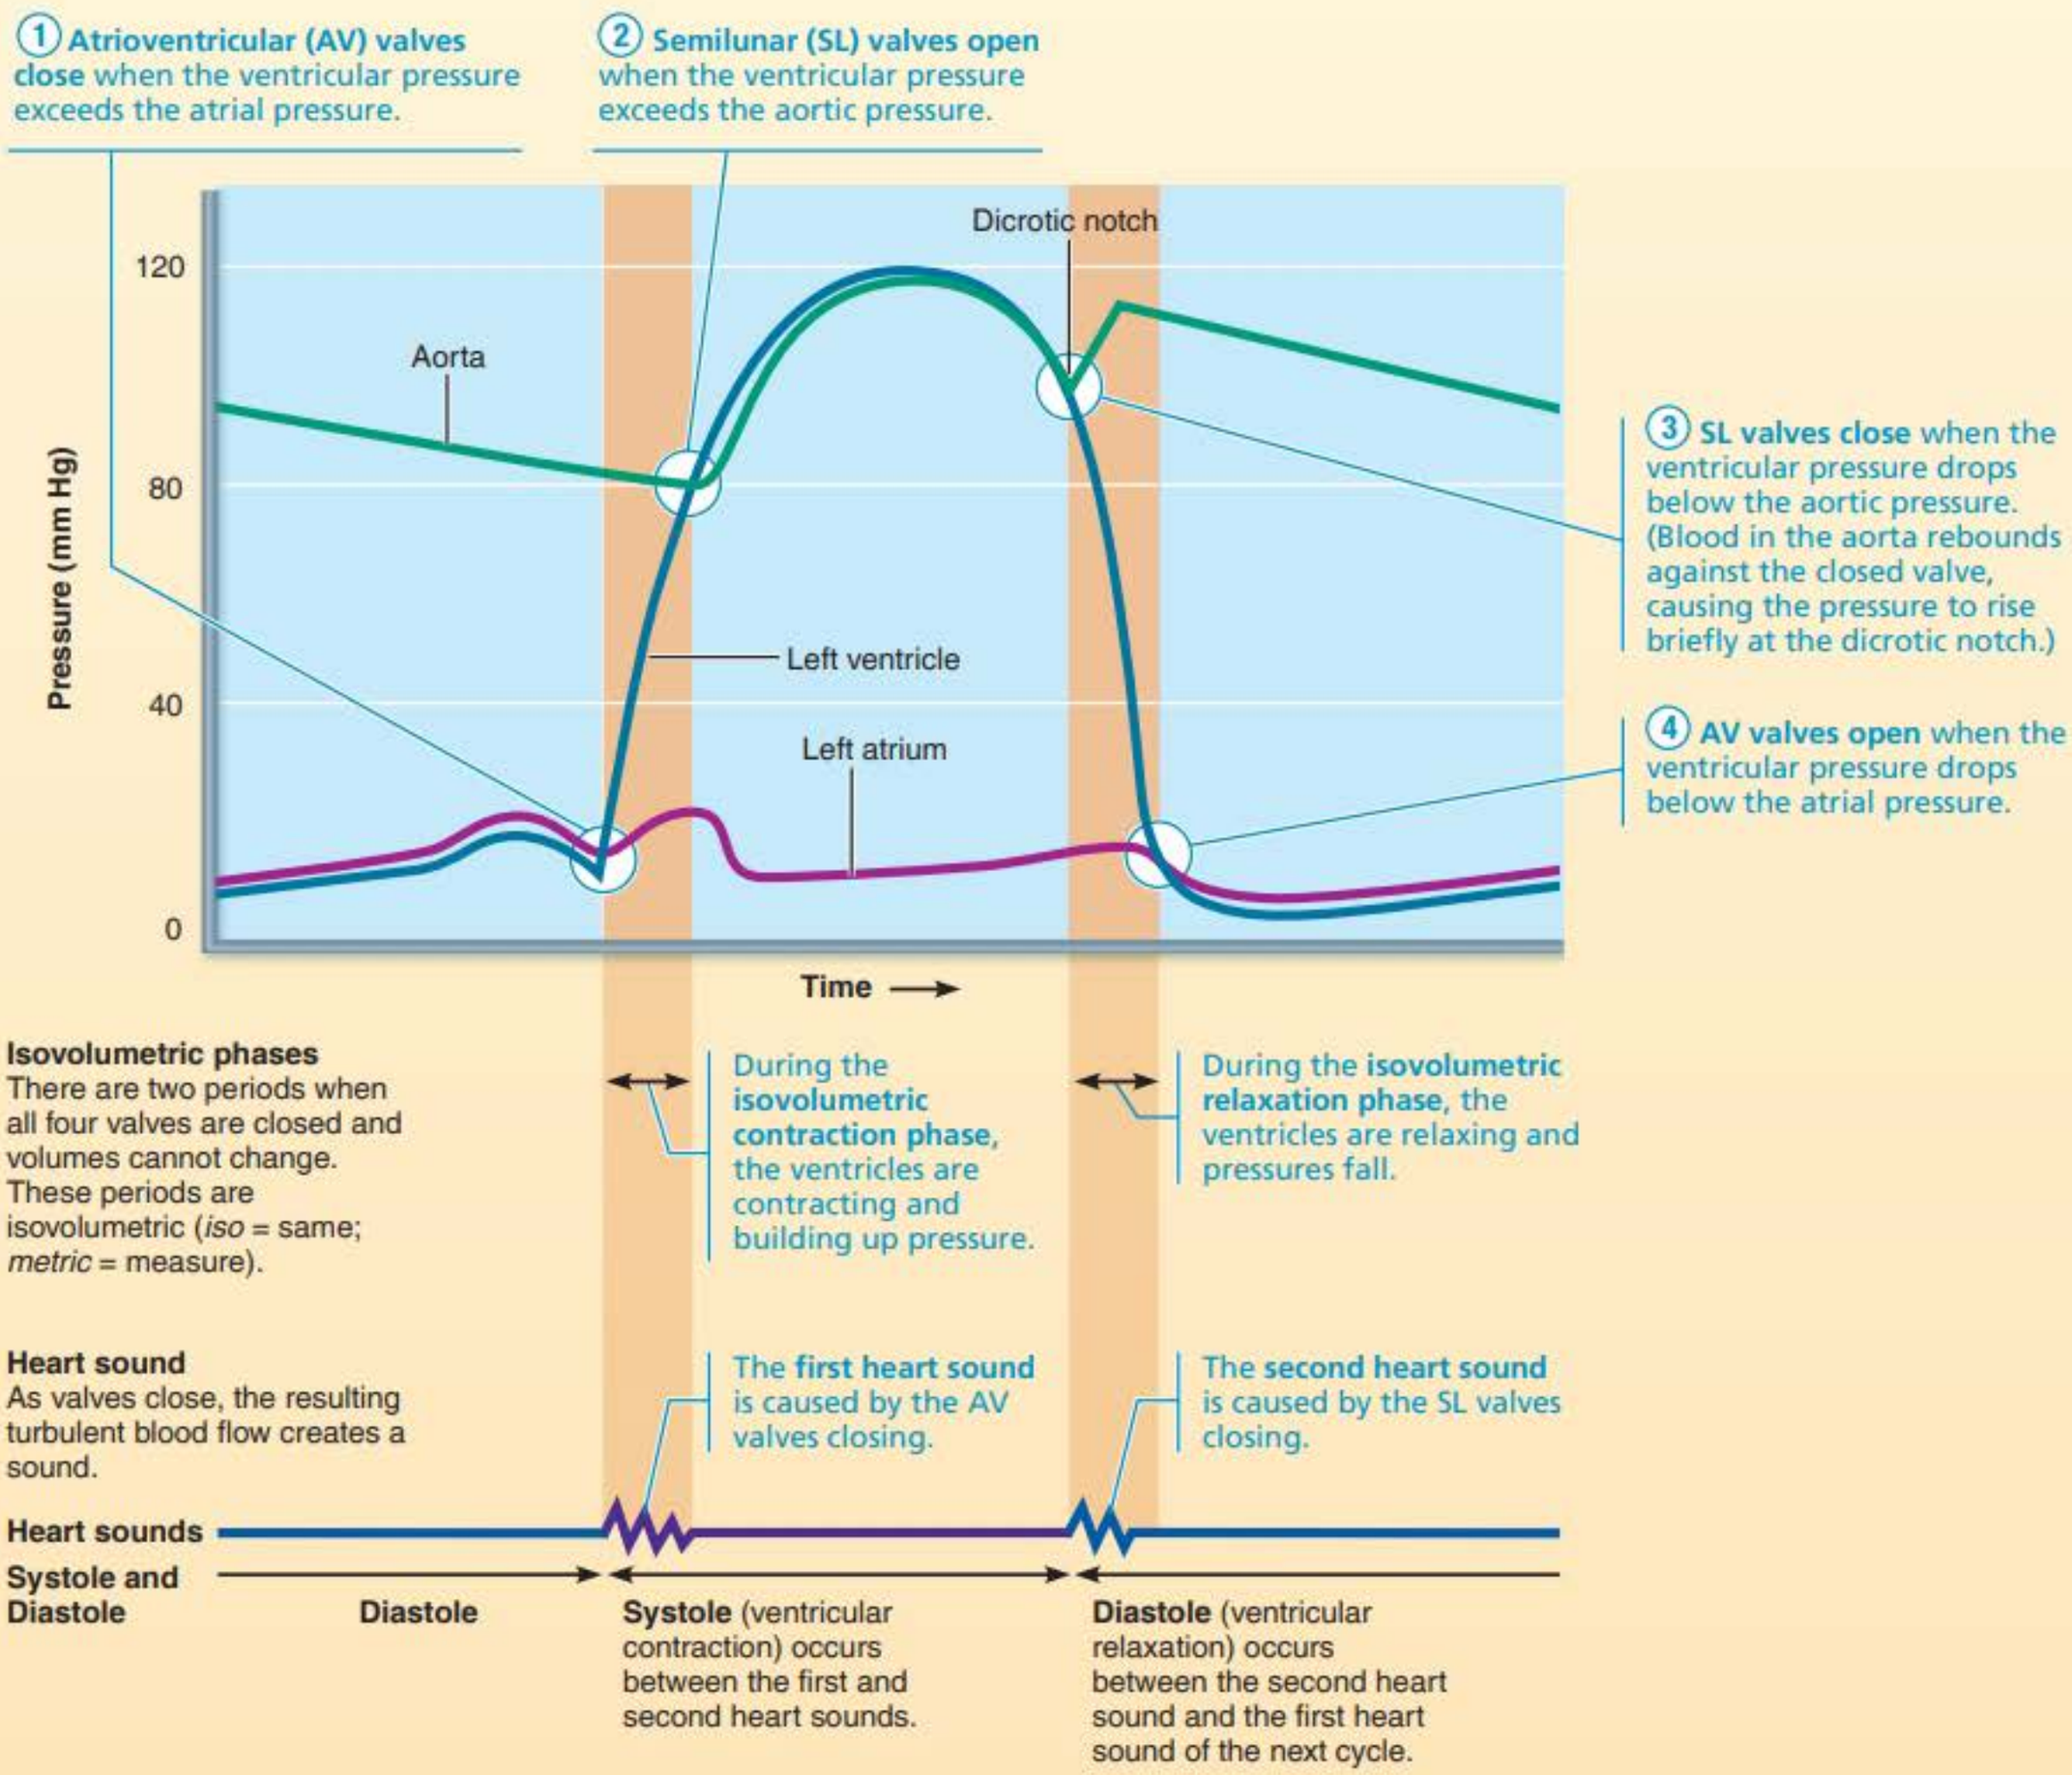
FOCUS FIGURE 18.2 The Cardiac Cycle

The cardiac cycle consists of the events during one heartbeat. By following pressure changes in an atrium, a ventricle, and a major artery, you can understand when cardiac valves open and close, allowing blood to flow.

Let's measure pressures in the left atrium, left ventricle, and aorta. Pressures from the right side would look the same, but would be lower.



Pressures and Valves
Recall that blood flows from high to low pressure, but only if valves are open. When lines cross on the pressure curve, valves either open or close. If you understand this, the other parts of the cardiac cycle will fall into place.



Isovolumetric phases
There are two periods when all four valves are closed and volumes cannot change. These periods are isovolumetric (*iso* = same; *metric* = measure).

During the **isovolumetric contraction phase**, the ventricles are contracting and building up pressure.

During the **isovolumetric relaxation phase**, the ventricles are relaxing and pressures fall.

Heart sound
As valves close, the resulting turbulent blood flow creates a sound.

The **first heart sound** is caused by the AV valves closing.

The **second heart sound** is caused by the SL valves closing.

Heart sounds

Systole and Diastole

Diastole

Systole (ventricular contraction) occurs between the first and second heart sounds.

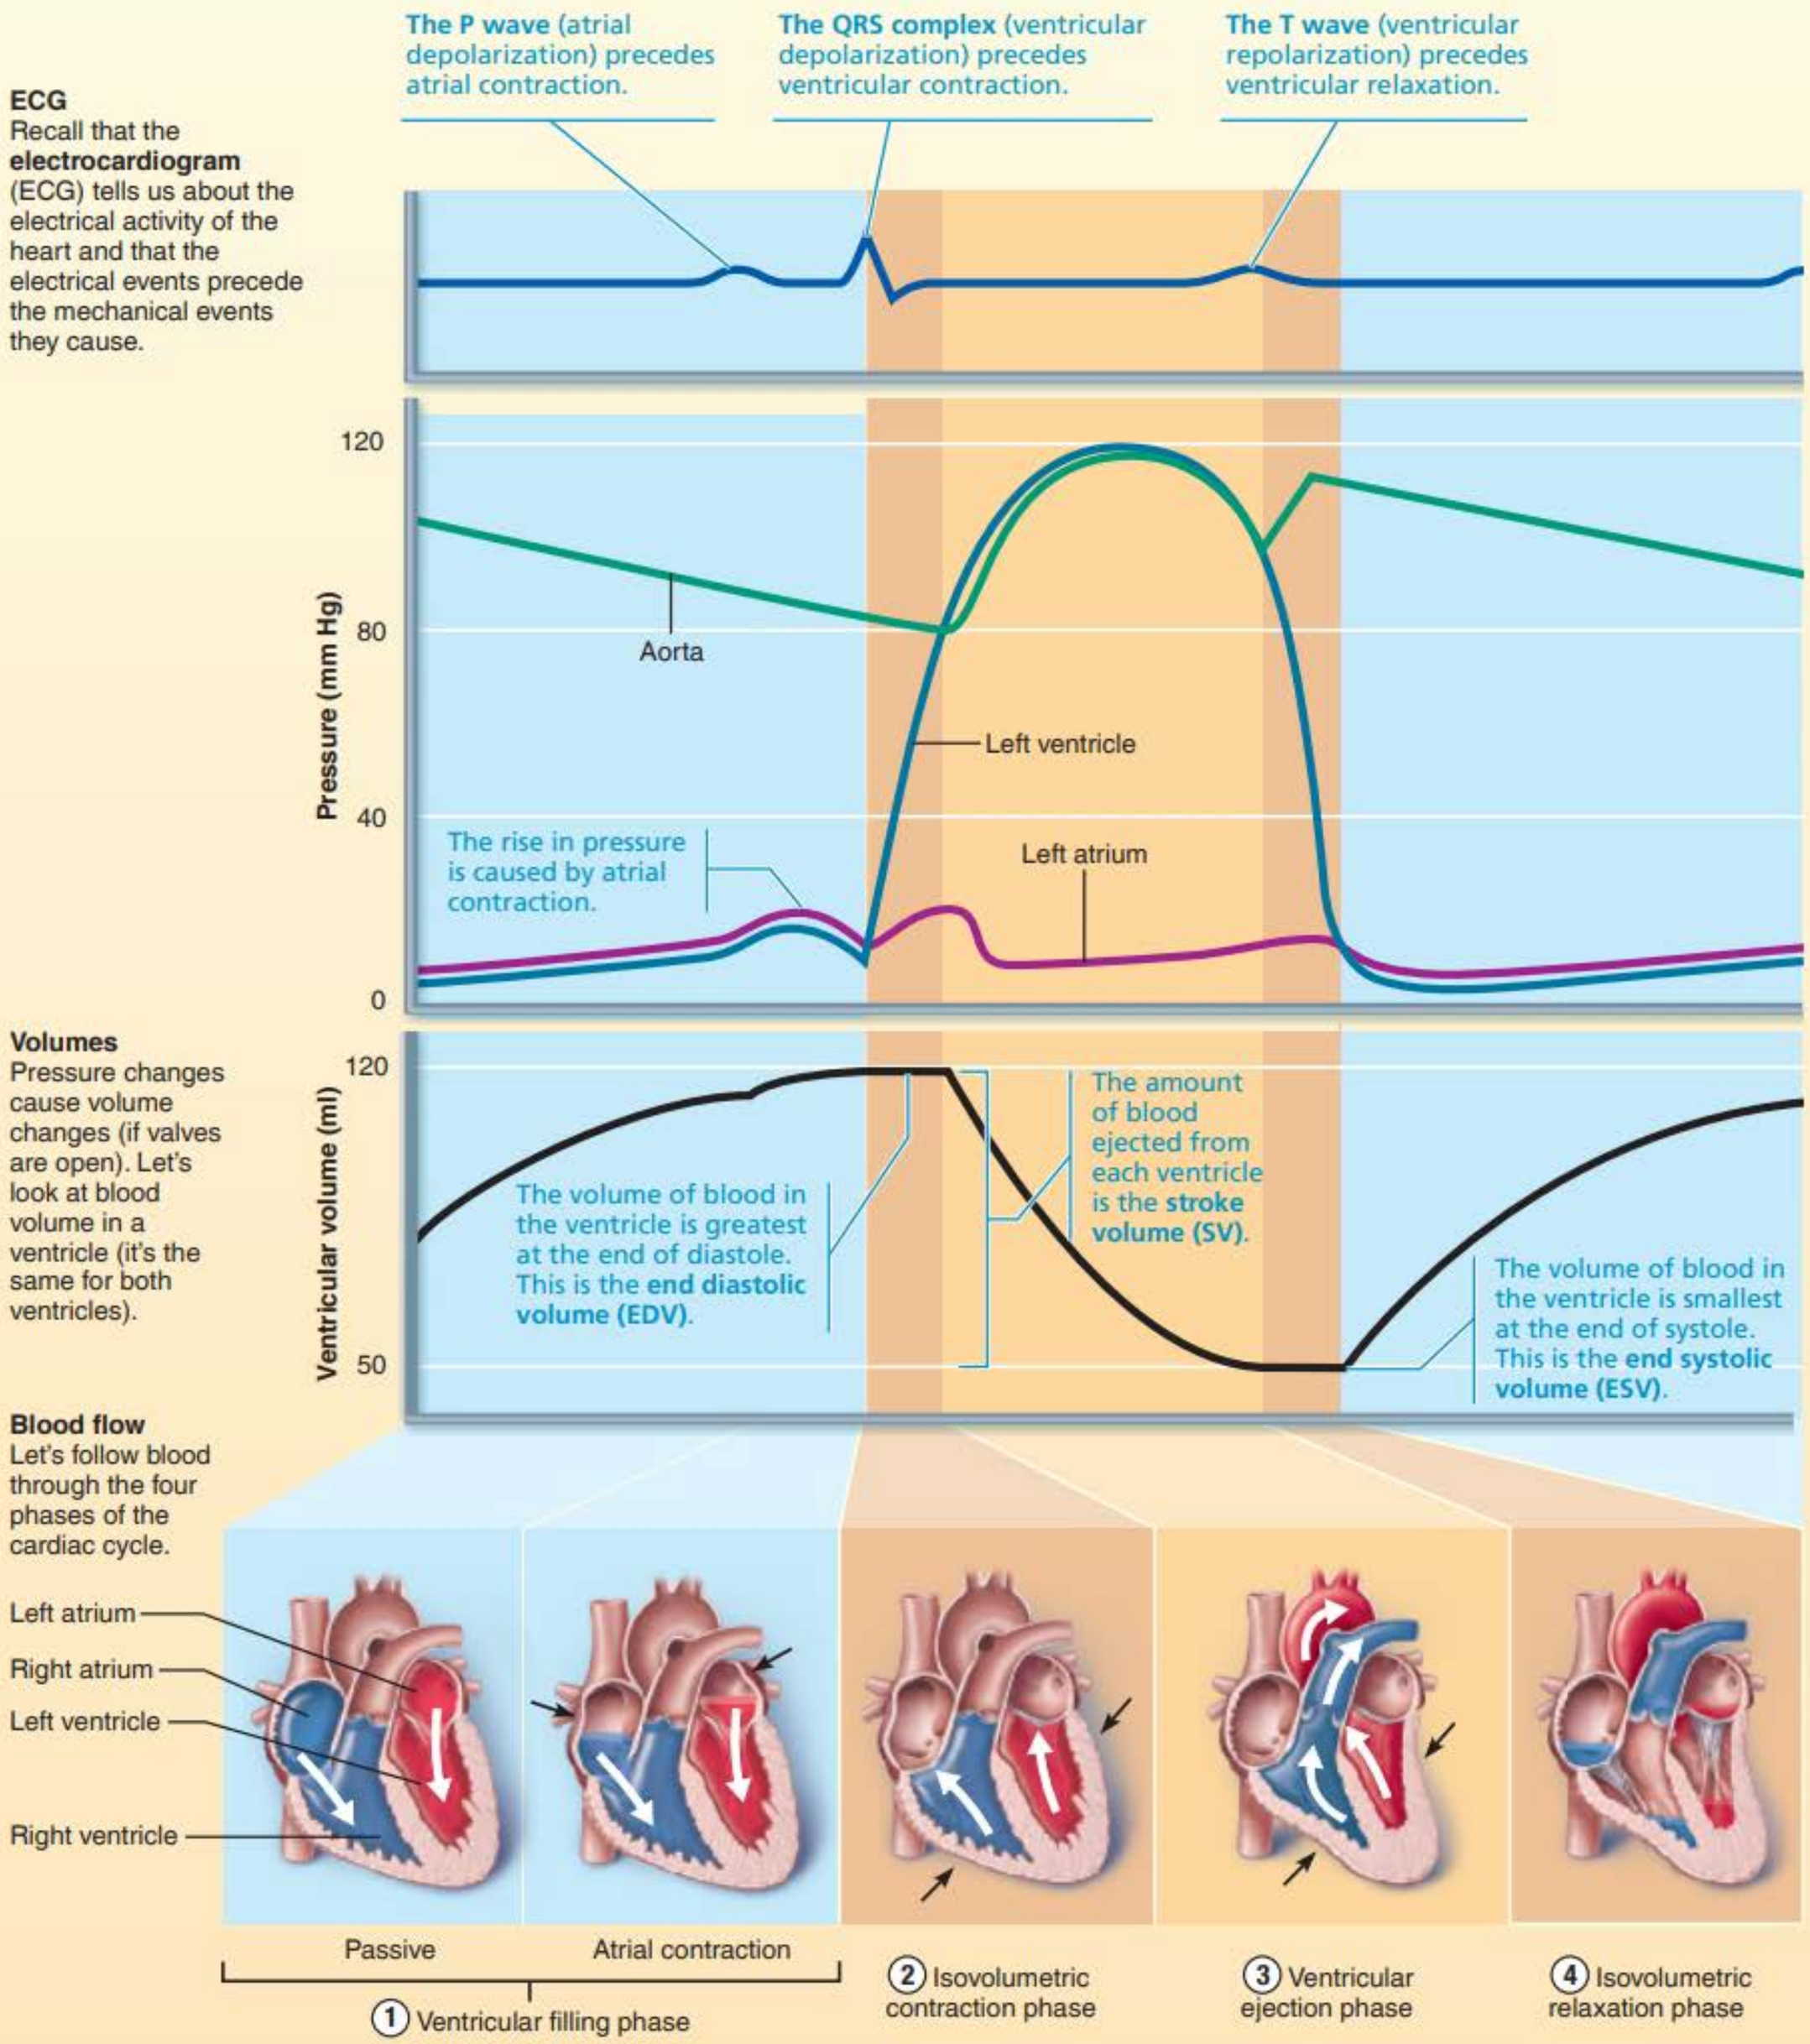
Diastole (ventricular relaxation) occurs between the second heart sound and the first heart sound of the next cycle.

Now that you understand the pressure changes, let's look at how they correspond to the electrical events and volume changes in the heart.

ECG
Recall that the **electrocardiogram** (ECG) tells us about the electrical activity of the heart and that the electrical events precede the mechanical events they cause.

Volumes
Pressure changes cause volume changes (if valves are open). Let's look at blood volume in a ventricle (it's the same for both ventricles).

Blood flow
Let's follow blood through the four phases of the cardiac cycle.



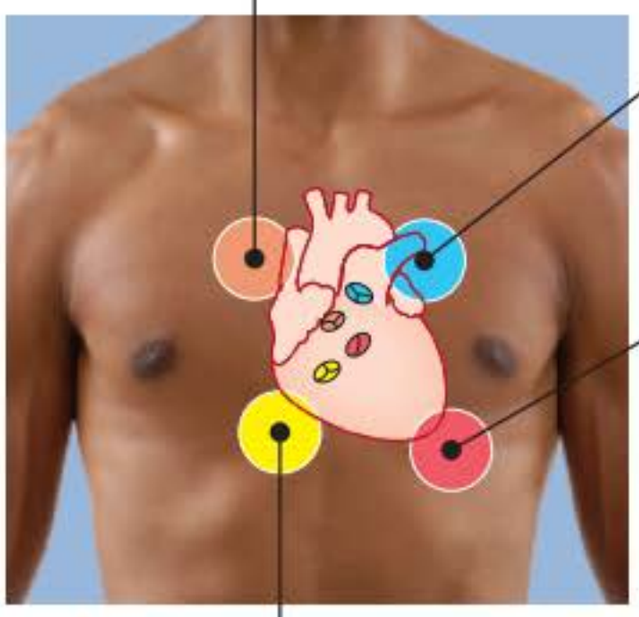


Figure 18.19 Areas of the thoracic surface where the sounds of individual valves are heard most clearly.

Because the mitral valve closes slightly before the tricuspid valve does, and the aortic SL valve generally snaps shut just before the pulmonary valve, it is possible to distinguish the individual valve sounds by auscultating four specific regions of the thorax (**Figure 18.19**). Notice that these four points, while not directly superficial to the valves (because the sounds take oblique paths to reach the chest wall), handily define the four corners of the normal heart. Knowing normal heart size and location is essential for recognizing an enlarged (and often diseased) heart.

HOMEOSTATIC IMBALANCE 18.6 — CLINICAL

Blood flows silently as long as its flow is smooth and uninterrupted. If blood strikes obstructions, however, its flow becomes turbulent and generates abnormal heart sounds, called **heart murmurs**, that can be heard with a stethoscope. Heart murmurs are quite common in young children (and some elderly people) with perfectly healthy hearts, probably because their heart walls are relatively thin and vibrate with rushing blood.

Sometimes, especially in adults, murmurs indicate valve problems. An *incompetent* or *insufficient* valve fails to close completely. There is a swishing sound as blood backflows or regurgitates through the partially open valve *after* the valve has (supposedly) closed.

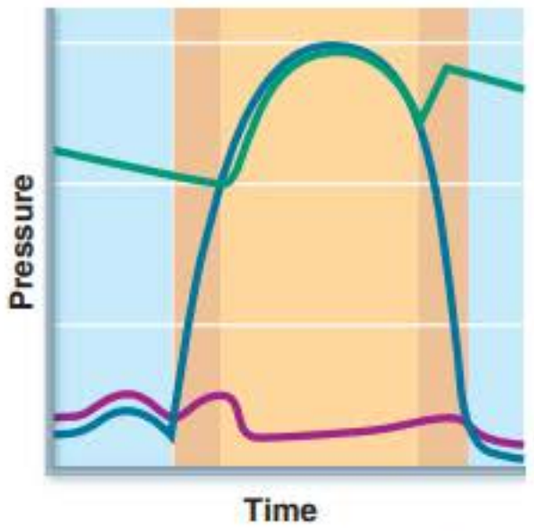
A *stenotic* valve fails to open completely and its narrow opening restricts blood flow *through* the valve. In a stenotic aortic valve, for instance, a high-pitched sound or click can be detected when the valve should be wide open during ventricular contraction, but is not.

Check Your Understanding

16. The second heart sound is associated with the closing of which valve(s)?

17. PREDICT If the mitral valve were insufficient, would you expect to hear the murmur (of blood flowing through the valve that should be closed) during ventricular systole or diastole?

18. DRAW The lines in the graph at right represent pressures in the left heart and aorta. Label each of the three lines. Label the points on the graph where AV valves open or close and where SL valves open or close. Label two periods during which all four valves are closed, using the appropriate terms.



For answers, see Answers Appendix.

18.7 Stroke volume and heart rate are regulated to alter cardiac output

Learning Outcomes

- **Name and explain the effects of various factors regulating stroke volume and heart rate.**
- **Explain the role of the autonomic nervous system in regulating cardiac output.**

Cardiac output (CO) is the amount of blood pumped out by *each* ventricle in 1 minute. It is the product of heart rate (HR) and stroke volume (SV). **Stroke volume** is defined as the volume of blood pumped out by one ventricle with each beat. In general, stroke volume correlates with the force of ventricular contraction.

Complete an interactive tutorial: MasteringA&P® > Study Area > Interactive Physiology

Using normal resting values for heart rate (75 beats/min) and stroke volume (70 ml/beat), the average adult cardiac output can be computed:

$$CO = HR \times SV = \frac{75 \text{ beats}}{\text{min}} \times \frac{70 \text{ ml}}{\text{beat}} = \frac{5250 \text{ ml}}{\text{min}} = \frac{5.25 \text{ L}}{\text{min}}$$

The normal adult blood volume is about 5 L (a little more than 1 gallon). As you can see, the entire blood supply passes through each side of the heart once each minute.

Notice that cardiac output varies directly with SV and HR. This means that CO increases when the stroke volume increases or the heart beats faster or both, and it decreases when either or both of these factors decrease.

Cardiac output is highly variable and increases markedly in response to special demands, such as running to catch a bus. **Cardiac reserve** is the difference between resting and maximal CO. In nonathletic people, cardiac reserve is typically four to five times resting CO (20–25 L/min), but CO in trained athletes during competition may reach 35 L/min (seven times resting CO).

How does the heart accomplish such tremendous increases in output? To understand this feat, let's look at how stroke volume and heart rate are regulated. See **Figure 18.20** for an overview of the factors that affect stroke volume and heart rate, and consequently, cardiac output. Work your way up from the bottom of the figure as we add more details in the following discussion.

Regulation of Stroke Volume

Mathematically, stroke volume (SV) represents the difference between **end diastolic volume (EDV)**, the amount of blood that collects in a ventricle during diastole, and **end systolic volume (ESV)**, the volume of blood remaining in a ventricle *after* it has contracted. The EDV, determined by how long ventricular diastole lasts and by venous pressure, is normally about 120 ml. (An increase in either factor *raises* EDV.) The ESV, determined by arterial blood pressure and the force of ventricular contraction, is approximately 50 ml. (The higher the arterial blood pressure, the higher the ESV.) To figure normal stroke volume, simply plug these values into this equation:

$$SV = EDV - ESV = \frac{120\ ml}{beat} - \frac{50\ ml}{beat} = \frac{70\ ml}{beat}$$

As you can see, each ventricle pumps out about 70 ml of blood with each beat, which is about 60% of the blood in its chambers.

So what is important here—how do we make sense out of this alphabet soup (SV, ESV, EDV)? Although many factors affect SV by altering EDV or ESV, the three most important are *preload, contractility*, and *afterload*. As we describe in detail next, preload affects EDV, whereas contractility and afterload affect the ESV.

Preload: Degree of Stretch of Heart Muscle

The degree to which cardiac muscle cells are stretched just before they contract, called the **preload**, controls stroke volume. In a normal heart, the higher the preload, the higher the stroke volume. This relationship between preload and stroke volume is called the **Frank-Starling law of the heart**.

Recall that at an *optimal length* of muscle fibers (and sarcomeres) (1) the maximum number of active cross bridge attachments is possible between actin and myosin, and (2) the force of contraction is maximal (◀ Figure 9.19, p. 307). Cardiac muscle, like skeletal muscle, exhibits a *length-tension relationship*.

Resting skeletal muscle fibers are kept near optimal length for developing maximal tension. In contrast, resting cardiac cells are normally *shorter* than optimal length. As a result, stretching cardiac cells can produce dramatic increases in contractile force. The most important factor stretching cardiac muscle is **venous return**, the amount of blood returning to the heart and distending its ventricles.

Anything that increases venous return increases EDV and, consequently, SV and contraction force (Figure 18.21). Basically:

↑ Venous return → ↑ EDV (preload) → ↑ SV → ↑ Cardiac output

(Frank-Starling law)

Both exercise and increased filling time increase EDV. Exercise increases venous return because both increased sympathetic nervous system activity and the squeezing action of the skeletal muscles compress the veins, decreasing the volume of blood they contain and returning more blood to the heart. During vigorous exercise, SV may double as a result of increased venous

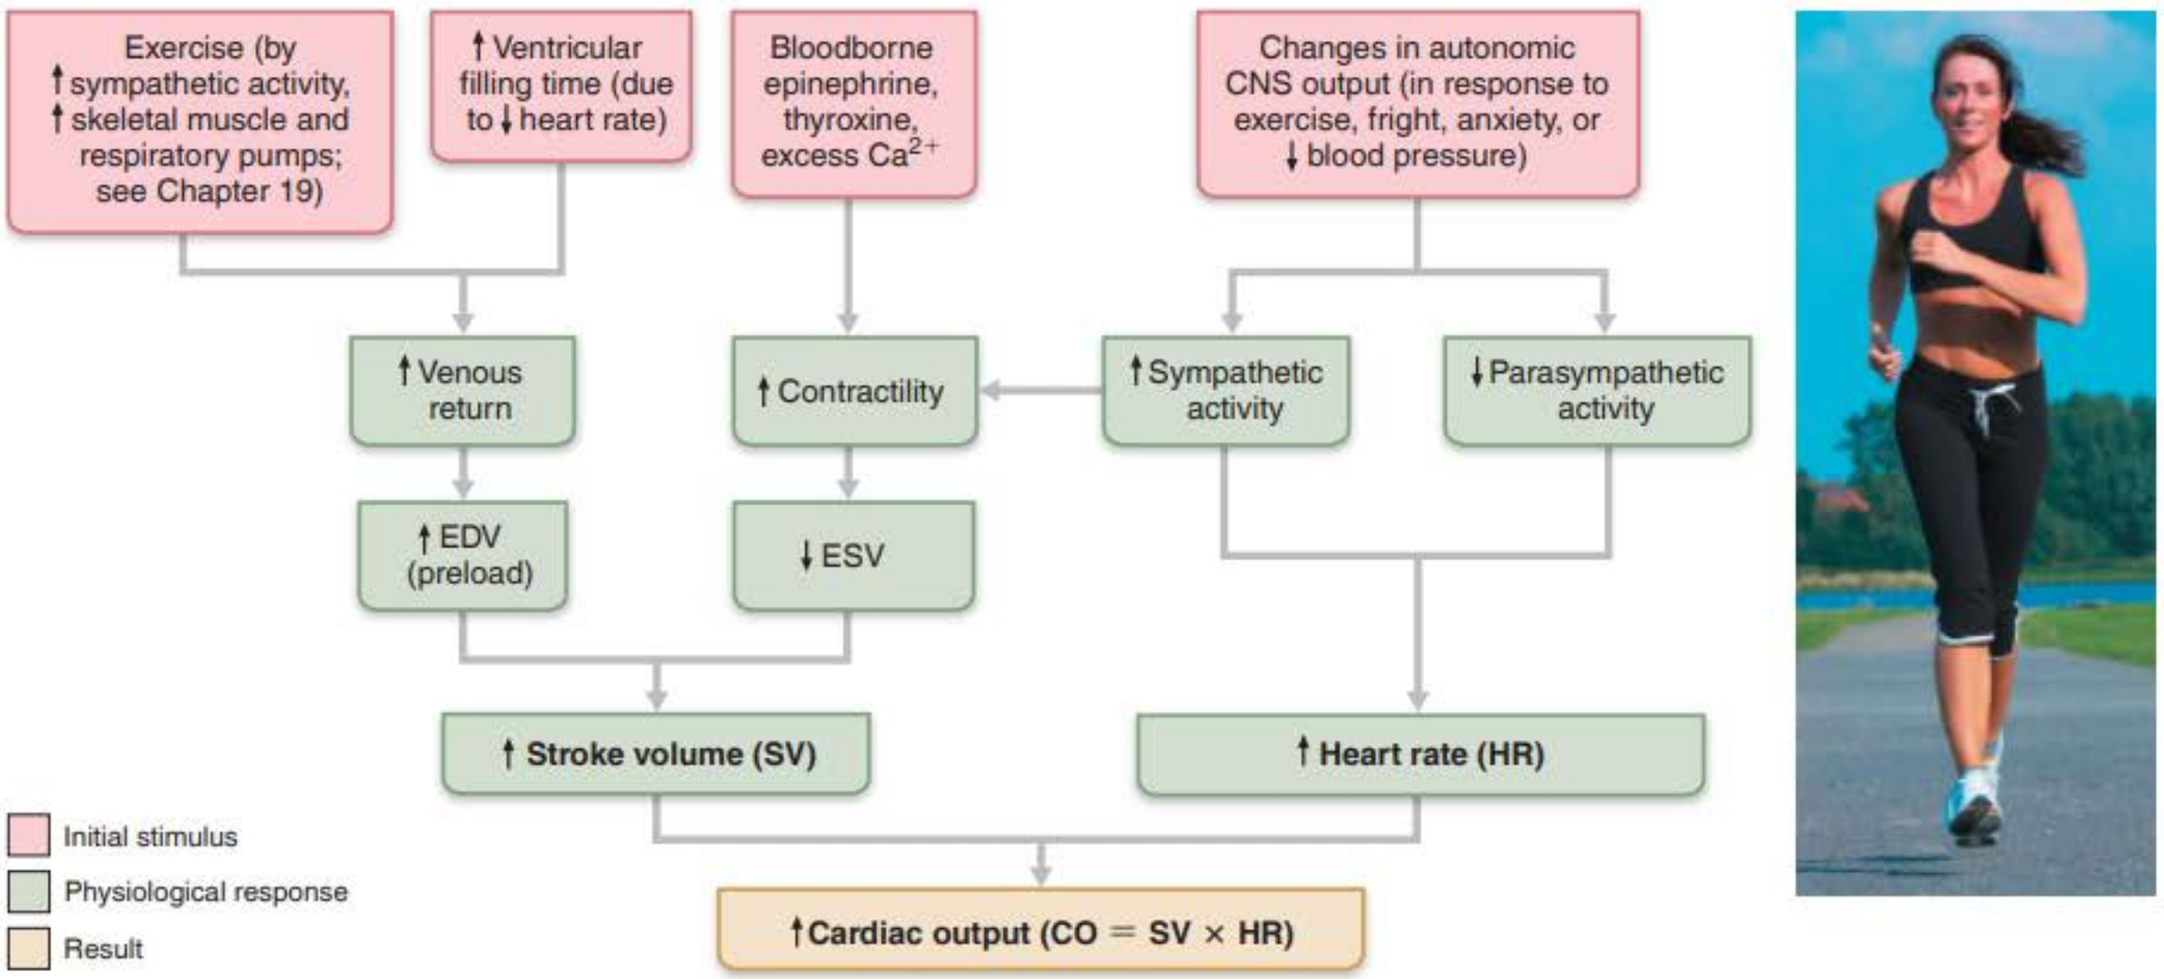


Figure 18.20 Factors involved in determining cardiac output. (EDV = end diastolic volume, ESV = end systolic volume)

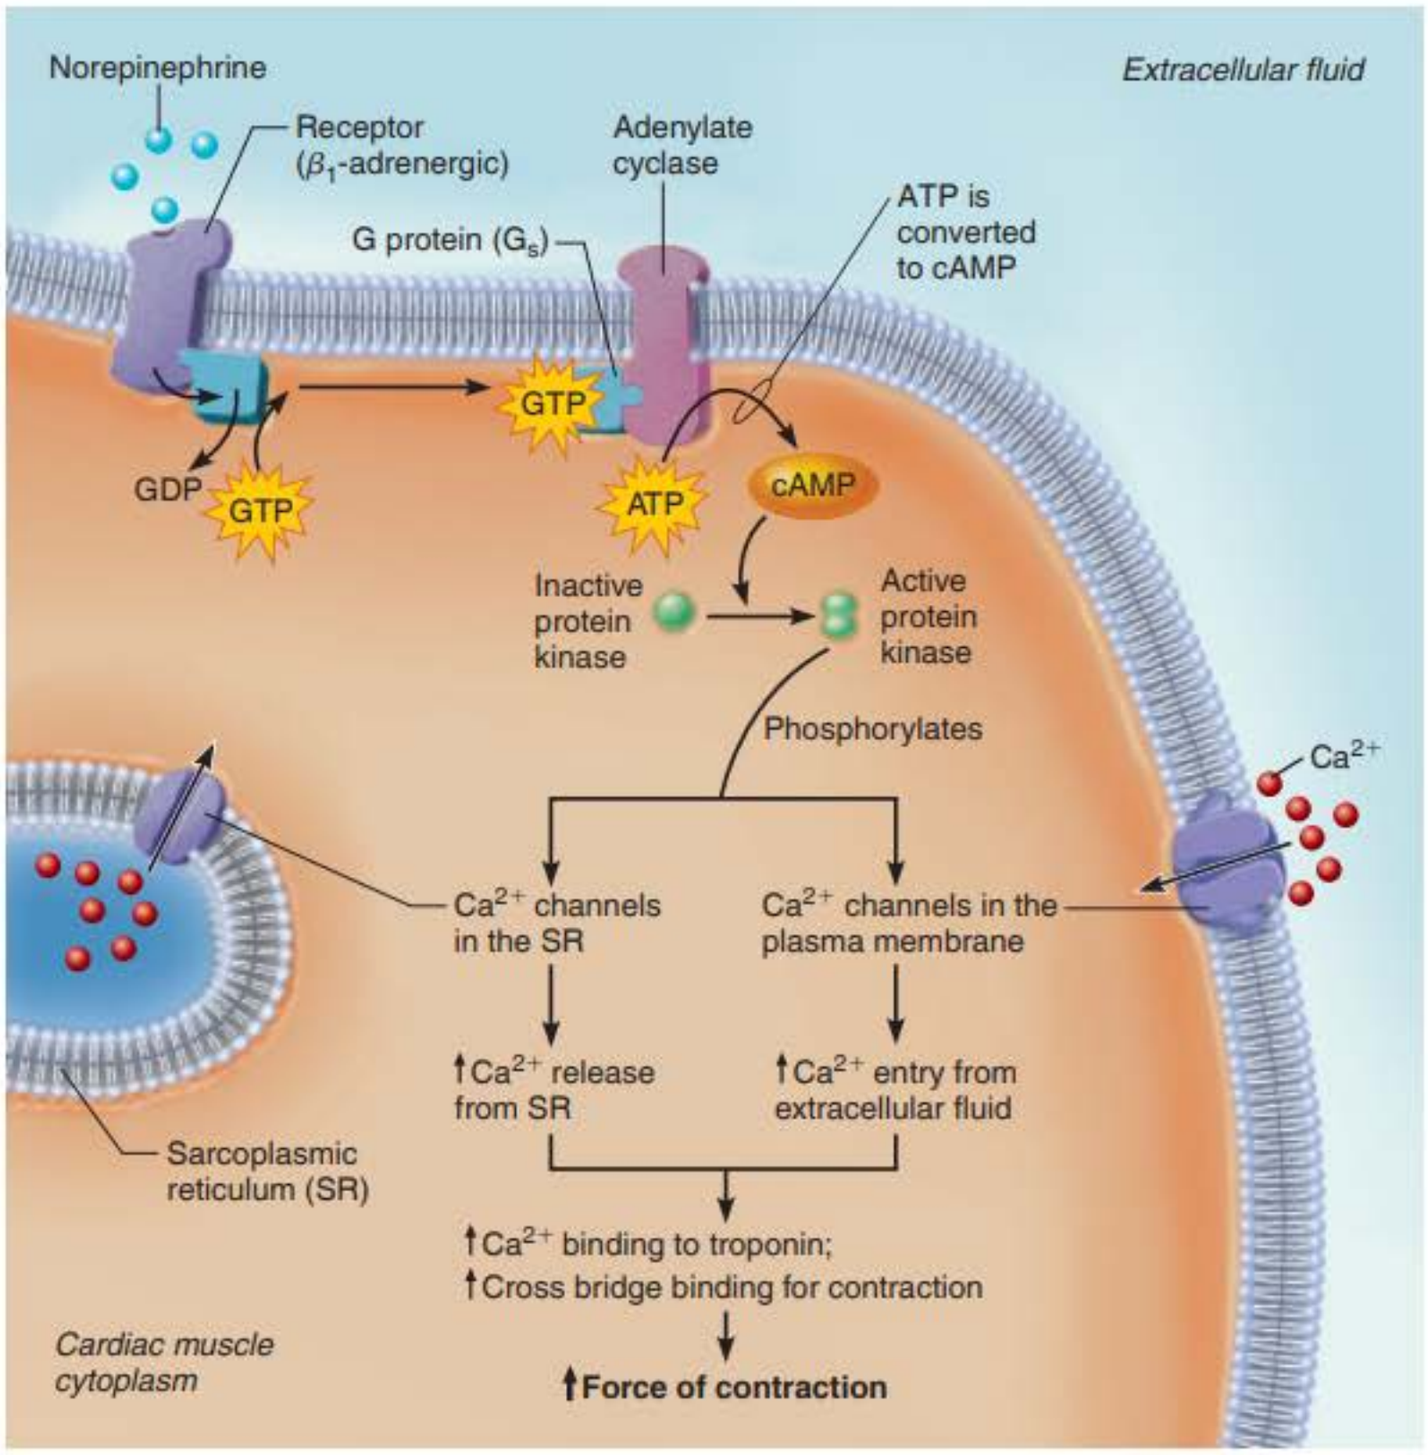

Figure 18.21 Norepinephrine increases heart contractility via a cyclic AMP second-messenger system. Cyclic AMP activates protein kinases that phosphorylate proteins that determine cytoplasmic Ca^{2+} concentrations.

return. Conversely, low venous return might result from severe blood loss or an extremely rapid heart rate that does not allow enough time for ventricular filling. Low venous return decreases EDV, causing the heart to beat less forcefully and lowering SV.

Because the systemic and pulmonary circulations are in series, the intrinsic mechanism we just described ensures equal outputs of the two ventricles and proper distribution of blood volume between the two circuits. If one side of the heart suddenly begins to pump more blood than the other, the increased venous return to the opposite ventricle forces that ventricle—through increased cardiac muscle stretch—to pump out an equal volume, preventing backup or accumulation of blood in the circulation.

Contractility

EDV is the major *intrinsic factor* influencing SV, but *extrinsic factors* that increase heart muscle contractility can also enhance SV. **Contractility** is defined as the contractile strength achieved at a given muscle length. Note in Figure 18.20 that contractility is *independent* of muscle stretch and EDV. Contractility rises when more Ca^{2+} enters the cytoplasm from the extracellular fluid and the SR. Enhanced contractility means more blood is ejected from the heart (greater SV), and so ESV is lower.

Increased sympathetic stimulation increases contractility. As noted on p. 689, sympathetic fibers serve not only the intrinsic conduction system but the entire heart. One effect of norepinephrine or epinephrine binding is to initiate a cyclic AMP second-messenger system that increases Ca^{2+} entry, which in turn promotes more cross bridge binding and enhances ventricular contractility (**Figure 18.21**).

A battery of other chemicals also influence contractility. Substances that increase contractility are called *positive inotropic agents* (*ino* = muscle, fiber). The hormones epinephrine, thyroxine, and glucagon; the drug digitalis; and high levels of extracellular Ca^{2+} are all positive inotropic agents. *Negative inotropic agents*, which impair or decrease contractility, include acidosis (excess H^+), rising extracellular K^+ levels, and drugs called calcium channel blockers.

Afterload: Back Pressure Exerted by Arterial Blood

Afterload is the pressure that the ventricles must overcome to eject blood. It is essentially the back pressure that arterial blood exerts on the aortic and pulmonary valves (about 80 mm Hg in the aorta and 10 mm Hg in the pulmonary trunk as we will see in Chapter 19).

In healthy individuals, afterload is not a major determinant of stroke volume because it is relatively constant. However, in people with hypertension (high blood pressure), afterload is important because it reduces the ability of the ventricles to eject blood. Consequently, more blood remains in the heart after systole, increasing ESV and reducing stroke volume.

Regulation of Heart Rate

Given a healthy cardiovascular system, SV tends to be relatively constant. However, when blood volume drops sharply or the heart is seriously weakened, SV declines and CO is maintained by increasing HR and contractility. Temporary stressors can also influence HR—and consequently CO—by acting through homeostatic mechanisms induced neurally, chemically, and physically. Factors that increase HR are called *positive chronotropic factors* (*chrono* = time), and those that decrease HR are *negative chronotropic factors*.

Autonomic Nervous System Regulation of Heart Rate

The autonomic nervous system exerts the most important extrinsic controls affecting heart rate, as shown on the right side of

Figure 18.20. When emotional or physical stressors (such as fright, anxiety, or exercise) activate the sympathetic nervous system, sympathetic nerve fibers release norepinephrine at their cardiac synapses. Norepinephrine binds to β_1-adrenergic receptors in the heart, causing threshold to be reached more quickly. As a result, the SA node fires more rapidly and the heart responds by beating faster.

Sympathetic stimulation also enhances contractility and speeds relaxation. It does this by enhancing Ca^{2+} movements in the contractile cells as we described above and in Figure 18.21. Enhanced contractility lowers ESV, so SV does not decline as it would if only heart *rate* increased. (Remember, when the heart beats faster, there is less time for ventricular filling and so a lower EDV.)

The parasympathetic division opposes sympathetic effects and effectively reduces heart rate when a stressful situation has passed. Parasympathetic-initiated cardiac responses are mediated by acetylcholine, which hyperpolarizes the membranes of its effector cells by *opening* K^+ channels. Because innervation of the ventricles by the vagus nerve is sparse, parasympathetic activity has little effect on cardiac contractility.

Under resting conditions, both autonomic divisions continuously send impulses to the SA node, but the *dominant* influence is inhibitory. For this reason, the heart is said to exhibit **vagal tone**, and heart rate is generally slower than it would be if the vagus nerves were not innervating it. Cutting the vagus nerves results in an almost immediate increase in heart rate of about 25 beats/min, reflecting the inherent rate (100 beats/min) of the pacemaking SA node.

When sensory input from various parts of the cardiovascular system activates either division of the autonomic nervous system more strongly, the other division is temporarily inhibited. Most such sensory input is generated by *baroreceptors* which respond to changes in systemic blood pressure, as we will discuss in Chapter 19. Another example, the **atrial (Bainbridge) reflex**, is an autonomic reflex initiated by increased venous return and increased atrial filling. Stretching the atrial walls increases heart rate by stimulating both the SA node and the atrial stretch receptors. Stretch receptor activation triggers reflexive adjustments of autonomic output to the SA node, increasing heart rate.

Increased or decreased CO results in corresponding changes to systemic blood pressure, so blood pressure regulation often involves reflexive controls of heart rate. In Chapter 19 we describe in more detail neural mechanisms that regulate blood pressure.

Chemical Regulation of Heart Rate

Chemicals normally present in the blood and other body fluids may influence heart rate.

- **Hormones.** *Epinephrine*, liberated by the adrenal medulla during sympathetic nervous system activation, produces the same cardiac effects as norepinephrine released by the sympathetic nerves: It enhances heart rate and contractility.

  Thyroxine is a thyroid gland hormone that increases metabolic rate and production of body heat. When released in large quantities, it causes a sustained increase in heart rate. Thyroxine acts directly on the heart but also *enhances* the effects of epinephrine and norepinephrine.
- **Ions.** Normal heart function depends on having normal levels of intracellular and extracellular ions. Plasma electrolyte imbalances pose real dangers to the heart.

HOMEOSTATIC IMBALANCE 18.7 CLINICAL

Reduced blood Ca^{2+} levels (*hypocalcemia*) depress the heart. Conversely, above-normal levels (*hypercalcemia*) increase heart rate and contractility—up to a point. Very high Ca^{2+} levels disrupt heart function and can cause life-threatening arrhythmias.

High or low blood K^+ levels are particularly dangerous and arise in a number of clinical conditions. Excessive K^+ (*hyperkalemia*) alters electrical activity in the heart by depolarizing the resting membrane potential, and may lead to heart block and cardiac arrest. *Hypokalemia* is also life threatening, in that the heart beats feebly and arrhythmically.

Other Factors That Regulate Heart Rate

Age, gender, exercise, and body temperature also influence HR, although they are less important than neural factors. Resting heart rate is fastest in the fetus (140–160 beats/min) and gradually declines throughout life. Average heart rate is faster in females (72–80 beats/min) than in males (64–72 beats/min).

Exercise raises HR by acting through the sympathetic nervous system (Figure 18.20). Exercise also increases systemic blood pressure and routes more blood to the working muscles. However, resting HR in the physically fit tends to be substantially lower than in those who are out of condition, and in trained athletes it may be as slow as 40 beats/min. We explain this apparent paradox below.

Heat increases HR by enhancing the metabolic rate of cardiac cells. This explains the rapid, pounding heartbeat you feel when you have a high fever and also accounts, in part, for the effect of exercise on HR (remember, working muscles generate heat). Cold directly decreases heart rate.

HOMEOSTATIC IMBALANCE 18.8 CLINICAL

HR varies with changes in activity, but marked and persistent rate changes usually signal cardiovascular disease.

Tachycardia (tak″e-kar′de-ah; "heart hurry") is an abnormally fast resting heart rate (more than 100 beats/min) that may result from elevated body temperature, stress, certain drugs, or heart disease. Persistent tachycardia is considered pathological because tachycardia occasionally promotes fibrillation.

Bradycardia (brad″e-kar′de-ah; *brady* = slow) is a resting heart rate slower than 60 beats/min. It may result from low body temperature, certain drugs, or parasympathetic nervous system activation. It is a known, and desirable, consequence of endurance training. With physical and cardiovascular conditioning, the heart hypertrophies and SV increases, allowing a lower resting heart rate while still providing the same cardiac output. However, in poorly conditioned people persistent bradycardia may result in grossly inadequate blood circulation to body tissues. Bradycardia is often a warning of brain edema after head trauma.

Homeostatic Imbalance of Cardiac Output

CLINICAL

The heart's pumping action ordinarily maintains a balance between cardiac output and venous return. Were this not so, a dangerous damming up of blood (blood congestion) would occur in the veins returning blood to the heart.

In **congestive heart failure (CHF)**, the heart is such an inefficient pump that blood circulation is inadequate to meet tissue needs. This progressively worsening disorder reflects weakening of the myocardium by various conditions that damage it in different ways. The most common causes include:

- **Coronary atherosclerosis.** Coronary atherosclerosis, essentially fatty buildup that clogs the coronary arteries, impairs blood and oxygen delivery to cardiac cells. The heart becomes increasingly hypoxic and begins to contract ineffectively.
- **Persistent high blood pressure.** Normally, pressure in the aorta during diastole is 80 mm Hg, and the left ventricle exerts only slightly over that amount of force to eject blood from its chamber. When aortic diastolic blood pressure rises to 90 mm Hg or more, the myocardium must exert more force to open the aortic valve and pump out the same amount of blood. If afterload is chronically elevated, ESV rises and the myocardium hypertrophies. Eventually, the stress takes its toll and the myocardium becomes progressively weaker.
- **Multiple myocardial infarctions.** A succession of MIs (heart attacks) depresses pumping efficiency because noncontractile fibrous (scar) tissue replaces the dead heart cells.
- **Dilated cardiomyopathy (DCM).** In this condition, the ventricles stretch and become flabby and the myocardium deteriorates, often for unknown reasons. Drug toxicity or chronic inflammation may be involved.

Because the heart is a double pump, each side can initially fail independently of the other. If the left side fails, **pulmonary congestion** occurs. The right side continues to propel blood to the lungs, but the left side does not adequately eject the returning blood into the systemic circulation. Blood vessels in the lungs become engorged with blood, the pressure in them increases, and fluid leaks from the blood vessels into the lung tissue, causing pulmonary edema. If the congestion is untreated, the person suffocates.

If the right side of the heart fails, **peripheral congestion** occurs. Blood stagnates in body organs, and pooled fluids in the tissue spaces impair the ability of body cells to obtain adequate nutrients and oxygen and rid themselves of wastes. The resulting edema is most noticeable in the extremities (feet, ankles, and fingers).

Failure of one side of the heart puts a greater strain on the other side, and ultimately the whole heart fails. A seriously weakened, or *decompensated*, heart is irreparable. Treatment is directed primarily toward (1) removing the excess leaked fluid with *diuretics* (drugs that increase the kidneys' excretion of Na^+ and water), (2) reducing afterload with drugs that drive down blood pressure, and (3) increasing contractility with digitalis derivatives. Heart transplants and other surgical or mechanical remedies to replace damaged heart muscle provide additional hope for some cardiac patients.

Check Your Understanding

19. APPLY After running to catch a bus, Josh noticed that his heart was beating faster than normal and was pounding forcefully in his chest. How did his increased HR and SV come about?
20. What problem of cardiac output might ensue if the heart beats far too rapidly for an extended period, that is, if tachycardia occurs? Why?

For answers, see Answers Appendix.

Developmental Aspects of the Heart

The human heart, derived from mesoderm and guided by powerful signaling molecules, begins as two simple endothelial tubes. They soon fuse to form a single chamber or heart tube that is busily pumping blood by the 22nd day of gestation (**Figure 18.22**).

The tube develops four slightly bulged areas that represent the earliest heart chambers. From tail to head, following the direction of blood flow, the four primitive chambers are the following (Figure 18.22b):

1. **Sinus venosus** (ven-o′sus). This chamber initially receives all the venous blood of the embryo. It will become the smooth-walled part of the right atrium and the coronary sinus. It also gives rise to the sinoatrial node, which takes control and sets heart rate early in embryonic development.
2. **Atrium.** This embryonic chamber eventually becomes the pectinate muscle–ridged parts of the atria.
3. **Ventricle.** This is the strongest pumping chamber of the early heart and becomes the *left* ventricle.
4. **Bulbus cordis.** This chamber plus its cranial extension, the *truncus arteriosus* (labeled 4a in Figure 18.22b), give rise to the pulmonary trunk, the first part of the aorta, and most of the *right* ventricle.

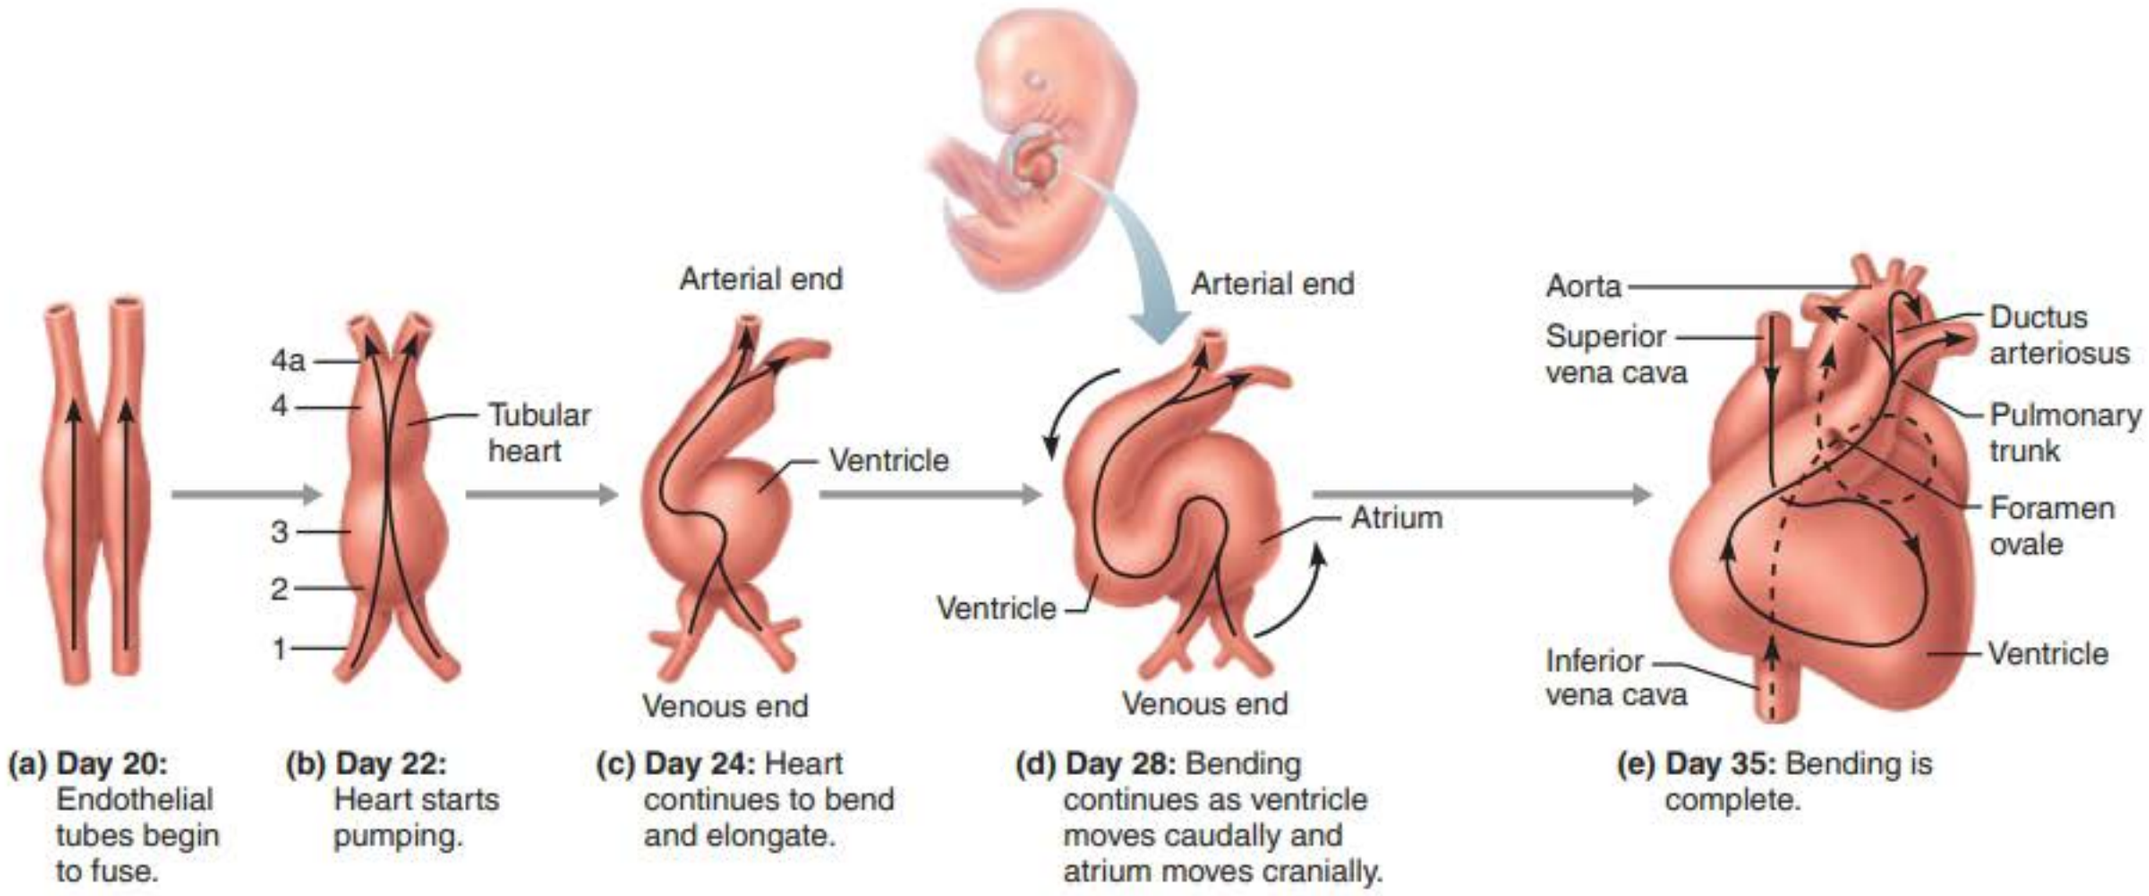
During the next three weeks, the heart "tube" contorts and major structural changes convert it into a four-chambered organ capable of acting as a double pump—all without missing a beat! After the second month, few changes other than growth occur until birth.

The interatrial septum of the fetal heart is incomplete. The **foramen ovale** (literally, "oval door") connects the two atria and allows blood entering the right heart to bypass the pulmonary circuit and the collapsed, nonfunctional fetal lungs (Figure 18.22e). Another lung bypass, the **ductus arteriosus**, exists between the pulmonary trunk and the aorta. At or shortly after birth, these shunts close, completing the separation between the right and left sides of the heart. We give a more complete description of the fetal and newborn circulation in Chapter 28 (see Focus Figure 28.2, pp. 1108–1109).

HOMEOSTATIC IMBALANCE 18.9

CLINICAL

Building a perfect heart is difficult. Each year about 40,000 infants are born in the U.S. with one or more of 30 different **congenital heart defects**, making them the most common of



(a) Day 20: Endothelial tubes begin to fuse.

(b) Day 22: Heart starts pumping.

(c) Day 24: Heart continues to bend and elongate.

(d) Day 28: Bending continues as ventricle moves caudally and atrium moves cranially.

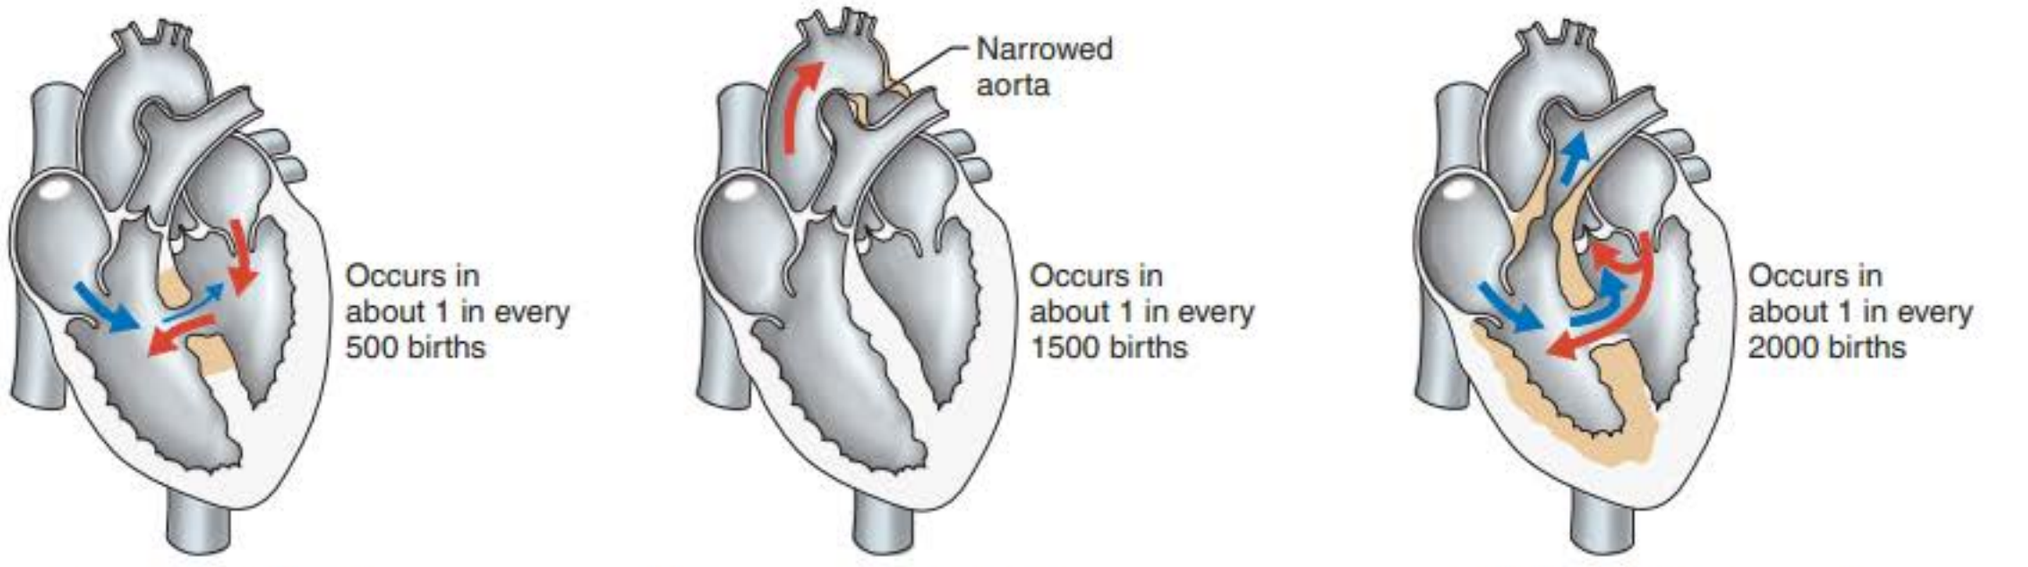
(e) Day 35: Bending is complete.

Figure 18.22 Development of the human heart. Ventral views, with the cranial direction toward the top of the figures. Arrows within the heart show the direction of blood flow. Days are approximate. **(b)** 1 is the sinus venosus; 2, the atrium; 3, the ventricle; 4, the bulbus cordis; and 4a, the truncus arteriosus.

all birth defects. Some congenital heart problems are traceable to environmental influences, such as maternal infection or drug intake during month 2 when the major events of heart formation occur.

The most prevalent abnormalities produce two basic kinds of disorders in the newborn. They either (1) lead to mixing of oxygen-poor blood with oxygenated blood (so that inadequately oxygenated blood reaches the body tissues) or (2) involve narrowed valves or vessels that greatly increase the workload on the heart.

Examples of the first type of defect are *septal defects* (**Figure 18.23a**) and *patent ductus arteriosus*, in which the connection between the aorta and pulmonary trunk remains open. *Coarctation of the aorta* (Figure 18.23b) is an example of the second type of problem. *Tetralogy of Fallot* (te-tral′o-je ov fal-o′), a serious condition in which the baby becomes cyanotic (turns blue) within minutes of birth, encompasses both types of disorders (Figure 18.23c). Surgery can usually correct these congenital defects.



(a) Ventricular septal defect. The superior part of the interventricular septum fails to form, allowing blood to mix between the two ventricles. More blood is shunted from left to right because the left ventricle is stronger.

(b) Coarctation of the aorta. A part of the aorta is narrowed, increasing the workload of the left ventricle.

(c) Tetralogy of Fallot. Multiple defects (*tetra* = four): (1) Pulmonary trunk too narrow and pulmonary valve stenosed, resulting in (2) hypertrophied right ventricle; (3) ventricular septal defect; (4) aorta receives blood from both ventricles.

Figure 18.23 Three examples of congenital heart defects. Tan areas indicate the locations of the defects.

CHAPTER SUMMARY

18.1 The heart has four chambers and pumps blood through the pulmonary and systemic circuits (pp. 671–678)

1. The right side of the heart is the pulmonary circuit pump. It pumps blood through the lungs, where the blood picks up oxygen and dumps carbon dioxide. The left side of the heart is the systemic circuit pump. It pumps blood through the body's tissues, supplying them with oxygen and nutrients and removing carbon dioxide.
2. The human heart, about the size of a clenched fist, is located obliquely within the mediastinum of the thorax.
3. The heart is enclosed within a double sac made up of the outer fibrous pericardium and the inner serous pericardium (parietal and visceral layers). The pericardial cavity between the serous layers contains lubricating serous fluid.
4. Layers of the heart wall, from the interior out, are the endocardium, myocardium (reinforced by a fibrous cardiac skeleton), and epicardium (visceral layer of the serous pericardium).
5. The heart has two superior atria and two inferior ventricles. Functionally, the heart is a double pump.
6. Entering the right atrium are the superior vena cava, inferior vena cava, and coronary sinus. Four pulmonary veins enter the left atrium.
7. The right ventricle discharges blood into the pulmonary trunk; the left ventricle pumps blood into the aorta.

18.2 Heart valves make blood flow in one direction (pp. 679–680)

1. The atrioventricular (AV) valves (tricuspid and mitral) prevent backflow into the atria when the ventricles are contracting; the semilunar (SL) valves (pulmonary and aortic) prevent backflow into the ventricles when the ventricles are relaxing.

18.3 Blood flows from atrium to ventricle, and then to either the lungs or the rest of the body (pp. 680–683)

1. Oxygen-poor systemic blood enters the right atrium, passes into the right ventricle, through the pulmonary trunk to the lungs, and back to the left atrium via the pulmonary veins. Oxygen-laden blood entering the left atrium from the lungs flows into the left ventricle and then into the aorta, which provides the functional supply of all body organs. Systemic veins return the oxygen-depleted blood to the right atrium.
2. The right and left coronary arteries branch from the aorta and supply the heart itself via their main branches (anterior and posterior interventricular, right marginal, and circumflex arteries). Venous blood, collected by the cardiac veins (great, middle, and small), empties into the coronary sinus.
3. Blood delivery to the myocardium occurs during heart relaxation.

18.4 Intercalated discs connect cardiac muscle fibers into a functional syncytium (pp. 683–686)

1. Cardiac muscle cells are branching, striated, generally uninucleate cells. They contain myofibrils consisting of typical sarcomeres.
2. Intercalated discs containing desmosomes and gap junctions connect adjacent cardiac cells. The myocardium behaves as a functional syncytium because of electrical coupling provided by gap junctions.
3. Ca^{2+} released by the SR and entering from the extracellular space couples the action potential to sliding of the myofilaments. Compared to skeletal muscle, cardiac muscle has a prolonged refractory period that prevents tetany.
4. Cardiac muscle has abundant mitochondria and depends almost entirely on aerobic respiration to form ATP.

18.5 Pacemaker cells trigger action potentials throughout the heart (pp. 686–692)

1. Certain noncontractile cardiac muscle cells exhibit automaticity and rhythmicity and can independently initiate action potentials. Such cells have an unstable resting potential called a pacemaker potential that gradually depolarizes, drifting toward threshold for firing. These cells compose the intrinsic conduction system of the heart.
2. The conduction system of the heart consists of the SA and AV nodes, the AV bundle and bundle branches, and the subendocardial conducting network. This system coordinates the depolarization of the heart and ensures that the heart beats as a unit. The SA node has the fastest rate of spontaneous depolarization and acts as the heart's pacemaker; it sets the sinus rhythm.
3. Defects in the intrinsic conduction system can cause arrhythmias, fibrillation, and heart block.
4. The autonomic nervous system innervates the heart. Cardiac centers in the medulla include the cardioacceleratory center, which projects to the T_1–T_5 region of the spinal cord, which in turn projects to the cervical and upper thoracic sympathetic trunk. Postganglionic fibers innervate the SA and AV nodes and the cardiac muscle fibers. The cardioinhibitory center exerts its influence via the parasympathetic vagus nerves (X), which project to the heart wall. Most parasympathetic fibers serve the SA and AV nodes.
5. The membrane depolarization of contractile myocytes causes opening of sodium channels and allows sodium to enter, which is responsible for the rising phase of the action potential curve. Depolarization also opens slow Ca^{2+} channels; Ca^{2+} entry prolongs the period of depolarization (creates the plateau).
6. An electrocardiogram (ECG) is a graphic representation of the cardiac conduction cycle. The P wave reflects atrial depolarization. The QRS complex indicates ventricular depolarization; the T wave represents ventricular repolarization.

Complete an interactive tutorial: MasteringA&P® > Study Area > Interactive Physiology > Cardiovascular System: Electrical Activity of the Heart

18.6 The cardiac cycle describes the mechanical events associated with blood flow through the heart (pp. 692–696)

1. A cardiac cycle consists of the events occurring during one heartbeat. During mid-to-late diastole, the ventricles fill and the atria contract. Ventricular systole consists of the isovolumetric contraction phase and the ventricular ejection phase. During early diastole, the ventricles are relaxed and are closed chambers until the atrial pressure exceeds the ventricular pressure, forcing the AV valves open. Then the cycle begins again. At a normal heart rate of 75 beats/min, a cardiac cycle lasts 0.8 s.

2. Pressure changes promote blood flow and valve opening and closing.

Complete an interactive tutorial: MasteringA&P® > Study Area > Interactive Physiology > Cardiovascular System: Cardiac Cycle

3. Normal heart sounds arise chiefly from turbulent blood flow during the closing of heart valves. Abnormal heart sounds, called murmurs, usually reflect valve problems.

18.7 Stroke volume and heart rate are regulated to alter cardiac output (pp. 696–700)

1. Cardiac output, typically 5 L/min, is the amount of blood pumped out by each ventricle in 1 minute. Stroke volume is the amount of blood pumped out by a ventricle with each contraction. Cardiac output = heart rate × stroke volume.
2. Stroke volume depends to a large extent on the degree to which venous return stretches cardiac muscle. Approximately 70 ml, it is the difference between end diastolic volume (EDV) and end systolic volume (ESV). Anything that influences heart rate or blood volume influences venous return, hence stroke volume.
3. Activation of the sympathetic nervous system increases heart rate and contractility; parasympathetic activation decreases heart rate but has little effect on contractility. Ordinarily, the heart exhibits vagal tone.
4. Chemical regulation of the heart is effected by hormones (epinephrine and thyroxine) and ions (particularly potassium and calcium). Ion imbalances severely impair heart activity.
5. Other factors influencing heart rate are age, sex, exercise, and body temperature.
6. Congestive heart failure occurs when the pumping ability of the heart cannot provide adequate circulation to meet body needs. Right heart failure leads to systemic edema; left heart failure results in pulmonary edema.

Complete an interactive tutorial: MasteringA&P® > Study Area > Interactive Physiology > Cardiovascular System: Cardiac Output

Developmental Aspects of the Heart (pp. 700–702)

1. The heart begins as a simple (mesodermal) tube that is pumping blood by the fourth week of gestation. The fetal heart has two lung bypasses: the foramen ovale and the ductus arteriosus.
2. Congenital heart defects are the most common of all birth defects. The most common of these disorders lead to inadequate oxygenation of blood or increase the workload of the heart.
3. Age-related changes include sclerosis and thickening of the valve flaps, declines in cardiac reserve, fibrosis of cardiac muscle, and atherosclerosis.
4. Risk factors for cardiac disease include dietary factors, excessive stress, cigarette smoking, and lack of exercise.

REVIEW QUESTIONS

To access additional practice questions using your smartphone, tablet, or computer: MasteringA&P® > Study Area > Practice Tests & Quizzes

Level 1 Remember/Understand

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. When the semilunar valves are open, which of the following are occurring?
   (1) coronary arteries fill
   (2) AV valves are closed
   (3) ventricles are in systole
   (4) ventricles are in diastole
   (5) blood enters aorta
   (6) blood enters pulmonary arteries
   (7) atria contract
   (a) 2, 3, 5, 6, **(b)** 1, 2, 3, 7, **(c)** 1, 3, 5, 6, **(d)** 2, 4, 5, 7.
2. The portion of the intrinsic conduction system located in the superior interventricular septum is the **(a)** AV node, **(b)** SA node, **(c)** AV bundle, **(d)** subendocardial conducting network.
3. An ECG provides information about **(a)** cardiac output, **(b)** movement of the excitation wave across the heart, **(c)** coronary circulation, **(d)** valve impairment.
4. The sequence of contraction of the heart chambers is **(a)** random, **(b)** left chambers followed by right chambers, **(c)** both atria followed by both ventricles, **(d)** right atrium, right ventricle, left atrium, left ventricle.
5. The fact that the left ventricular wall is thicker than the right reveals that it **(a)** pumps a greater volume of blood, **(b)** pumps blood against greater resistance, **(c)** expands the thoracic cage, **(d)** pumps blood through a smaller valve.
6. The chordae tendineae **(a)** close the atrioventricular valves, **(b)** prevent the AV valve flaps from everting, **(c)** contract the papillary muscles, **(d)** open the semilunar valves.
7. In the heart, which of the following apply? **(1)** Action potentials are conducted from cell to cell across the myocardium via gap junctions, **(2)** the SA node sets the pace for the heart as a whole, **(3)** spontaneous depolarization of cardiac cells can occur in the absence of nerve stimulation, **(4)** cardiac muscle can continue to contract for long periods in the absence of oxygen. **(a)** all of the above, **(b)** 1, 3, 4, **(c)** 1, 2, 3, **(d)** 2, 3.
8. Freshly oxygenated blood is first received by the **(a)** right atrium, **(b)** left atrium, **(c)** right ventricle, **(d)** left ventricle.
9. Describe the location and position of the heart in the body.
10. The refractory period of cardiac muscle is much longer than that of skeletal muscle. Why is this a desirable functional property?
11. Draw a normal ECG pattern. Label and explain the significance of its deflection waves.
12. Define cardiac cycle, and follow the events of one cycle.
13. What is cardiac output, and how is it calculated?
14. As Cara worked at her dissection, she became frustrated that several of the structures she had to learn about had more than one common name. Provide another name for each of these structures: **(a)** atrioventricular groove, **(b)** tricuspid valve, **(c)** bicuspid valve (give two synonyms), and **(d)** atrioventricular bundle.

Level 2 Apply/Analyze

15. The activity of the heart depends on intrinsic properties of cardiac muscle and on neural factors. Thus, **(a)** vagus nerve stimulation of the heart reduces heart rate, **(b)** sympathetic nerve stimulation of the heart decreases time available for ventricular filling, **(c)** sympathetic stimulation of the heart increases its force of contraction, **(d)** all of the above.
16. Describe the pericardium and distinguish between the fibrous and the serous pericardia relative to histological structure and location.

17. Trace one drop of blood from the time it enters the right atrium until it enters the left atrium. What is this circuit called?
18. **(a)** Describe how heart contraction and relaxation influence coronary blood flow. **(b)** Name the major branches of the coronary arteries, and note the heart regions served by each.
19. **(a)** Name the elements of the intrinsic conduction system of the heart in order, beginning with the pacemaker. **(b)** What is the important function of this conduction system?
20. Discuss how the Frank-Starling law of the heart helps to explain the influence of venous return on stroke volume.
21. **(a)** Describe the common function of the foramen ovale and the ductus arteriosus in a fetus. **(b)** What problems result if these shunts remain patent (open) after birth?
22. You have been called upon to demonstrate the technique for listening to valve sounds. **(a)** Explain where you would position your stethoscope to auscultate (1) the aortic valve of a patient with severe aortic valve insufficiency and (2) a stenotic mitral valve. **(b)** During which period(s) would you hear these abnormal valve sounds most clearly? (During atrial diastole, ventricular systole, ventricular diastole, or atrial systole?) **(c)** What cues would you use to differentiate between an insufficient and a stenotic valve?
23. Gabriel, a heroin addict, feels tired, is weak and feverish, and has vague aches and pains. Terrified that he has AIDS, he goes to a doctor and is informed that he is suffering not from AIDS, but from a heart murmur accompanied by endocarditis. What is the most likely way that Gabriel contracted endocarditis? (Hint: See Related Clinical Terms.)

Level 3 Evaluate/Synthesize

24. Florita Santos, a middle-aged woman, is admitted to the coronary care unit with a diagnosis of left ventricular failure resulting from a myocardial infarction. Her history indicates that she awoke in the middle of the night with severe chest pain. Her skin is pale and cold, and moist sounds are heard over the lower regions of both lungs. Explain how failure of the left ventricle can cause these signs and symptoms.
25. Hannah, a newborn baby, needs surgery because she was born with an aorta that arises from the right ventricle and a pulmonary trunk that issues from the left ventricle, a condition called transposition of the great vessels. What are the physiological consequences of this defect?

CLINICAL CASE STUDY

54-Year-Old Female with a Defective Heart Valve

Dr. El-Sheikh is a 54-year-old Egyptian female who complains of weakness, fatigue, shortness of breath, chest pain, and dizziness. Her heart rate is 96 beats/min, and her blood pressure is 148/54 mm Hg. You notice that she nods her head with every heartbeat, and her radial pulse is very strong and abrupt. Her heart sounds are abnormal, with a long diastolic murmur at the right sternal margin in the second intercostal space.

Her doctor orders an echocardiogram, which shows that Dr. El-Sheikh has severe aortic regurgitation (backflow of blood through an incompetent valve) and an enlarged left ventricle.

1. Why does an incompetent aortic valve cause a diastolic murmur?
2. How will blood leaking through the incompetent aortic valve during diastole affect the preload and stroke volume of the left ventricle?
3. Why is Dr. El-Sheikh's systolic blood pressure abnormally high and her diastolic blood pressure abnormally low?
4. ✚ NCLEX-STYLE In a patient with an incompetent aortic valve, the nurse expects the patient to show signs and symptoms of which of the following?
   a. Peripheral congestion
   b. Pulmonary congestion
   c. Cerebral congestion
   d. Hepatic congestion
5. The additional muscle in Dr. El-Sheikh's enlarged left ventricle means that it requires more oxygen. Which arteries are most important for supplying this ventricle?
6. ✚ NCLEX-STYLE Although Dr. El-Sheikh has a high systolic blood pressure, her heart rate is also high. This is most likely due to:
   a. The Bainbridge reflex, caused by increased atrial filling
   b. Parasympathetic activation
   c. Excessive vagus nerve firing
   d. Sympathetic stimulation

19 The Cardiovascular System: Blood Vessels

In this chapter, you will learn that

Blood vessels are dynamic structures that control the delivery of blood to body tissues

Blood vessels are sometimes compared to a system of pipes with blood circulating in them, but this analogy is only a starting point. Unlike rigid pipes, blood vessels are dynamic structures that pulsate, constrict, relax, and even proliferate (multiply). In this chapter we examine the structure and function of these important circulatory passageways.

The **blood vessels** of the body form a closed delivery system that begins and ends at the heart. The idea that blood circulates in the body dates back to the 1620s with the inspired experiments of William Harvey, an English physician. Prior to that time, people thought, as proposed by the ancient Greek physician Galen, that blood moved through the body like an ocean tide, first moving out from the heart and then ebbing back in the same vessels.

PART 1

BLOOD VESSEL STRUCTURE AND FUNCTION

The three major types of blood vessels are *arteries*, *capillaries*, and *veins*. As the heart contracts, it forces blood into the large arteries leaving the ventricles. The blood then moves into successively smaller arteries, finally reaching their smallest branches, the *arterioles* (ar-te′re-ōlz; "little arteries"), which feed into the capillary beds of body organs and tissues. Blood drains from the capillaries into *venules* (ven′ūlz), the smallest veins, and then on into larger and larger veins that merge to form the large veins that ultimately empty into the heart. Altogether, the blood vessels in the adult human stretch for about 100,000 km (60,000 miles) through the internal body landscape!

Arteries carry blood *away from* the heart, so they are said to "branch," "diverge," or "fork" as they form smaller and smaller divisions. **Veins**, by contrast, carry blood *toward* the heart and so are said to "join," "merge," and "converge" into the successively larger vessels approaching the heart. In the systemic circulation, arteries always carry oxygenated blood and veins always carry oxygen-poor blood. The opposite is true in two special locations:

- In the pulmonary circulation, the arteries, still defined as the vessels leading away from the heart, carry oxygen-poor blood to the lungs, and the veins carry oxygen-rich blood from the lungs to the heart.
- In the special umbilical vessels of a fetus, the roles of veins and arteries also differ with respect to oxygenation.

Of all the blood vessels, only the capillaries have intimate contact with tissue cells and directly serve cellular needs. Exchanges between the blood and tissue cells occur primarily through the gossamer-thin capillary walls.

Figure 19.1 summarizes how these vascular channels relate to one another and to vessels of the lymphatic system. The lymphatic system recovers fluids that leak from the blood vessels and is described in Chapter 20.

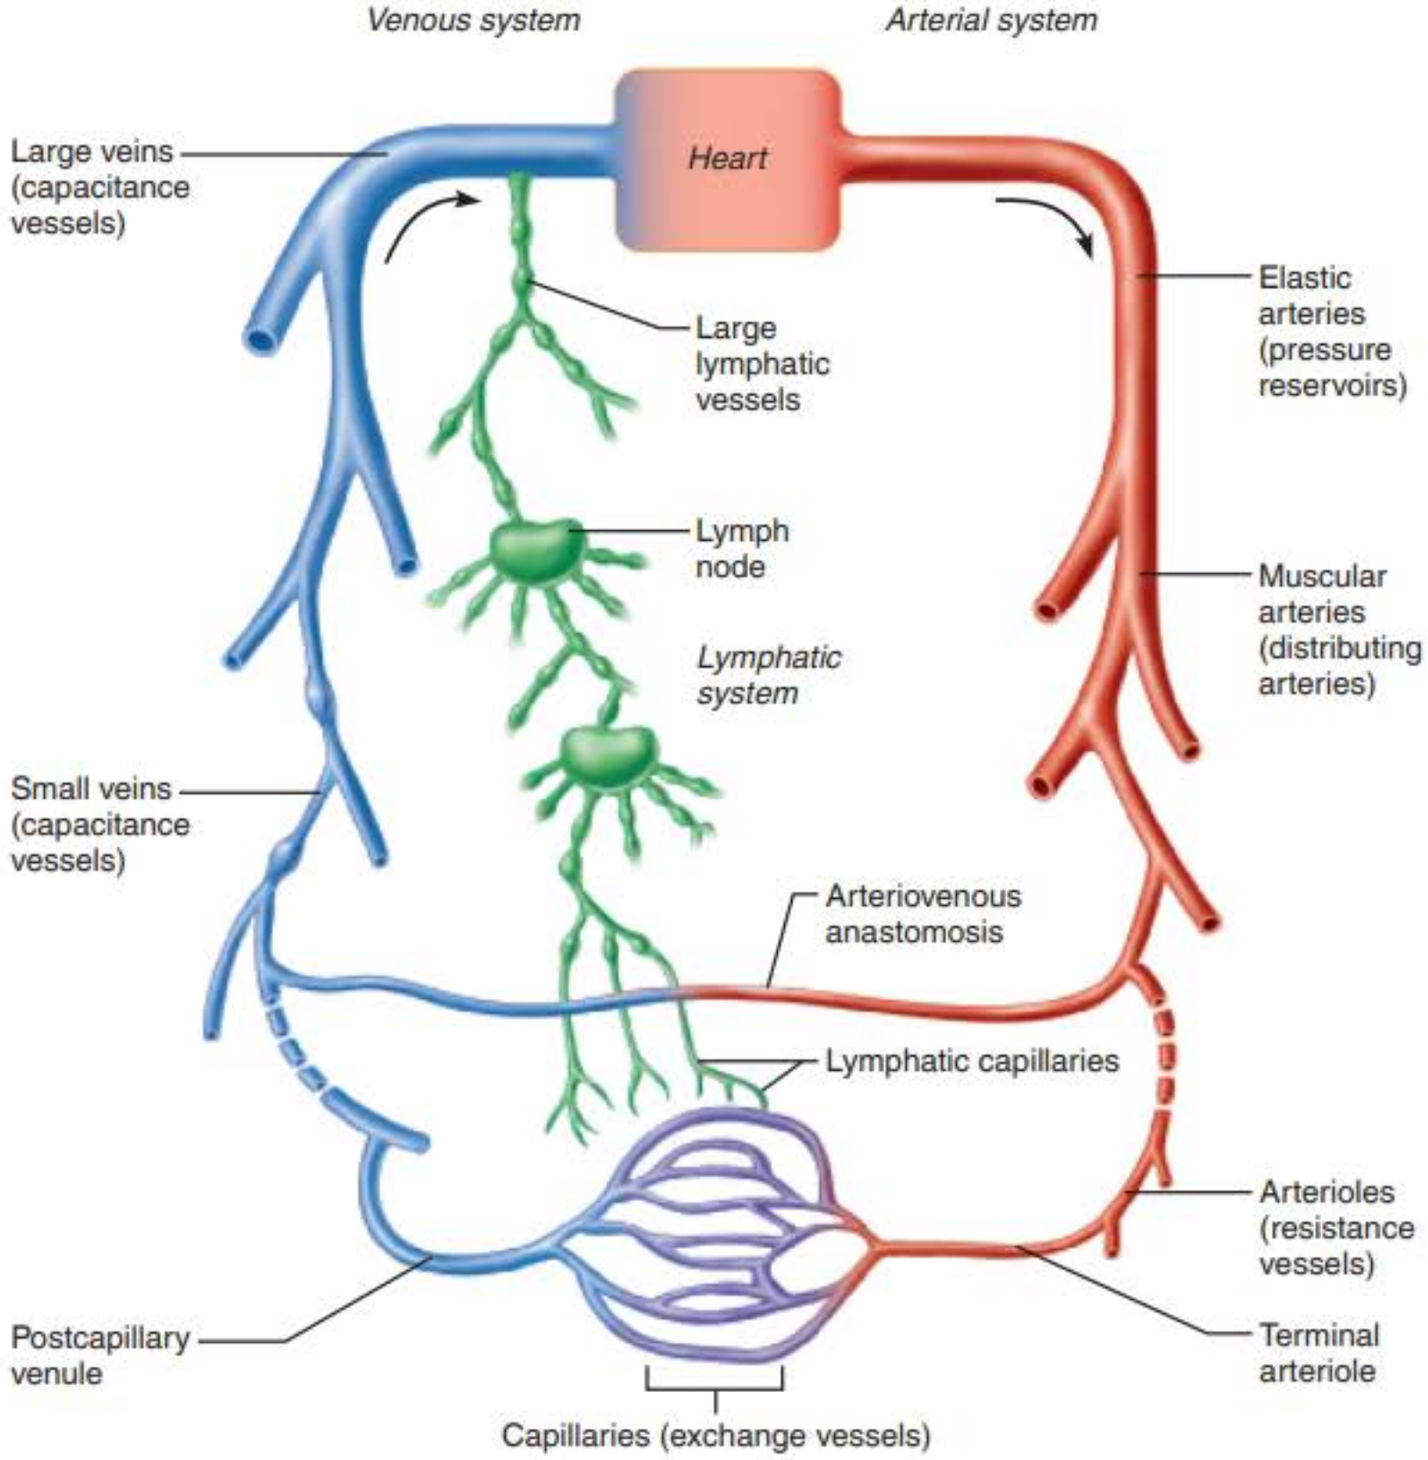

Figure 19.1 The relationship of blood vessels to each other and to lymphatic vessels. Lymphatic vessels recover excess tissue fluid and return it to the blood.

19.1 Most blood vessel walls have three layers

Learning Outcomes

- **Describe the three layers that typically form the wall of a blood vessel, and state the function of each.**
- **Define vasoconstriction and vasodilation.**

The walls of all blood vessels, except the very smallest, have three distinct layers, or *tunics* ("coverings"), that surround a central blood-containing space, the vessel **lumen** (**Figure 19.2**).

The innermost tunic is the **tunica intima** (in′tĭ-mah). The name is easy to remember once you know that this tunic is in *intimate* contact with the blood in the lumen. The tunica intima contains the **endothelium**, the simple squamous epithelium that lines the lumen of all vessels (◀ p. 121). The endothelium is continuous with the endocardial lining of the heart, and its flat cells fit closely together, forming a slick surface that minimizes friction as blood moves through the lumen. In vessels larger than 1 mm in diameter, a *subendothelial layer*, consisting of a basement membrane and loose connective tissue, supports the endothelium.

The middle tunic, the **tunica media** (me′de-ah), is mostly circularly arranged smooth muscle cells and sheets of elastin. The activity of the smooth muscle is regulated by sympathetic *vasomotor nerve fibers* of the autonomic nervous system and a whole battery of chemicals. Depending on the body's needs at any given moment, regulation causes either **vasoconstriction** (lumen diameter decreases as the smooth muscle contracts) or **vasodilation** (lumen diameter increases as the smooth muscle relaxes). The activities of the tunica media are critical in regulating circulatory dynamics because small changes in vessel diameter greatly influence blood flow and blood pressure. Generally, the tunica media is the bulkiest layer in arteries, which bear the chief responsibility for maintaining blood pressure and circulation.

The outermost layer of a blood vessel wall, the **tunica externa** (also called the *tunica adventitia*; ad″ven-tish′e-ah; "coming from outside"), is composed largely of loosely woven collagen fibers that protect and reinforce the vessel, and anchor it to surrounding structures. The tunica externa is infiltrated with nerve fibers, lymphatic vessels, and, in larger veins, a network of elastic fibers. In larger vessels, the tunica externa contains a system of tiny blood vessels, the **vasa vasorum** (va′sah va-sor′um)—literally, "vessels of the vessels"—that nourish the more external tissues of the blood vessel wall. The innermost (luminal) portion of the vessel obtains nutrients directly from blood in the lumen.

The three vessel types vary in length, diameter, wall thickness, and tissue makeup (see **Table 19.1**).

Check Your Understanding

1. Which branch of the autonomic nervous system innervates blood vessels? Which layer of the blood vessel wall do these nerves innervate? What are the effectors (cells that carry out the response)?
2. When vascular smooth muscle contracts, what happens to the diameter of the blood vessel? What is this called?

For answers, see Answers Appendix.

Table 19.1 Summary of Blood Vessel Anatomy

VESSEL TYPE/ ILLUSTRATION*	AVERAGE LUMEN DIAMETER (D) AND WALL THICKNESS (T)	RELATIVE TISSUE MAKEUP			
		Endothelium	*Elastic Tissues*	*Smooth Muscles*	*Fibrous (Collagenous) Tissues*
ARTERIES					
Elastic artery	D: 1.5 cm T: 1.0 mm				
Muscular artery	D: 6.0 mm T: 1.0 mm				
Arteriole	D: 37.0 µm T: 6.0 µm				
CAPILLARIES					
	D: 9.0 µm T: 0.5 µm				
VEINS					
 Venule	D: 20.0 µm T: 1.0 µm				
Vein	D: 5.0 mm T: 0.5 mm				

*Size relationships are not proportional. Smaller vessels are drawn relatively larger so detail can be seen. See column 2 for actual dimensions.

19.2 Arteries are pressure reservoirs, distributing vessels, or resistance vessels

Learning Outcome

- **Compare and contrast the structure and function of the three types of arteries.**

In terms of relative size and function, arteries can be divided into three groups—elastic arteries, muscular arteries, and arterioles.

Elastic Arteries

Elastic arteries are the thick-walled arteries near the heart—the aorta and its major branches (Figure 19.1). These arteries are the largest in diameter, ranging from 2.5 cm to 1 cm, and the most elastic (Table 19.1). Because their large lumens make them low-resistance pathways that conduct blood from the heart to medium-sized arteries, elastic arteries are sometimes called *conducting arteries*.

Elastic arteries contain more elastin than any other vessel type. It is present in all three tunics, but the tunica media contains the most. There the elastin constructs concentric "holey" sheets of elastic connective tissue that look like slices of Swiss cheese sandwiched between layers of smooth muscle cells. Although elastic arteries also contain substantial amounts of smooth muscle, they are relatively inactive in vasoconstriction. Thus, in terms of function, they can be visualized as simple elastic tubes.

Elastic arteries are *pressure reservoirs*, expanding and recoiling as the heart ejects blood. Consequently, blood flows fairly continuously rather than starting and stopping with the pulsating rhythm of the heartbeat. If the blood vessels become hard and unyielding, as in atherosclerosis, blood flows more intermittently, similar to the way water flows through a hard rubber garden hose attached to a faucet. When the faucet is on, the high pressure makes the water gush out of the hose. But when the faucet is shut off, the water flow abruptly becomes a trickle and then stops, because the hose walls cannot recoil to keep the water under pressure. Also, without the pressure-smoothing effect of the elastic arteries, the walls of arteries throughout the body experience higher pressures. Battered by high pressures, the arteries eventually weaken and may balloon out (as an *aneurysm*) or even burst (see **A Closer Look** on p. 760).

Muscular Arteries

Distally the elastic arteries give way to the **muscular arteries**, which deliver blood to specific body organs (and so are sometimes called *distributing arteries*). Muscular arteries account for most of the named arteries studied in the anatomy laboratory. Their internal diameter ranges from that of a little finger to that of a pencil lead.

Proportionately, muscular arteries have the thickest tunica media of all vessels. Their tunica media contains relatively more smooth muscle and less elastic tissue than do elastic arteries (Table 19.1). For this reason, they are more active in vasoconstriction and less capable of stretching. In muscular arteries, however, there *is* an *elastic membrane* on each face of the tunica media.

Arterioles

The smallest of the arteries, **arterioles** have a lumen diameter ranging from 0.3 mm down to 10 μm. Larger arterioles have all three tunics, but their tunica media is chiefly smooth muscle with a few scattered elastic fibers. Smaller arterioles, which lead into the capillary beds, are little more than a single layer of smooth muscle cells spiraling around the endothelial lining.

Minute-to-minute blood flow into the capillary beds is determined by arteriolar diameter, which varies in response to changing neural, hormonal, and local chemical influences. Changing diameter changes resistance to blood flow, and so arterioles are called *resistance vessels*. When arterioles constrict, the tissues served are largely bypassed. When arterioles dilate, blood flow into the local capillaries increases dramatically.

Check Your Understanding

3. Name the type of artery that matches each description: major role in dampening the pulsatile pressure of heart contractions; vasodilation or constriction determines blood flow to individual capillary beds; have the thickest tunica media relative to their lumen size.

For answers, see Answers Appendix.

19.3 Capillaries are exchange vessels

Learning Outcome

- **Describe the structure and function of a capillary bed.**

The microscopic **capillaries** are the smallest blood vessels (Figure 19.2b). Their exceedingly thin walls consist of just a thin tunica intima surrounded by a basement membrane (◀ p. 118). In some cases, a single endothelial cell forms the entire circumference of the capillary wall. At strategic locations along the outer surface of some capillaries are spider-shaped **pericytes**, contractile stem cells that can generate new vessels or scar tissue, stabilize the capillary wall, and help control capillary permeability (**Figure 19.3a**).

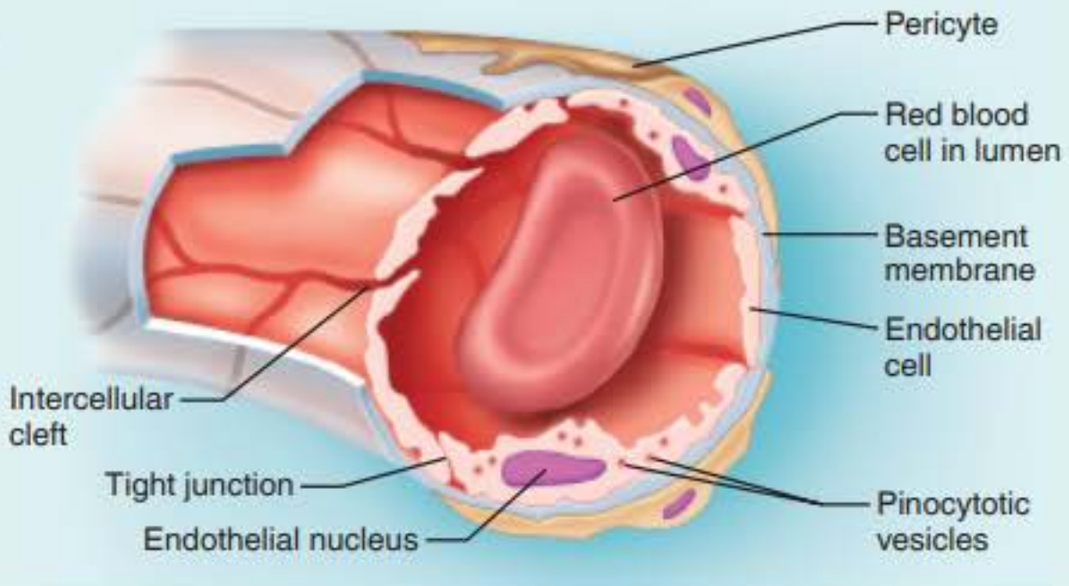
Average capillary length is 1 mm and average lumen diameter is 8–10 μm, just large enough for red blood cells to slip through in single file. Most tissues have a rich capillary supply, but there are exceptions. Tendons and ligaments are poorly vascularized (and so heal poorly). Cartilage and epithelia lack capillaries but receive nutrients from blood vessels in nearby connective tissues, and the avascular cornea and lens of the eye receive nutrients from the aqueous humor.

If we compare arteries and arterioles to expressways and roads, capillaries are the back alleys and driveways that provide direct access to nearly every cell in the body. Given their location and thin walls, capillaries are ideally suited for their role—exchange of materials (gases, nutrients, hormones, and so on) between the blood and the interstitial fluid. We describe

(a) Continuous capillary

Continuous capillaries are the least permeable and most common.

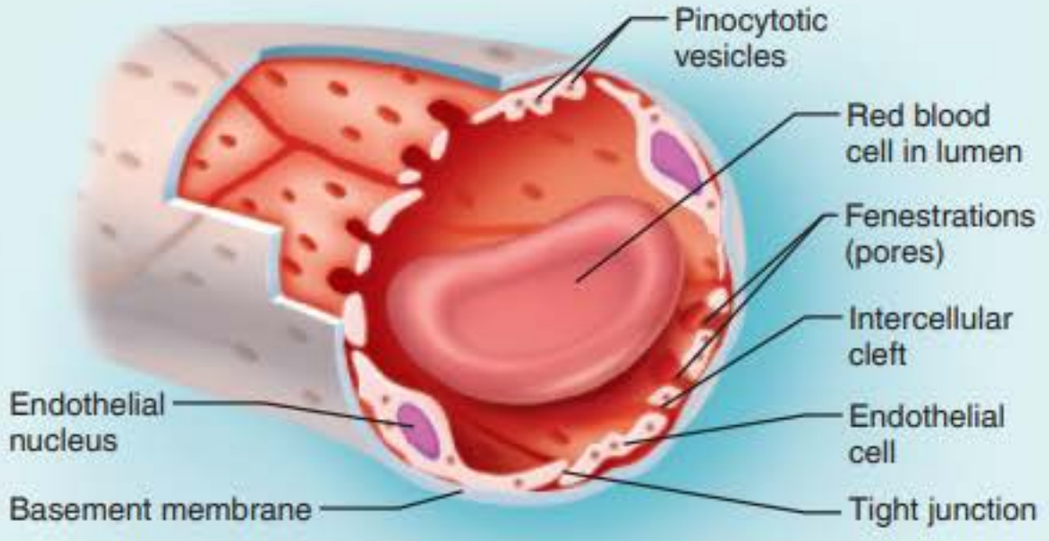
- Abundant in skin, muscles, lungs, and CNS.
- Often have associated pericytes.
- Pinocytotic vesicles ferry fluid across the endothelial cell.
- Most continuous capillaries have intercellular clefts between endothelial cells. However, brain capillary endothelial cells lack intercellular clefts and have tight junctions around their entire perimeter. (This is the structural basis of the *blood brain barrier* described in Chapter 12.)



(b) Fenestrated capillary

Fenestrated capillaries have large fenestrations (pores) that increase permeability.

- Occur in areas of active filtration (e.g., kidney) or absorption (e.g., small intestine), and areas of endocrine hormone secretion.
- Fenestrations are Swiss cheese–like holes that tunnel *through* endothelial cells.
- Fenestrations are usually covered by a very thin layer of condensed extracellular glycoproteins. This layer has little effect on solute and fluid movement.
- In some digestive tract organs, the number of fenestrations in capillaries increases during active absorption of nutrients.



(c) Sinusoid capillary

Sinusoid capillaries are the most permeable and occur in limited locations.

- Occur in liver, bone marrow, spleen, and adrenal medulla.
- Have large intercellular clefts as well as fenestrations; few tight junctions.
- Have incomplete basement membranes.
- Are irregularly shaped and have larger lumens than other capillaries.
- Allow large molecules and even cells to pass across their walls.
- Blood flows *slowly* through their tortuous channels.
- Macrophages may extend processes through the clefts to catch "prey" or, in liver, form part of the sinusoid wall.

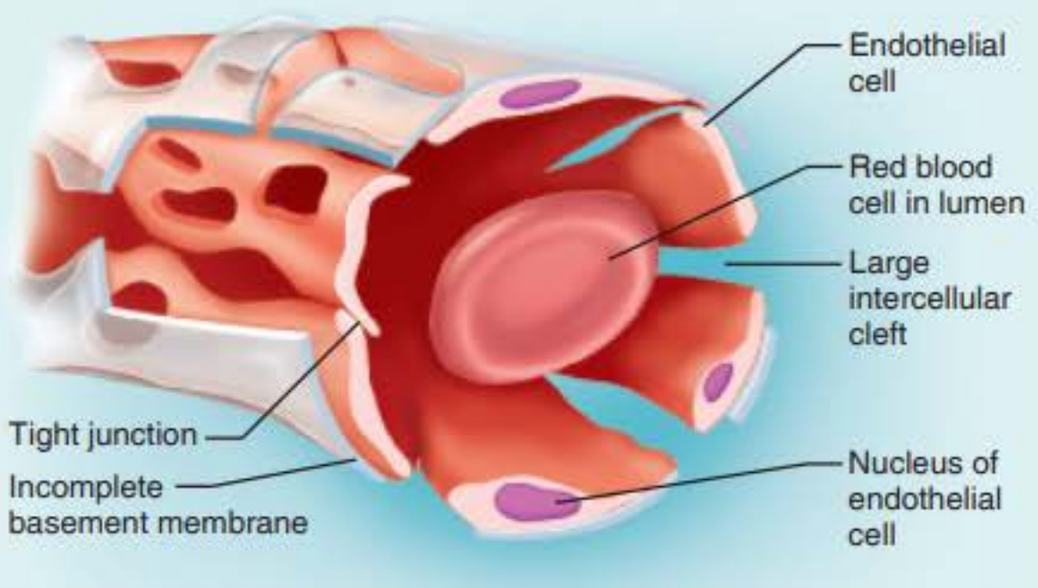


Figure 19.3 Capillary structure.

these exchanges later in this chapter. Here, we focus on capillary structure.

Types of Capillaries

Structurally, there are three types of capillaries—*continuous*, *fenestrated*, and *sinusoid*. As you study their properties in Figure 19.3, notice that all three types have *tight junctions* that join their endothelial cells together. However, these junctions are usually incomplete and leave gaps of unjoined membrane called **intercellular clefts**, which allow limited passage of fluids and small solutes. Leakier capillaries have specialized passageways that increase fluid movement.

Capillary Beds

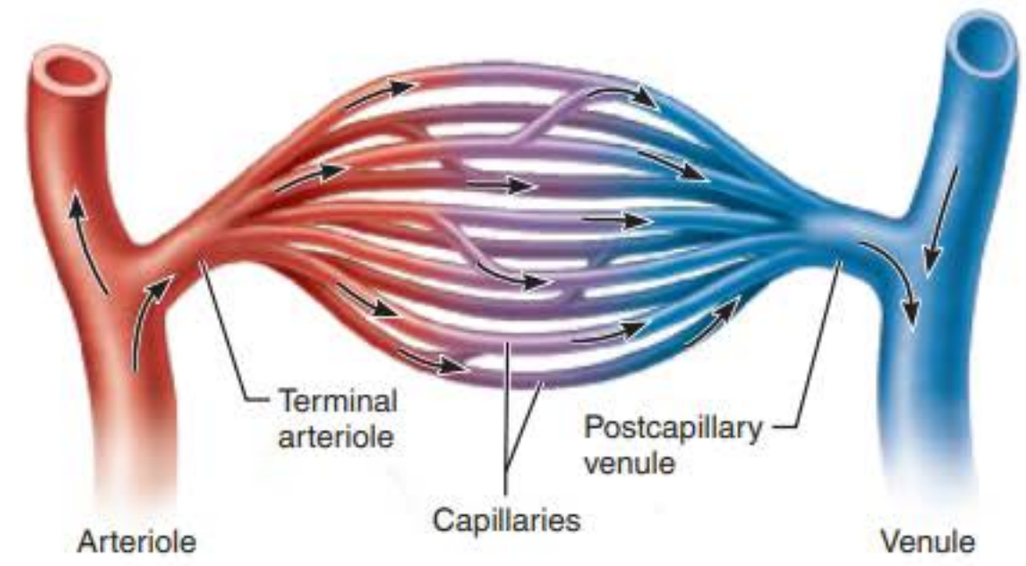
Capillaries do not function independently. Instead they form interweaving networks called **capillary beds**. The flow of blood from an arteriole to a venule—that is, through a capillary bed—is called the **microcirculation**. In most body regions, a **terminal arteriole** branches into 10 to 20 **capillaries** (*exchange vessels*) that form the capillary bed. These then drain into a **postcapillary venule** (**Figure 19.4**). Blood flow through the capillary bed is controlled by the diameter of the terminal arteriole as well as by all of the arterioles upstream from it. As blood flows through the capillaries, it takes part in exchanges of gases, nutrients, and wastes with the surrounding tissue cells.

Local chemical conditions and arteriolar vasomotor nerve fibers regulate the amount of blood entering a capillary bed. A bed may be flooded with blood or almost completely bypassed, depending on conditions in the body or in that specific organ. For example, suppose you have just eaten and are sitting relaxed, listening to your favorite musical group. Food is being digested, and blood is circulating freely through the capillaries of your gastrointestinal organs to receive the breakdown products of digestion. Between meals, however, most of these same capillary pathways are closed.

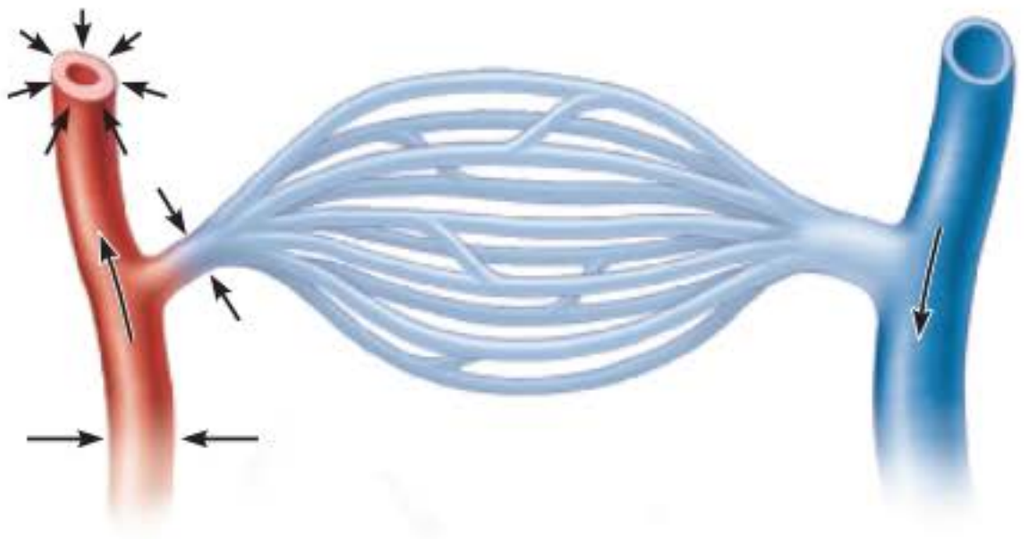
To take another example, when you exercise vigorously, blood is rerouted from your digestive organs (food or no food) to the capillary beds of your skeletal muscles where it is more immediately needed. This rerouting helps explain why vigorous exercise right after a meal can cause indigestion or abdominal cramps.

In the serous membranes that hold the intestines in place (mesenteries), there are two additional features that form a special arrangement of capillaries (**Figure 19.5**):

- There is a *vascular shunt* that directly connects the terminal arteriole to the postcapillary venule, so that blood can bypass the *true capillaries*. This shunt consists of a *metarteriole* and a *thoroughfare channel*.
- As it branches from the metarteriole, each true capillary is surrounded by a cuff of smooth muscle called a **precapillary sphincter**. The precapillary sphincter acts as a valve to regulate blood flow into the capillary. The precapillary sphincters are not innervated, and so are controlled only by local chemical conditions.



(a) Arterioles dilated—blood flows through capillaries.



(b) Arterioles constricted—no blood flows through capillaries.

Figure 19.4 Anatomy of a typical capillary bed.

Check Your Understanding

4. APPLY Look at Figure 19.4 and assume that the capillary bed depicted is in your calf muscle. Which condition—(a) or (b)—would the bed be in if you were doing calf raises at the gym?

For answers, see Answers Appendix.

19.4 Veins are blood reservoirs that return blood toward the heart

Learning Outcome

- **Describe the structure and function of veins, and explain how veins differ from arteries.**

Veins carry blood from the capillary beds toward the heart. Along the route, the diameter of successive venous vessels increases, and their walls gradually thicken as they progress from venules to larger and larger veins.

Venules

Capillaries unite to form **venules**, which range from 8 to 100 μm in diameter. The smallest venules, the *postcapillary venules*, consist entirely of endothelium around which pericytes congregate. Postcapillary venules are extremely porous (more like capillaries than veins in this way), and fluid and white blood cells move easily from the bloodstream through their walls. Indeed, a well-recognized sign of inflammation is adhesion of white blood cells to the postcapillary venule endothelium, followed by their migration through the wall into the inflamed tissue.

Larger venules have a thin tunica media (one or two layers of smooth muscle cells) and a thin tunica externa as well.

Veins

Venules join to form *veins*. Veins usually have three distinct tunics, but their walls are always thinner and their lumens larger than those of corresponding arteries (see Figure 19.2 and Table 19.1). Consequently, in histological preparations, veins are usually collapsed and their lumens appear slitlike.

There is relatively little smooth muscle or elastin in the tunica media, which is poorly developed and tends to be thin even in the largest veins. The tunica externa is the heaviest wall layer. Consisting of thick longitudinal bundles of collagen fibers and elastic networks, it is often several times thicker than the tunica media. In the largest veins—the venae cavae, which return blood directly to the heart—longitudinal bands of smooth muscle make the tunica externa even thicker.

With their large lumens and thin walls, veins can accommodate a fairly large blood volume. Veins are called *capacitance vessels* and *blood reservoirs* because they can hold up to 65% of the body's blood supply at any time (**Figure 19.6**). Even so, these distensible vessels are usually not filled to capacity.

The walls of veins can be much thinner than arterial walls without danger of bursting because the blood pressure in veins is low. However, the low-pressure condition demands several structural adaptations to ensure that veins return blood to the heart at the same rate it was pumped into the circulation. One such adaptation is their large-diameter lumens, which offer relatively little resistance to blood flow.

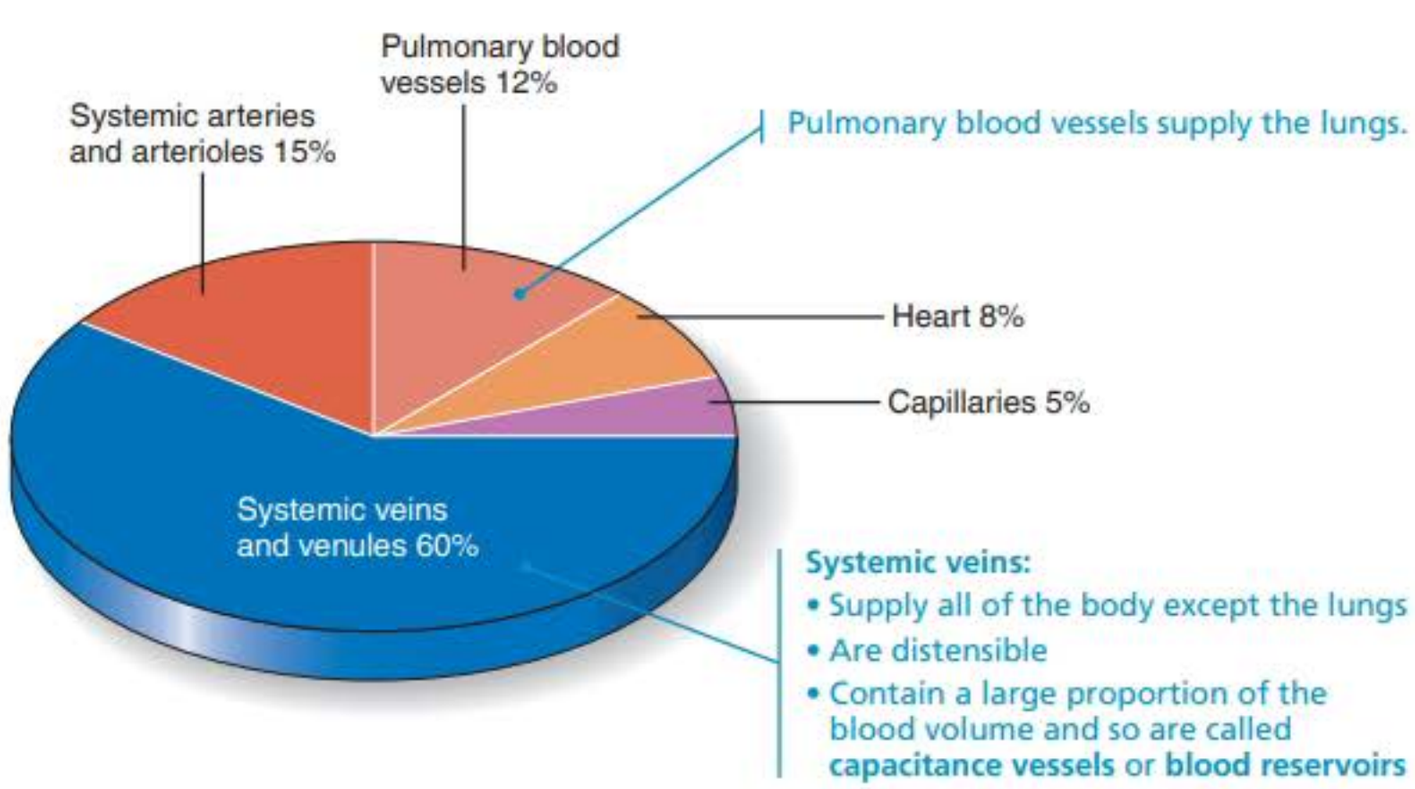

Figure 19.6 Relative proportion of blood volume throughout the cardiovascular system.

Venous Valves

Venous valves prevent blood from flowing backward in veins just as valves do in the heart, and represent another adaptation to compensate for low venous pressure. They are formed from folds of the tunica intima and resemble the semilunar valves of the heart (◀ p. 680) (see Figure 19.2). Venous valves are most abundant in the veins of the limbs, where gravity opposes the upward flow of blood. They are usually absent in veins of the thoracic and abdominal body cavities.

The effectiveness of venous valves is demonstrated by this simple experiment: Hang one hand by your side until the blood vessels on its dorsal aspect distend with blood. Next place two fingertips against one of the distended veins, and pressing firmly, move the superior finger proximally along the vein and then release that finger. The vein will remain collapsed (flat) despite the pull of gravity. Finally, remove your distal fingertip and watch the vein refill with blood.

HOMEOSTATIC IMBALANCE 19.1 CLINICAL

Varicose veins are veins that are tortuous and dilated because of incompetent (leaky) valves. More than 15% of adults suffer from varicose veins, usually in the lower limbs.

Several factors contribute, including heredity and conditions that hinder venous return, such as prolonged standing in one position, obesity, or pregnancy. Both the "potbelly" of an overweight person and the enlarged uterus of a pregnant woman exert downward pressure on vessels of the groin, restricting return of blood to the heart. Consequently, blood pools in the lower limbs, and with time, the valves weaken and the venous walls stretch. Superficial veins, which receive little support from surrounding tissues, are especially susceptible.

Elevated venous pressure can also cause varicose veins. For example, straining to deliver a baby or have a bowel movement raises intra-abdominal pressure, preventing blood from draining from anal veins. The resulting varicosities in the anal veins are called *hemorrhoids* (hem′ŏ-roidz).

Venous Sinuses

Venous sinuses are highly specialized, flattened veins with extremely thin walls composed only of endothelium. They are supported by the tissues that surround them, rather than by any additional tunics. (Do not confuse venous sinuses with the

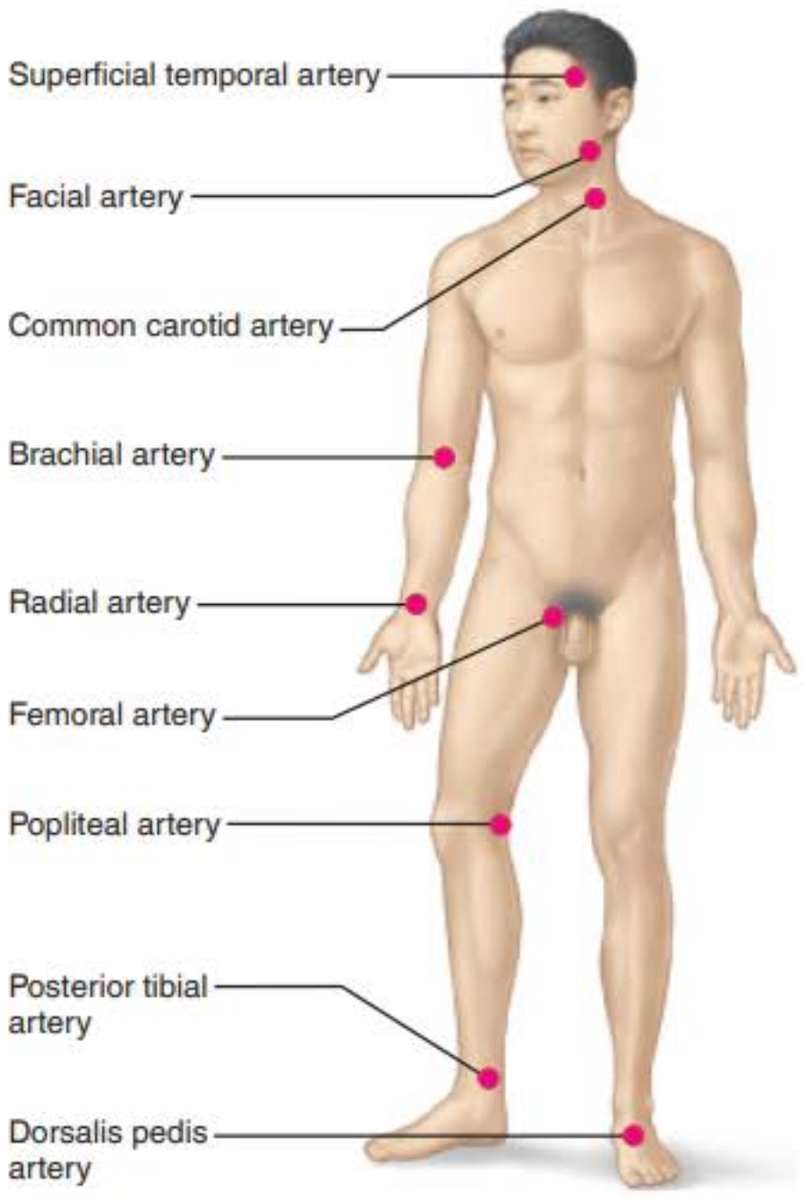

Figure 19.8 Body sites where the pulse is most easily palpated. (We discuss the specific arteries indicated on pp. 738–749.)

Taking a Pulse You can feel a pulse in any artery that lies close to the body surface by compressing the artery against firm tissue, and this provides an easy way to count heart rate. Because it is so accessible, the point where the radial artery surfaces at the wrist, the *radial pulse*, is routinely used to take a pulse measurement, but there are several other clinically important arterial pulse points (**Figure 19.8**).

These pulse points are also called **pressure points** because they are compressed to stop blood flow into distal tissues during hemorrhage. For example, if you seriously lacerate your hand, you can slow or stop the bleeding by compressing your radial or brachial artery.

Monitoring pulse rate is an easy way to assess the effects of activity, postural changes, and emotions on heart rate. For example, the pulse of a healthy man may be around 66 beats per minute when he is lying down, 70 when he sits up, and 80 if he suddenly stands. During vigorous exercise or emotional upset, pulse rates between 140 and 180 are not unusual because of sympathetic nervous system effects on the heart.

Measuring Blood Pressure Most often, you measure systemic arterial blood pressure indirectly in the brachial artery of the arm by the **auscultatory method** (aw-skul′tah-to″re). The steps of this procedure are:

1. Wrap the *blood pressure cuff*, or *sphygmomanometer* (sfig″mo-mah-nom′ĕ-ter; *sphygmo* = pulse), snugly around the person's arm just superior to the elbow.
2. Inflate the cuff until the cuff pressure exceeds systolic pressure. At this point, blood flow into the arm stops and a brachial pulse cannot be felt or heard.
3. Reduce the cuff pressure gradually and listen (auscultate) with a stethoscope for sounds in the brachial artery.

The pressure read when the first soft tapping sounds are heard (the first point at which a small amount of blood is spurting through the constricted artery) is systolic pressure. As the cuff pressure is reduced further, these sounds, called the *sounds of Korotkoff*, become louder and more distinct. However, when the artery is no longer constricted and blood flows freely, the sounds can no longer be heard. The pressure at which the sounds disappear is the diastolic pressure.

Capillary Blood Pressure

As Figure 19.7 shows, by the time blood reaches the capillaries, blood pressure has dropped to approximately 35 mm Hg and by the end of the capillary beds is only around 17 mm Hg. Such low capillary pressures are desirable because:

- Capillaries are fragile and high pressures would rupture them.
- Most capillaries are extremely permeable and so even the low capillary pressure can force solute-containing fluids (filtrate) out of the bloodstream into the interstitial space.

As we describe later in this chapter, these fluid flows are important for continuously refreshing the interstitial fluid.

Venous Blood Pressure

Unlike arterial pressure, which pulsates with each contraction of the left ventricle, venous blood pressure is steady and changes very little during the cardiac cycle. The pressure gradient in the veins, from venules to the termini of the venae cavae, is only about 15 mm Hg (that from the aorta to the ends of the arterioles is about 60 mm Hg).

The difference in pressure between an artery and a vein becomes very clear when the vessels are cut. If a vein is cut, the blood flows evenly from the wound, but a lacerated artery spurts blood. The very low pressure in the venous system reflects the cumulative effects of total peripheral resistance, which dissipates most of the energy of blood pressure (as heat) during each circuit.

Despite the structural modifications of veins (large lumens and valves), venous pressure is normally too low to promote adequate venous return. For this reason, three functional adaptations are critically important to venous return:

- **The muscular pump.** The **muscular pump** consists of skeletal muscle activity. As the skeletal muscles surrounding the deep veins contract and relax, they squeeze or "milk" blood

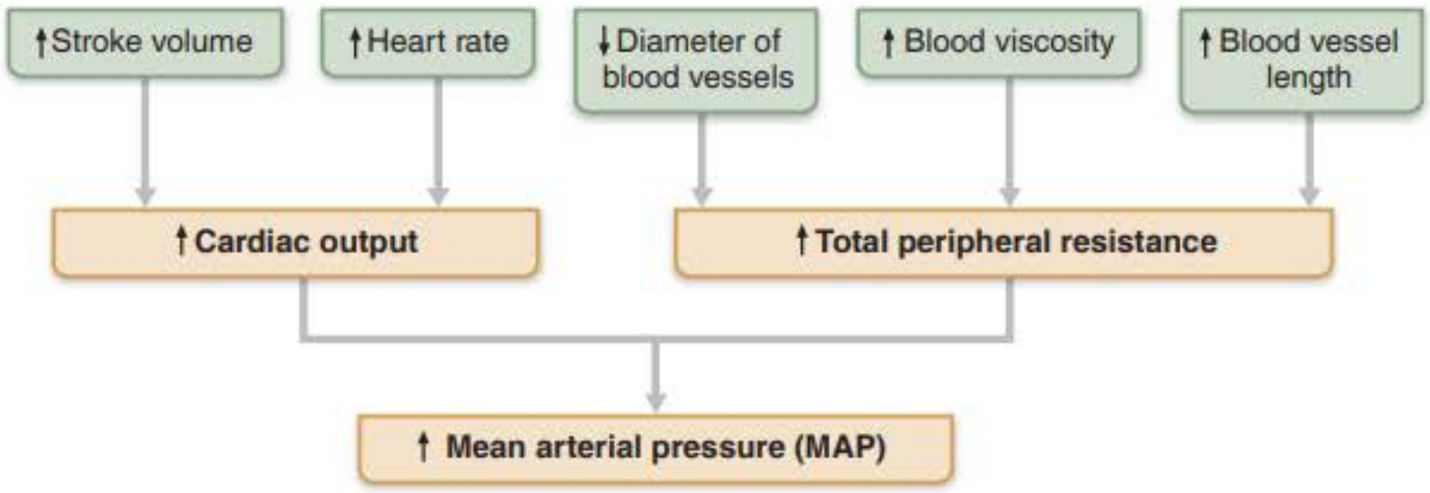

Figure 19.10 Major factors that increase MAP. In addition, cardiac output increases as blood volume increases (not shown).

stroke volume (by enhancing cardiac muscle contractility). The resulting increase in CO increases MAP.

We also know that total peripheral resistance is determined by three variables, the most important of which is blood vessel diameter (◀ pp. 714–715). **Figure 19.10** summarizes the relationships between the factors controlling CO and resistance. Keep these relationships in mind as you read through the sections that follow, because each blood pressure regulation mechanism acts on one or more of these variables.

Also be aware that things aren't quite that simple in real life. A change in any variable that threatens blood pressure homeostasis is usually compensated for by changes in the other variables so that a constant blood pressure is maintained.

We will now explore two classes of mechanisms that regulate blood pressure. *Short-term regulation* by the nervous system and bloodborne hormones alters blood pressure by changing total peripheral resistance and CO. *Long-term regulation* alters blood volume via the kidneys. Figure 19.13 (p. 723) summarizes the influence of nearly all of the important factors.

Short-Term Regulation: Neural Controls

Neural controls alter both cardiac output and total peripheral resistance. We discussed neural control of cardiac output in Chapter 18, so we will focus on total peripheral resistance here. Neural controls of total peripheral resistance are directed at two main goals:

- Maintaining adequate MAP by altering blood vessel diameter on a moment-to-moment basis. (Remember, very small changes in blood vessel diameter cause substantial changes in total peripheral resistance, and so in systemic blood pressure.) Under conditions of low blood volume, all vessels except those supplying the heart and brain are constricted to allow as much blood as possible to flow to those two vital organs.
- Altering blood distribution to respond to specific demands of various organs. For example, during exercise blood is shunted temporarily from the digestive organs to the skeletal muscles.

Most neural controls operate via reflex arcs involving *baroreceptors* (pressure-sensitive mechanoreceptors that respond to changes in arterial pressure and stretch) and associated afferent fibers. These reflexes are integrated in the cardiovascular center of the medulla, and their output travels via autonomic fibers to the heart and vascular smooth muscle. Occasionally, inputs from *chemoreceptors* (receptors that respond to changes in blood levels of carbon dioxide, H^+, and oxygen) and higher brain centers also influence the neural control mechanism.

Role of the Cardiovascular Center

Several clusters of neurons in the medulla oblongata act together to integrate blood pressure control by altering cardiac output and blood vessel diameter. This **cardiovascular center** consists of the *cardiac centers* (the cardioacceleratory and cardioinhibitory centers discussed in Chapter 18, ◀ p. 689) and the **vasomotor center** that controls the diameter of blood vessels.

The vasomotor center transmits impulses at a fairly steady rate along sympathetic efferents called **vasomotor fibers**. These fibers exit from the T_1 through L_2 levels of the spinal cord and innervate the smooth muscle of blood vessels, mainly arterioles. As a result, the arterioles are almost always in a state of moderate constriction, called **vasomotor tone** (◀ p. 545).

The degree of vasomotor tone varies from organ to organ. Generally, arterioles of the skin and digestive viscera receive vasomotor impulses more frequently and tend to be more strongly constricted than those of skeletal muscles. Any increase in sympathetic activity produces generalized vasoconstriction and raises blood pressure. Decreased sympathetic activity allows the vascular smooth muscle to relax somewhat and lowers blood pressure to basal levels.

Cardiovascular center activity is modified by inputs from baroreceptors, chemoreceptors, and higher brain centers. Let's take a look.

Baroreceptor Reflexes

When arterial blood pressure rises, it activates **baroreceptors**. These stretch receptors are located in the *carotid sinuses* (dilations in the internal carotid arteries, which provide the major blood supply to the brain), in the *aortic arch*, and in the walls of nearly every large artery of the neck and thorax. When stretched, baroreceptors send a rapid stream of impulses to the

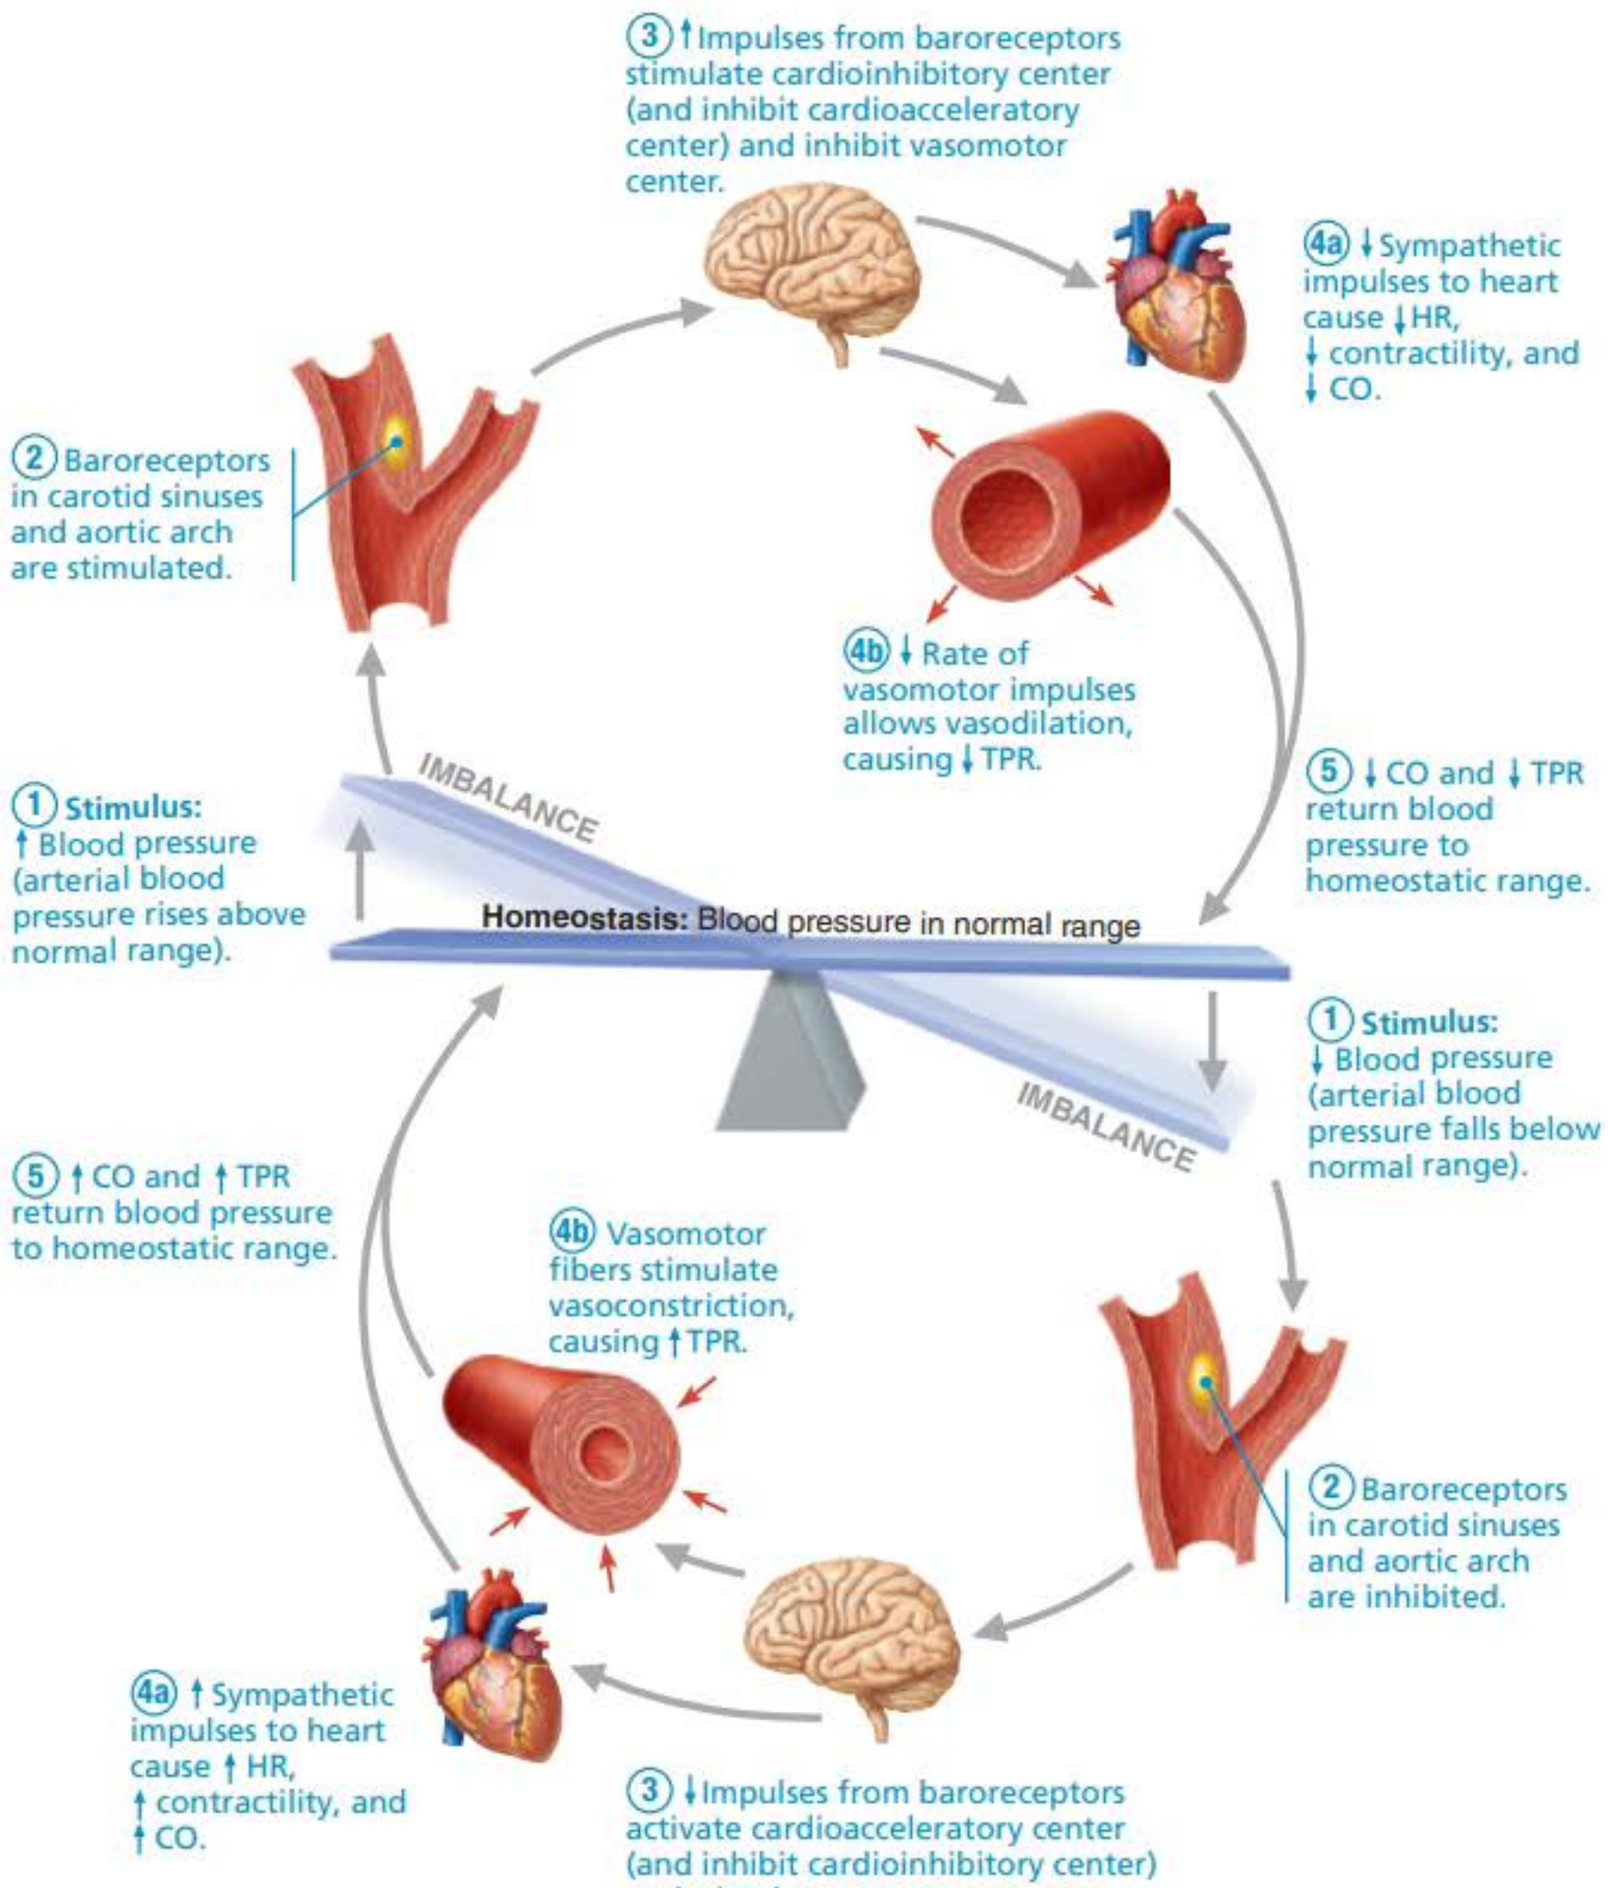

Figure 19.11 Baroreceptor reflexes that help maintain blood pressure homeostasis.
(CO = cardiac output; TPR = total peripheral resistance; HR = heart rate; BP = blood pressure)

cardiovascular center, inhibiting the vasomotor and cardioacceleratory centers and stimulating the cardioinhibitory center. The result is a decrease in blood pressure (**Figure 19.11**).

Two mechanisms bring this about:

- **Vasodilation.** Decreased output from the vasomotor center allows arterioles and veins to dilate. **Arteriolar vasodilation** reduces total peripheral resistance, so MAP falls. **Venodilation** shifts blood to the venous reservoirs, which decreases venous return and cardiac output.
- **Decreased cardiac output.** Impulses to the cardiac centers inhibit sympathetic activity and stimulate parasympathetic activity, reducing heart rate and contractile force. As CO falls, so does MAP.

In the opposite situation, a decline in MAP initiates reflex vasoconstriction and increases cardiac output, bringing blood pressure back up. In this way, total peripheral resistance and cardiac output are regulated in tandem to minimize changes in blood pressure.

Rapidly responding baroreceptors protect the circulation against short-term (acute) changes in blood pressure. For example, blood pressure falls (particularly in the head) when you stand up after reclining. Baroreceptors taking part in the **carotid sinus reflex** protect the blood supply to your brain, whereas those activated in the **aortic reflex** help maintain adequate blood pressure in your systemic circuit as a whole. Failure of the baroreceptor reflex results in orthostatic hypotension (◀ p. 549).

Baroreceptors are relatively *ineffective* in protecting us against sustained pressure changes, as evidenced by the fact that many people develop chronic hypertension. In such cases, the baroreceptors are "reprogrammed" (adapt) to monitor pressure changes at a higher set point.

Chemoreceptor Reflexes

When the carbon dioxide levels rise, or the pH falls, or oxygen content of the blood drops sharply, **chemoreceptors** in the aortic arch and large arteries of the neck transmit impulses to the cardioacceleratory center, which then increases cardiac output. Chemoreceptors also activate the vasomotor center, which causes reflex vasoconstriction. The rise in blood pressure that follows speeds the return of blood to the heart and lungs.

The most prominent chemoreceptors are the *carotid* and *aortic bodies* located close by the baroreceptors in the carotid sinuses and aortic arch. Chemoreceptors play a larger role in regulating respiratory rate than blood pressure, so we consider their function in Chapter 22.

Homeostatic Imbalances in Blood Pressure

CLINICAL

Normal blood pressure for resting adults is a systolic pressure of less than 120 mm Hg and a diastolic pressure of less than 80 mm Hg. Transient elevations in blood pressure occur as normal adaptations during changes in posture, physical exertion, emotional upset, and fever. Age, sex, weight, and race also affect blood pressure.

Hypertension

Chronically elevated blood pressure is called **hypertension** and is characterized by a sustained increase in either systolic pressure (above 140 mm Hg) or diastolic pressure (above 90 mm Hg). The American Heart Association considers individuals to have *prehypertension* if their blood pressure values are elevated but not yet in the hypertension range. These individuals are at higher risk for developing full-blown hypertension and are often advised to change their lifestyles to reduce their risk of developing full-blown hypertension.

Chronic hypertension is a common and dangerous disease. An estimated 30% of people over age 50 are hypertensive. Although this "silent killer" is usually asymptomatic for the first 10 to 20 years, it slowly but surely strains the heart and damages the arteries. Prolonged hypertension is the major cause of heart failure, vascular disease, renal failure, and stroke. The higher the pressure, the greater the risk for these serious problems.

Because the heart is forced to pump against greater resistance, it must work harder, and over time the myocardium enlarges. When finally strained beyond its capacity, the heart weakens and its walls become flabby. Hypertension also ravages the blood vessels, accelerating the progress of atherosclerosis (see *A Closer Look* on p. 760). As the vessels become increasingly blocked, blood flow to the tissues becomes inadequate and vascular complications appear in the brain, heart, kidneys, and retinas of the eyes.

Primary Hypertension Although hypertension and atherosclerosis are often linked, it is often difficult to blame hypertension on any distinct anatomical pathology. Indeed, about 90% of hypertensive people have **primary**, or **essential**, **hypertension**, for which no underlying cause has been identified. This is because primary hypertension is due to a rich interplay between your genes and a variety of environmental factors:

- **Heredity.** Children of hypertensive parents are twice as likely to develop hypertension as are children of normotensive parents, and more blacks than whites are hypertensive. Many of the factors listed here require a genetic predisposition, and the course of the disease varies in different population groups.
- **Diet.** Dietary factors that contribute to hypertension include high intakes of salt (NaCl), saturated fat, and cholesterol, and deficiencies in certain metal ions (K^+, Ca^{2+}, and Mg^{2+}).
- **Obesity.** Obesity causes hypertension in a number of ways that are not yet well understood. For example, adipocytes release hormones that appear to increase sympathetic tone and interfere with the ability of endothelial cells to induce vasodilation.
- **Age.** Hypertension usually appears after age 40.
- **Diabetes mellitus.**
- **Stress.** Particularly at risk are "hot reactors," people whose blood pressure zooms upward during every stressful event.
- **Smoking.** Nicotine causes intense vasoconstriction not only by directly stimulating postganglionic sympathetic neurons but also by prompting release of large amounts of epinephrine and NE. Chemicals in cigarette smoke also damage the tunica intima, interfering with its ability to chemically regulate arteriolar diameter.

Primary hypertension cannot be cured, but most cases can be controlled. Improving diet, increasing exercise and losing weight, stopping smoking, managing stress, and taking antihypertensive drugs can all help. Drugs commonly used are diuretics, beta-blockers, calcium channel blockers, angiotensin converting enzyme (ACE) inhibitors, and angiotensin II receptor blockers. Inhibiting ACE or blocking receptors for angiotensin II suppresses the renin-angiotensin-aldosterone mechanism.

Secondary Hypertension **Secondary hypertension** accounts for 10% of cases. It is due to identifiable conditions, for example obstructed renal arteries, kidney disease, and endocrine disorders such as hyperthyroidism and Cushing's syndrome. Treatment for secondary hypertension focuses on correcting the problem that caused it.

Hypotension

In many cases, **hypotension**, or low blood pressure (below 90/60 mm Hg), simply reflects individual variations and is no cause for concern. In fact, low blood pressure is often associated with long life and an old age free of cardiovascular disease.

Orthostatic hypotension is a temporary drop in blood pressure resulting in dizziness (due to inadequate oxygen delivery to the brain) when a person rises suddenly from a reclining or sitting position. Elderly people are prone to orthostatic hypotension because the aging sympathetic nervous system does not respond as quickly as it once did to postural changes. Blood pools briefly in the lower limbs, reducing blood pressure and consequently blood delivery to the brain. Changing position slowly gives the nervous system time to adjust and usually prevents this problem.

Occasionally, *chronic hypotension* is a sign of a serious underlying condition. Addison's disease (inadequate adrenal cortex function), hypothyroidism, or severe malnutrition can cause chronic hypotension.

Hypotension is usually a concern only if it leads to inadequate blood flow to tissues. *Acute hypotension* is one of the most important signs of circulatory shock.

Circulatory Shock

Circulatory shock is any condition in which blood vessels are inadequately filled and blood cannot circulate normally. Blood

flow is inadequate to meet tissue needs. If circulatory shock persists, cells die and organ damage follows.

Hypovolemic Shock The most common form of circulatory shock is **hypovolemic shock** (hi″po-vo-le′mik; *hypo* = low, deficient; *volemia* = blood volume), which results from large-scale blood or fluid loss, as might follow acute hemorrhage, severe vomiting or diarrhea, or extensive burns. If blood volume drops rapidly, heart rate increases in an attempt to correct the problem. A weak, "thready" (barely detectable) pulse is often the first sign of hypovolemic shock. Intense vasoconstriction also occurs, which shifts blood from the various blood reservoirs into the major circulatory channels and enhances venous return.

Blood pressure is stable at first, but eventually drops if blood loss continues. A sharp drop in blood pressure is a serious, and late, sign of hypovolemic shock. The key to managing hypovolemic shock is to replace fluid volume as quickly as possible.

Vascular Shock In **vascular shock**, blood volume is normal, but circulation is poor as a result of extreme vasodilation. A huge drop in total peripheral resistance follows, as revealed by rapidly falling blood pressure.

There are three common types of vascular shock:

- *Anaphylactic shock* is a loss of vasomotor tone due to *anaphylaxis*, a systemic allergic reaction in which the massive release of the chemical messenger histamine triggers body-wide vasodilation.
- *Neurogenic shock* results from failure of autonomic nervous system regulation.
- *Septic shock* (septicemia) is due to severe systemic bacterial infection (bacterial toxins are notorious vasodilators).

Cardiogenic Shock **Cardiogenic shock**, or pump failure, occurs when the heart is so inefficient that it cannot sustain adequate circulation. Its usual cause is myocardial damage, as might follow numerous myocardial infarctions (heart attacks).

Check Your Understanding

13. Describe the baroreceptor reflex changes that occur to maintain blood pressure when you rise from a lying-down to a standing position.

14. The kidneys play an important role in maintaining MAP by influencing which variable? Explain how renal artery obstruction could cause secondary hypertension.

15. APPLY Your neighbor, Bob, calls you because he thinks he is having an allergic reaction to a medication. You find Bob on the verge of losing consciousness and having trouble breathing. When paramedics arrive, they note his blood pressure is 63/38 and he has a rapid, thready pulse. Explain Bob's low blood pressure and rapid heart rate.

16. MAKE CONNECTIONS You have just learned that hypertension can be treated with a variety of different drugs including diuretics, beta-blockers, and calcium channel blockers. Using your knowledge of the autonomic nervous system (Chapter 14), smooth muscle (Chapter 9), and cardiac muscle (Chapter 18), explain how these drugs work to decrease blood pressure.

For answers, see Answers Appendix.

19.9 Intrinsic and extrinsic controls determine blood flow through tissues

Learning Outcome

- **Explain how blood flow through tissues is regulated in general and in specific organs.**

Blood flow through body tissues, or **tissue perfusion**, is involved in:

- Delivering oxygen and nutrients to tissue cells, and removing carbon dioxide and wastes
- Exchanging gases in the lungs
- Absorbing nutrients from the digestive tract
- Forming urine in the kidneys

The rate of blood flow to each tissue and organ is almost exactly the right amount to provide for proper function—no more, no less. This is achieved by **intrinsic controls** (*autoregulation*) acting automatically on the smooth muscle of arterioles that feed any given tissue. We will examine these intrinsic mechanisms in the next section.

First, let's step back and look at the big picture. What do you think would happen if all of the arterioles in your body dilated at once? Because there is only a finite amount of blood, blood pressure would fall. Critical tissues, such as the brain, would be deprived of the oxygen and nutrients they need and would stop functioning. **Extrinsic controls** keep this from happening by acting on arteriolar smooth muscle to maintain blood pressure. The extrinsic controls act via the nerves (sympathetic nervous system) and hormones of the nervous and endocrine systems, the two major control systems of the body. They reduce blood flow to regions that need it the least, maintaining a constant MAP and allowing intrinsic mechanisms to direct blood flow to where it is most needed.

A number of physiological processes are under both intrinsic and extrinsic control (**Figure 19.14**). (Note that these are control mechanisms, and not related in any way to the intrinsic and extrinsic pathways of blood clotting.)

Intrinsic controls
- Control is entirely from within the tissue or organ
- Uses paracrines or properties of muscle tissue
- Also known as *autoregulation* or *local control*

Extrinsic controls
- Control is from outside of the tissue or organ
- Uses nerves or hormones

Examples where both control mechanisms occur:
- Stroke volume in heart (◀ pp. 697–698)
- Arteriolar diameter (see Figure 19.16)
- Glomerular filtration in kidneys (see Chapter 25)

Figure 19.14 A quick summary of intrinsic versus extrinsic control mechanisms.

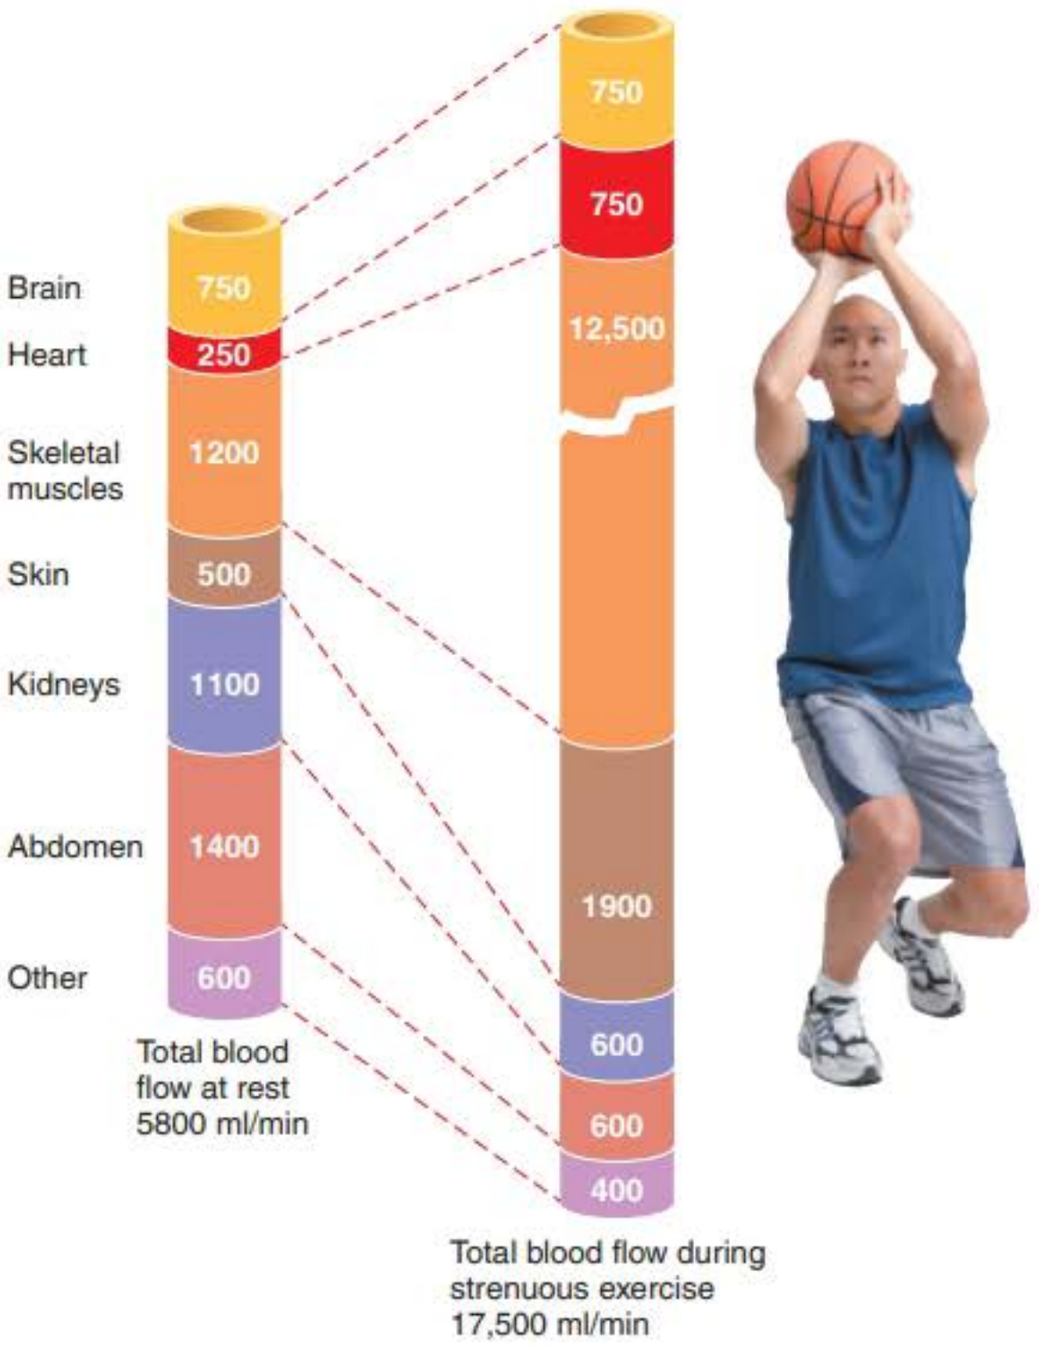

Figure 19.15 Distribution of blood flow at rest and during strenuous exercise.

The redistribution of blood during exercise provides an example of how intrinsic and extrinsic controls work together (**Figure 19.15**). When the body is at rest, the brain receives about 13% of total blood flow, the heart 4%, kidneys 20%, and abdominal organs 24%. Skeletal muscles, which make up almost half of body mass, normally receive about 20% of total blood flow. During exercise, however, nearly all of the increased cardiac output flushes into the skeletal muscles as intrinsic autoregulatory controls dilate skeletal muscle arterioles. To maintain blood pressure in spite of the widespread dilation of arterioles in skeletal muscle, the extrinsic controls act to decrease blood flow to the kidneys and digestive organs.

Autoregulation: Intrinsic (Local) Regulation of Blood Flow

As our activities change throughout the day, how does each organ or tissue manage to get the blood flow it needs? The answer is **autoregulation**. Local conditions regulate blood flow independent of control by nerves or hormones. Changes in blood flow through individual organs are controlled *intrinsically* by modifying the diameter of local arterioles feeding the capillaries.

You can compare blood flow autoregulation to water use in your home. Whether you have several taps open or none, the pressure in the main water pipe in the street remains relatively constant, as it does in the even larger water lines closer to the pumping station. Similarly, local conditions in the arterioles feeding the capillary beds of an organ have little effect on pressure in the muscular artery feeding that organ, or in the large elastic arteries. The pumping station is, of course, the heart. As long as the water company (circulatory feedback mechanisms) maintains a relatively constant water pressure (MAP), local demand regulates the amount of fluid (blood) delivered to various areas.

Organs regulate their own blood flows by varying the resistance of their arterioles. These intrinsic control mechanisms may be classed as *metabolic* (chemical) or *myogenic* (physical). Generally, both metabolic and myogenic factors determine the final autoregulatory response of a tissue. For example, **reactive hyperemia** (hi″per-e′me-ah) refers to the dramatically increased blood flow into a tissue that occurs after the blood supply to the area has been temporarily blocked. It results both from the myogenic response and from the metabolic wastes that accumulated during occlusion. **Figure 19.16** summarizes the various intrinsic (local) and extrinsic controls of arteriolar diameter.

Metabolic Controls

When blood flow is too low to meet a tissue's metabolic needs, oxygen levels decline and metabolic products (which act as paracrines) accumulate. These changes serve as stimuli that lead to automatic increases in tissue blood flow.

The metabolic factors that regulate blood flow are low oxygen levels, and increases in H^+ (from CO_2 and lactic acid), K^+, adenosine, and prostaglandins. The relative importance of these factors is not clear. Many of them act directly to relax vascular smooth muscle, but some may act by causing vascular endothelial cells to release nitric oxide.

Nitric oxide (NO) is a powerful vasodilator, but its effects are very brief because it is quickly destroyed. Even so, NO is the major player in controlling local vasodilation, often overriding sympathetic vasoconstriction when tissues need more blood flow.

The endothelium also releases potent vasoconstrictors, including the family of peptides called **endothelins**, which are among the most potent vasoconstrictors known. Normally, NO and endothelin released from endothelial cells are in a dynamic balance, but this balance tips in favor of NO when blood flow is too low for metabolic needs.

The net result of metabolically controlled autoregulation is immediate vasodilation of the arterioles serving the capillary beds of the "needy" tissues. Blood flow to the area rises temporarily, allowing blood to surge through the capillaries and become available to the tissue cells.

Inflammatory chemicals released in injury, infection, or allergic reactions also cause local vasodilation. Inflammatory vasodilation helps the defense mechanisms clear microorganisms and toxins from the area, and promotes healing.

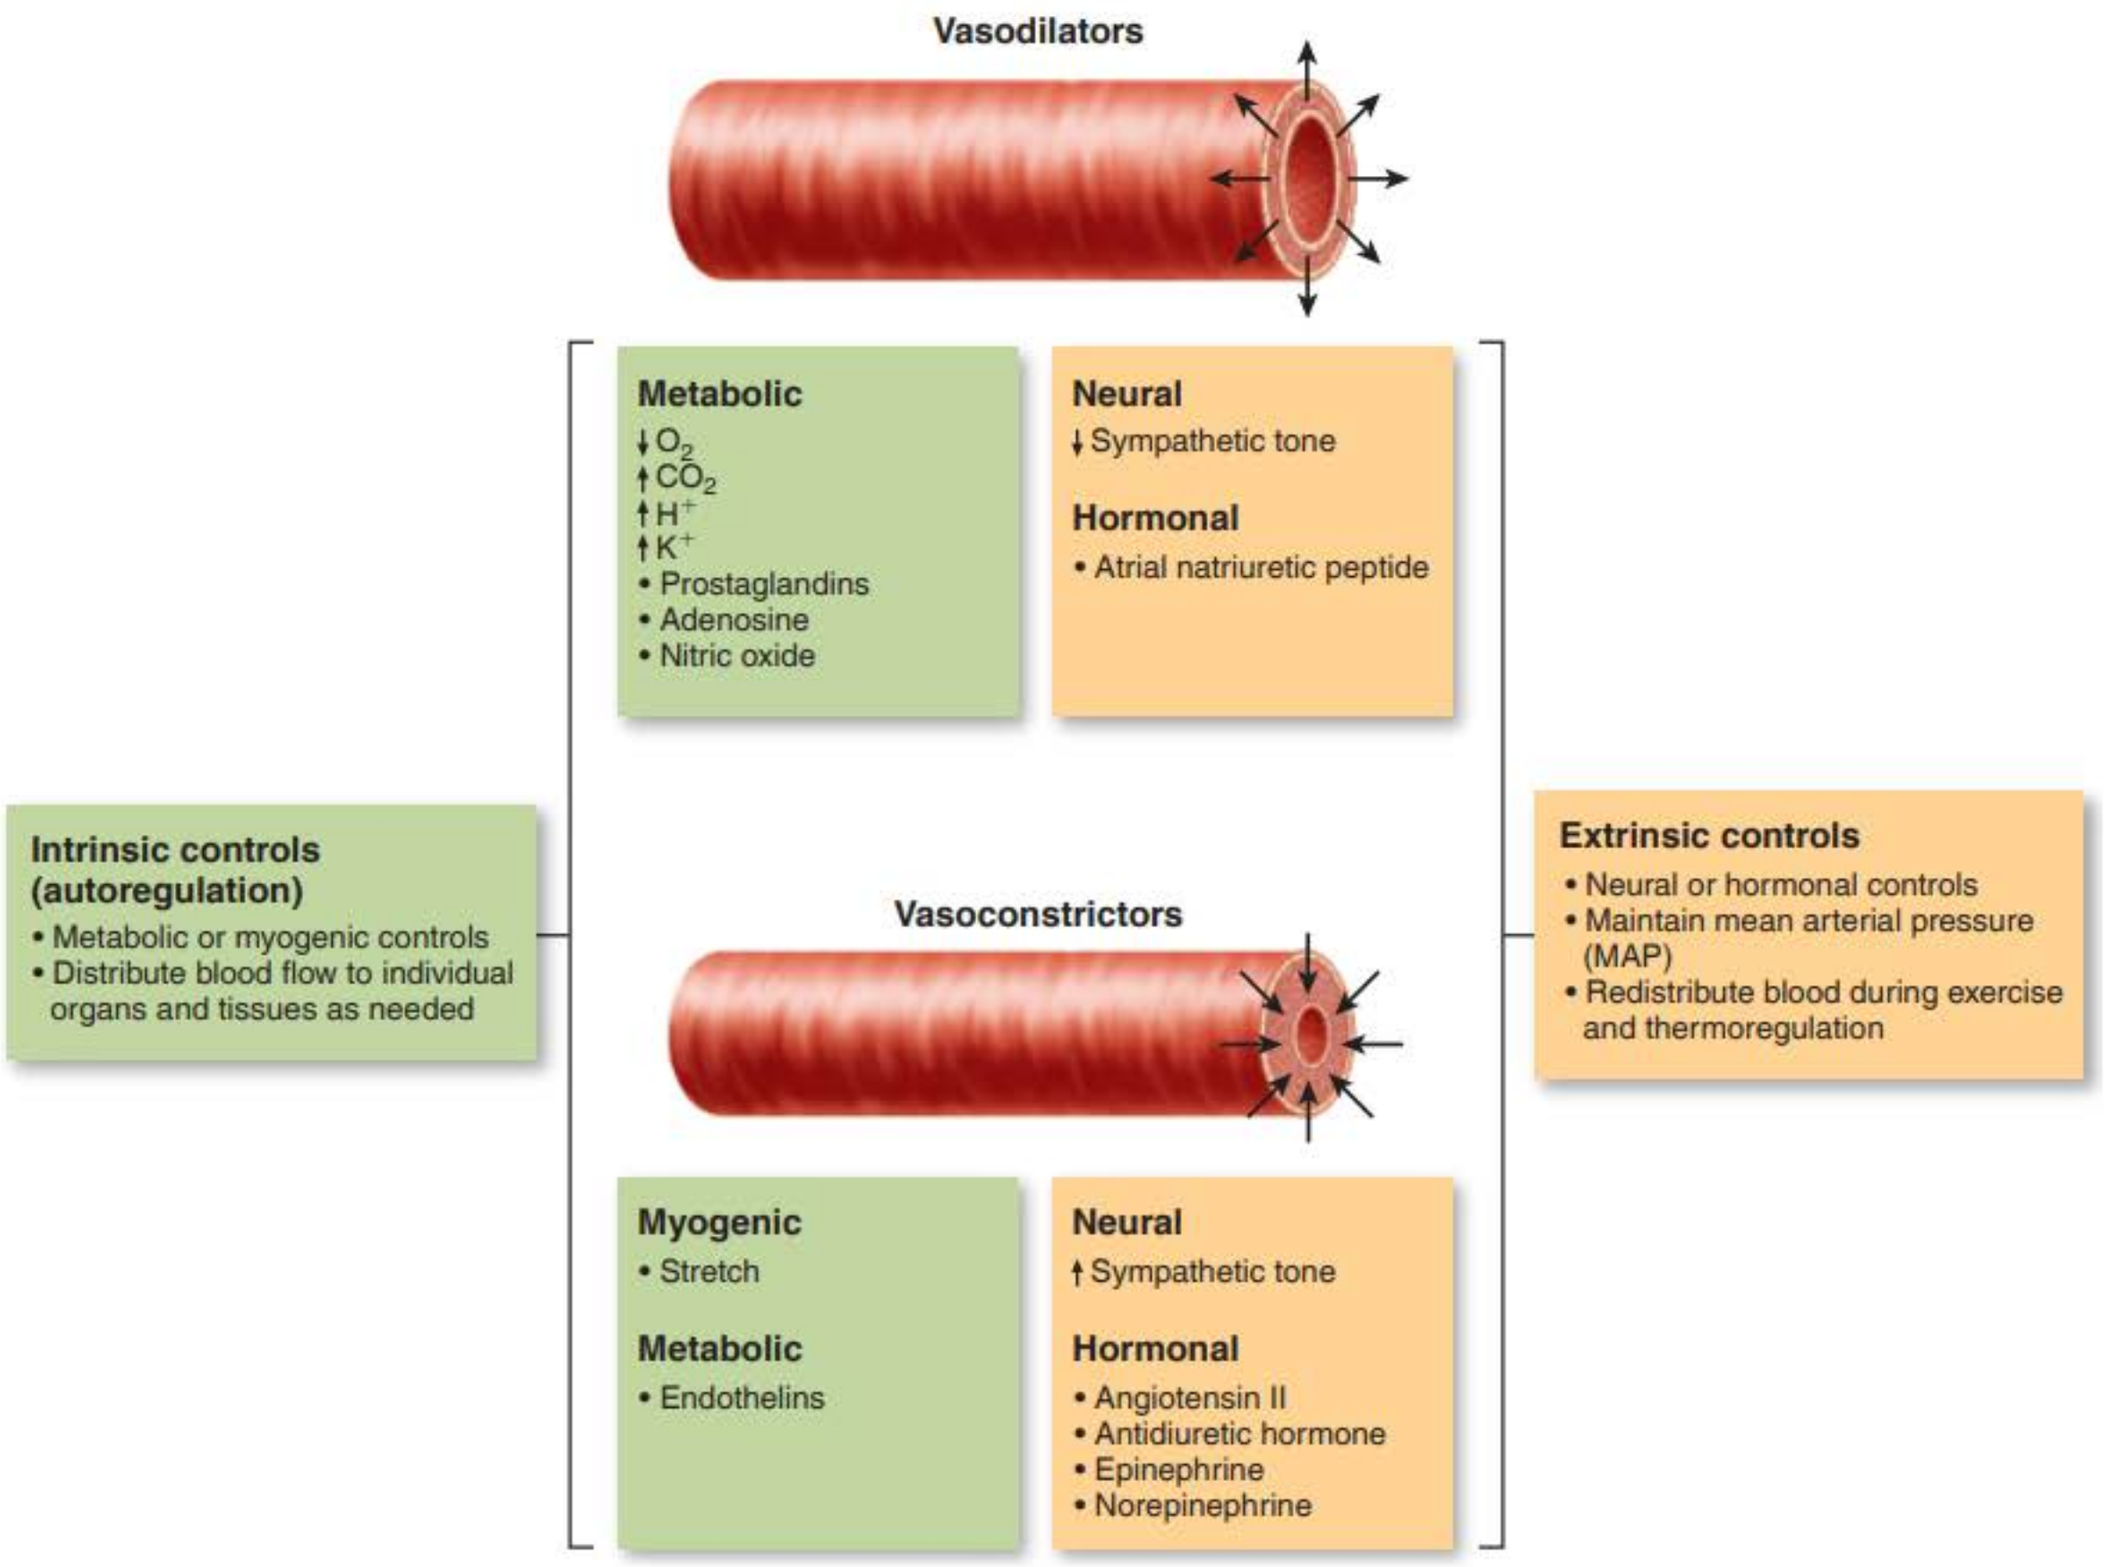

Figure 19.16 Intrinsic and extrinsic control of arteriolar smooth muscle in the systemic circulation. Controls are listed in the boxes below the arterioles. Epinephrine and norepinephrine constrict arteriolar smooth muscle by acting at α-adrenergic receptors. β-adrenergic receptors (causing vasodilation) are present in arterioles supplying skeletal and heart muscle, but their physiological relevance is minimal.

Myogenic Controls

Fluctuations in systemic blood pressure would cause problems for individual organs were it not for the **myogenic responses** (*myo* = muscle, *gen* = origin) of vascular smooth muscle. Inadequate blood perfusion through an organ is quickly followed by a decline in the organ's metabolic rate and, if prolonged, organ death. Likewise, excessively high arterial pressure can be dangerous because it may rupture more fragile blood vessels.

Fortunately, vascular smooth muscle prevents these problems by responding directly to passive stretch (caused by increased intravascular pressure) with increased tone, which resists the stretch and causes vasoconstriction. In contrast, reduced stretch (due to decreased intravascular pressure) results in vasodilation and increases blood flow into the tissue. These myogenic responses keep tissue perfusion fairly constant despite most variations in systemic pressure.

Long-Term Autoregulation

If a tissue needs more nutrients than short-term autoregulatory mechanisms can supply, a long-term autoregulatory mechanism may develop over weeks or months to enrich local blood flow still more. The number of blood vessels in the region increases, and existing vessels enlarge. This phenomenon, called *angiogenesis*, is particularly common in the heart when a coronary vessel is partially occluded. It occurs throughout the body in people who live in high-altitude areas, where the air contains less oxygen.

Blood Flow in Special Areas

Each organ has special requirements and functions that are revealed in its pattern of autoregulation. Autoregulation in the brain, heart, and kidneys is extraordinarily efficient, maintaining adequate perfusion even when MAP fluctuates.

Skeletal Muscles

Blood flow in skeletal muscle varies with fiber type and muscle activity. Generally speaking, capillary density and blood flow are greater in red (slow oxidative) fibers than in white (fast glycolytic) fibers. Resting skeletal muscles receive about 1 L of blood per minute, and only about 25% of their capillaries are open. During rest, myogenic and general neural mechanisms predominate.

Without question, strenuous exercise is one of the most demanding conditions the cardiovascular system faces. Ultimately, the major factor determining how long muscles can contract vigorously is the ability of the cardiovascular system to deliver adequate oxygen and nutrients and remove waste products.

When muscles become active, blood flow increases (*hyperemia*) in direct proportion to their greater *metabolic* activity, a phenomenon called **active hyperemia** (**Figure 19.17**). This form of autoregulation occurs almost entirely in response to the decreased oxygen concentration and accumulated metabolic factors that result from the "revved-up" metabolism of working muscles.

However, systemic adjustments mediated by the vasomotor center must also occur to ensure that blood delivery to the muscles is both faster and more abundant. During exercise, sympathetic nervous system activity increases. Norepinephrine released from sympathetic nerve endings causes vasoconstriction of arterioles throughout the body. This temporarily diverts blood away from most regions not essential for exercise, ensuring that there is sufficient blood pressure to supply the muscles.

In skeletal muscles, the sympathetic nervous system and local metabolic controls have opposing effects on arteriolar diameter. During exercise, local controls *override* sympathetic vasoconstriction. Consequently, blood flow to skeletal muscles can increase tenfold or more during physical activity, as you saw in Figure 19.15, and virtually all capillaries in the active muscles open to accommodate the increased flow.*

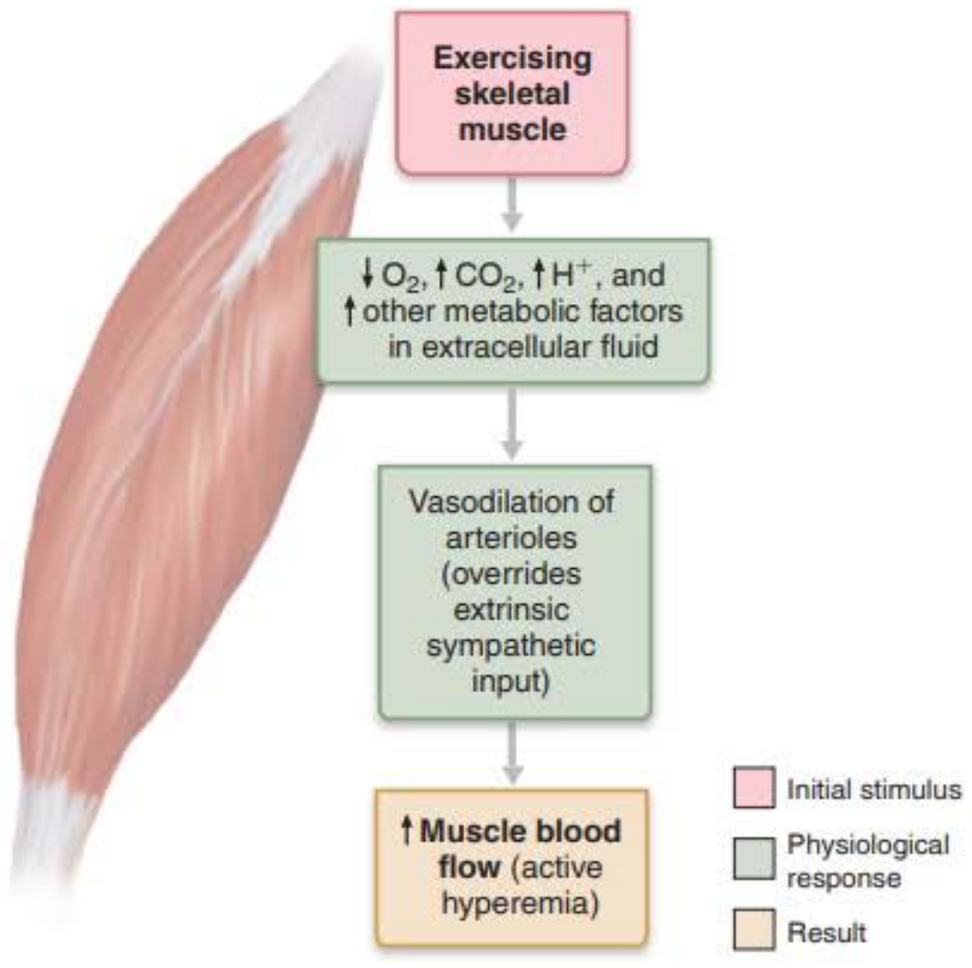

Figure 19.17 Active hyperemia. Blood flow in exercising skeletal muscle is largely controlled by metabolic autoregulation.

The Brain

Blood flow to the brain averages 750 ml/min and is maintained at a relatively constant level. Constant cerebral blood flow is necessary because neurons are totally intolerant of ischemia. Also, the brain is unable to store essential nutrients despite being the most metabolically active organ in the body.

Cerebral blood flow is regulated by one of the body's most precise autoregulatory systems and is tailored to local neuronal need. For example, when you make a fist with your right hand, the neurons in the left cerebral motor cortex controlling that movement receive more blood than the adjoining neurons. Brain tissue is exceptionally sensitive to declining pH, and increased blood carbon dioxide levels (resulting in acidic conditions in brain tissue) cause marked vasodilation. Low blood levels of oxygen are a much less potent stimulus for autoregulation. However, very high carbon dioxide levels abolish autoregulatory mechanisms and severely depress brain activity.

Besides metabolic controls, the brain also has a myogenic mechanism that protects it from possibly damaging changes in blood pressure. When MAP declines, cerebral vessels dilate to ensure adequate brain perfusion. When MAP rises, cerebral vessels constrict, protecting the small, more fragile vessels farther along the pathway from excessive pressure. Under certain circumstances, such as brain ischemia caused by rising intracranial pressure (as with a brain tumor), the brain (via the medullary cardiovascular centers) regulates its own blood flow by triggering a rise in systemic blood pressure.

However, when systemic pressure changes are extreme, the brain becomes vulnerable. Fainting, or *syncope* (sin′cuh-pe; "cutting short"), occurs when MAP falls below 60 mm Hg. Cerebral edema is the usual result of pressures over 160 mm Hg, which dramatically increase brain capillary permeability.

The Skin

Blood flow through the skin:

- Supplies nutrients to cells
- Helps regulate body temperature
- Provides a blood reservoir

Autoregulation serves the first function in response to the need for oxygen, but the other two require neural intervention. The primary function of the cutaneous circulation is to help maintain body temperature.

Below the skin surface are extensive venous plexuses (networks of intertwining vessels). The blood flow through these plexuses can change from 50 ml/min to as much as 2500 ml/min, depending on body temperature. This capability reflects neural adjustments of blood flow through arterioles and through

*Epinephrine acting at beta (β) adrenergic receptors and acetylcholine acting at cholinergic receptors were once thought to contribute to arteriolar dilation during exercise. However, these appear to have little physiological importance in controlling human skeletal muscle blood flow.

unique coiled arteriovenous anastomoses. These tiny arteriovenous shunts are located mainly in the fingertips, palms of the hands, toes, soles of the feet, ears, nose, and lips. Richly supplied with sympathetic nerve endings (unlike the shunts of some other capillary beds), they are controlled by reflexes initiated by temperature receptors or signals from higher CNS centers. The arterioles, in addition, respond to metabolic autoregulatory stimuli.

When the skin is exposed to heat, or body temperature rises for other reasons (such as vigorous exercise), the hypothalamic "thermostat" signals for reduced vasomotor stimulation of the skin vessels. As a result, warm blood flushes into the capillary beds and heat radiates from the skin surface. (This is why Figure 19.15 shows an increase in blood flow to the skin during exercise.)

When the ambient temperature is cold and body temperature drops, superficial skin vessels strongly constrict. As a result, blood almost entirely bypasses the capillaries associated with the arteriovenous anastomoses, diverting the warm blood to the deeper, more vital organs. Paradoxically, the skin may stay quite rosy because some blood gets "trapped" in the superficial capillary loops as the shunts swing into operation. The trapped blood remains red because the chilled skin cells take up less O_2.

The Lungs

Blood flow through the pulmonary circuit to and from the lungs is unusual in many ways. The pathway is relatively short, and pulmonary arteries and arterioles are structurally like veins and venules. That is, they have thin walls and large lumens. Because resistance to blood flow is low in the pulmonary arterial system, less pressure is needed to propel blood through those vessels. Consequently, arterial pressure in the pulmonary circulation is much lower than in the systemic circulation (24/10 versus 120/80 mm Hg).

In the pulmonary circulation, the autoregulatory mechanism is the *opposite* of what is seen in most tissues: Low pulmonary oxygen levels cause local vasoconstriction, and high levels promote vasodilation. While this may seem odd, it is perfectly consistent with the gas exchange role of this circulation. When the air sacs of the lungs are flooded with oxygen-rich air, the pulmonary capillaries become flushed with blood and ready to receive the oxygen load. In contrast, if the air sacs are collapsed or blocked with mucus, the oxygen content in those areas is low, and blood largely bypasses those nonfunctional areas.

The Heart

Aortic pressure and the pumping activity of the ventricles influence the movement of blood through the smaller vessels of the coronary circulation. When the ventricles contract and compress the coronary blood vessels, blood flow through the myocardium stops. As the heart relaxes, the high aortic pressure forces blood through the coronary circulation.

Under normal circumstances, the myoglobin in cardiac cells stores sufficient oxygen to satisfy the cells' oxygen needs during systole. However, an abnormally rapid heartbeat seriously reduces the ability of the myocardium to receive adequate oxygen and nutrients during diastole.

Under resting conditions, blood flow through the heart is about 250 ml/min and is controlled by a myogenic mechanism. Consequently, blood flow remains fairly constant despite wide variations (50 to 140 mm Hg) in coronary perfusion pressure. During strenuous exercise, the coronary vessels dilate in response to local accumulation of vasodilators (particularly adenosine), and blood flow may increase three to four times (see Figure 19.15). Additionally, any event that decreases the oxygen content of the blood releases vasodilators that adjust the O_2 supply to the O_2 demand.

This enhanced blood flow during increased heart activity is important because under resting conditions, cardiac cells use as much as 65% of the oxygen carried to them in blood. (Most other tissue cells use about 25% of the delivered oxygen.) Consequently, increasing the blood flow is the only way to provide more oxygen to a vigorously working heart.

Check Your Understanding

17. Suppose you are in a bicycle race. What happens to the smooth muscle in the arterioles supplying your leg muscles? What is the key mechanism in this case?
18. If many arterioles in your body dilated at once, you would expect MAP to plummet. What prevents MAP from decreasing during your bicycle race?

For answers, see Answers Appendix.

19.10 Slow blood flow through capillaries promotes diffusion of nutrients and gases, and bulk flow of fluids

Learning Outcome

- **Outline factors involved in capillary exchange and bulk flow, and explain the significance of each.**

Velocity of Blood Flow

Have you ever watched a swift river emptying into a large lake? The water's speed decreases as it enters the lake until its flow becomes almost imperceptible. This is because the total cross-sectional area of the lake is much larger than that of the river. Velocity in this case is *inversely* related to cross-sectional area. The same thing happens with blood flow inside our blood vessels.

As shown in **Figure 19.18**, the speed or velocity of blood flow changes as blood travels through the systemic circulation. It is fastest in the aorta and other large arteries (the river), slowest in the capillaries (whose large total cross-sectional area makes them analogous to the lake), and then picks up speed again in the veins (the river again).

Just as in our analogy of the river and lake, blood flows fastest where the total cross-sectional area is least. As the arterial system branches, the total cross-sectional area of the vascular bed increases, and the velocity of blood flow declines proportionately. Even though the individual branches have smaller lumens, their *combined* cross-sectional areas and thus the volume of blood they can hold are much greater than that of the aorta.

For example, the cross-sectional area of the aorta is 2.5 cm^2, but the combined cross-sectional area of all the capillaries is 4500 cm^2. This difference results in fast blood flow in the aorta (40–50 cm/s) and slow blood flow in the capillaries (about 0.03 cm/s). Slow capillary flow is beneficial because it allows adequate time for exchanges between the blood and tissue cells.

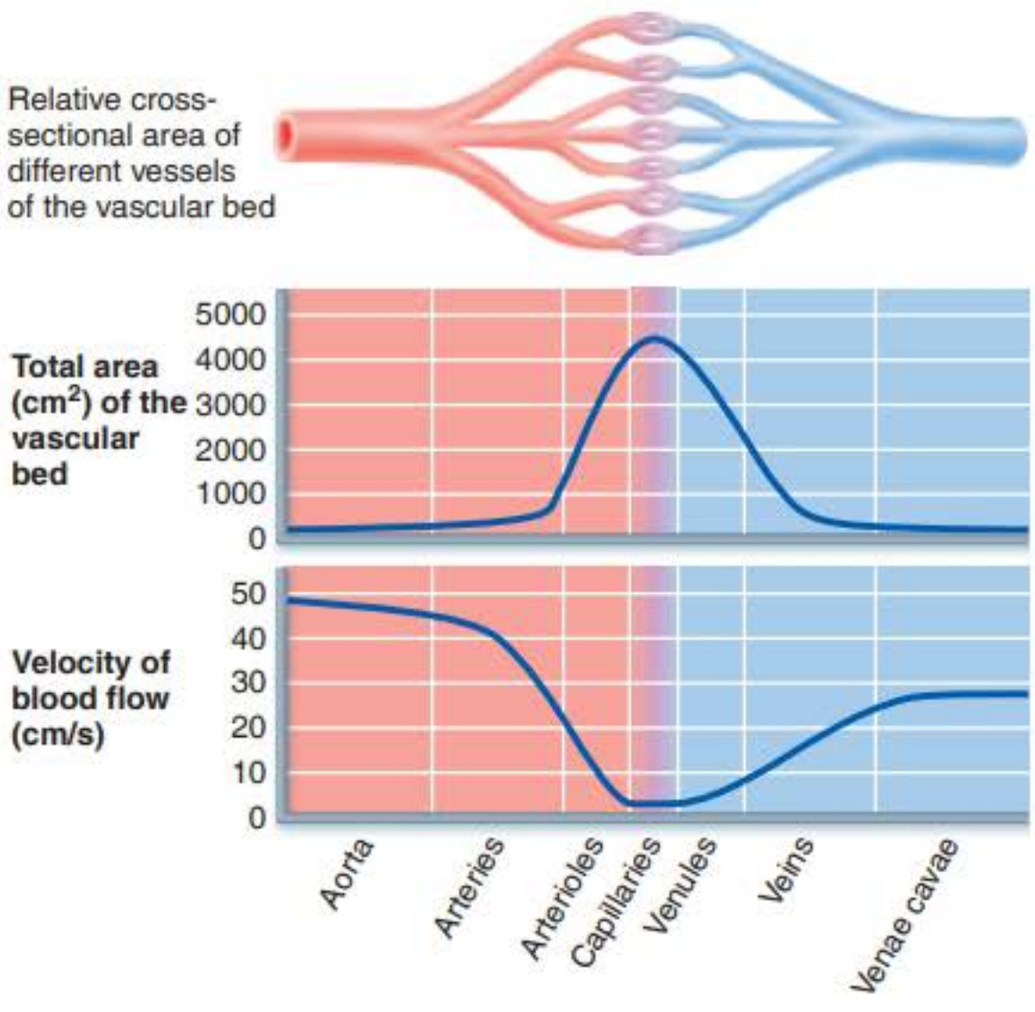

Figure 19.18 Blood flow velocity and total cross-sectional area of vessels. Various blood vessels of the systemic circulation differ in their total cross-sectional area (e.g., the cross section of all systemic capillaries combined versus the cross section of all systemic arteries combined), which affects the velocity of blood flow through them.

Vasomotion

Blood flow through capillaries is not only slow, it is also intermittent. The intermittent flow of blood through a capillary bed is due to **vasomotion**, the on/off constriction/dilation of arterioles, mostly in response to local chemical conditions (intrinsic control). Precapillary sphincters also respond to the same local autoregulatory signals that affect arteriolar diameter.

Capillary Exchange of Respiratory Gases and Nutrients

Oxygen, carbon dioxide, most nutrients, and metabolic wastes pass between the blood and interstitial fluid by diffusion. Recall that in **diffusion**, net movement always occurs along a concentration gradient—each substance moving from an area of its higher concentration to an area of its lower concentration. As a result, oxygen and nutrients pass from the blood, where their concentration is fairly high, through the interstitial fluid to the tissue cells. Carbon dioxide and metabolic wastes leave the cells, where their content is higher, and diffuse into the capillary blood.

There are four different routes across capillaries for different types of molecules, as **Figure 19.19** shows. (1) Lipid-soluble molecules, such as respiratory gases, diffuse through the lipid bilayer of the endothelial cell plasma membranes. Recall that the plasma membrane is a major barrier to diffusion of solutes that are not lipid soluble (◀ p. 70). Small water-soluble solutes, such as amino acids and sugars, pass through (2) fluid-filled intercellular capillary clefts or (3) fenestrations. (4) Some larger molecules, such as proteins, are actively transported in pinocytotic vesicles.

As we mentioned earlier, capillaries differ in their "leakiness," or permeability. Liver capillaries, for instance, are sinusoids that allow even proteins to pass freely, whereas brain capillaries are impermeable to most substances.

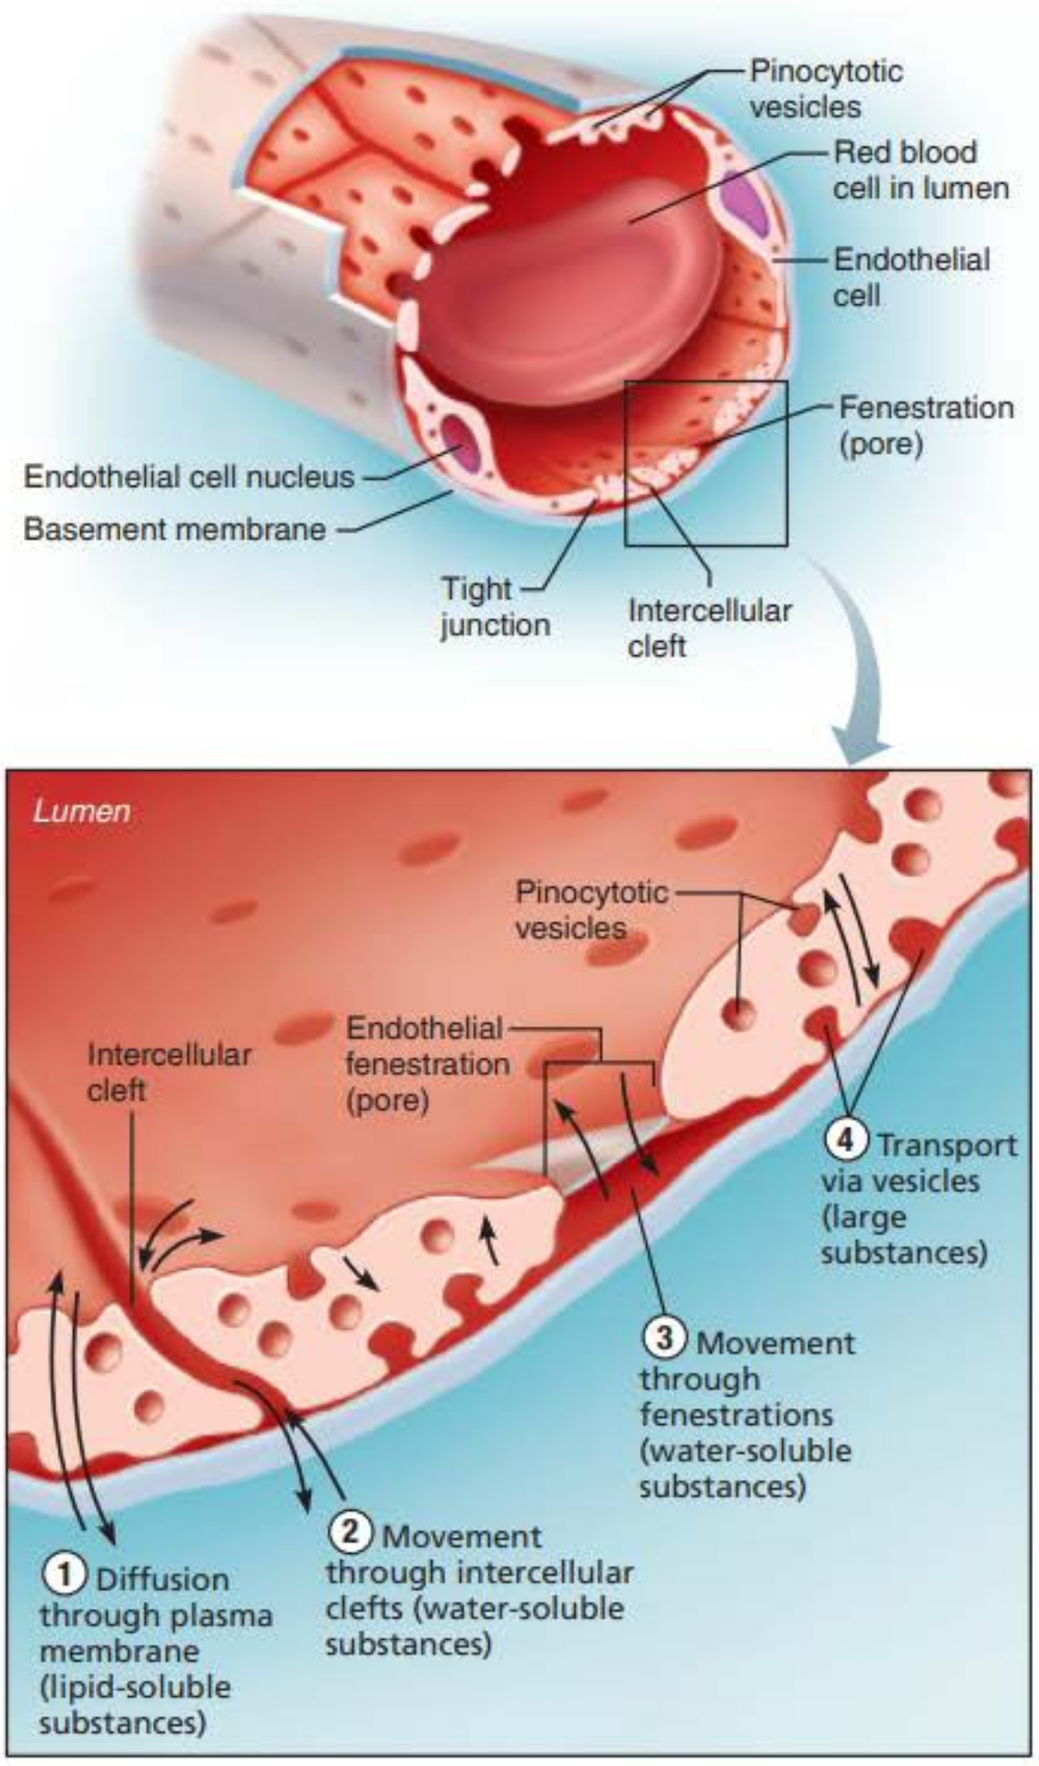

Figure 19.19 Capillary transport mechanisms. The four possible pathways or routes of transport across the endothelial cell wall of a fenestrated capillary.

Fluid Movements: Bulk Flow

While nutrient and gas exchanges are occurring across the capillary walls by diffusion, bulk fluid flows are also going on. Fluid is forced out of the capillaries through the clefts at the arterial end of the bed, but most of it returns to the bloodstream at the venous end. Though relatively unimportant to capillary exchange of nutrients and wastes, bulk flow is extremely important in determining the relative fluid volumes in the bloodstream and the interstitial space. (Approximately 20 L of fluid filter out of the capillaries each day before being returned to the blood—almost seven times the total plasma volume!)

As we describe next and show in *Focus on Bulk Flow across Capillary Walls* (**Focus Figure 19.1** on pp. 732–733), the *direction and amount* of flow across capillary walls reflect the balance between two dynamic and opposing forces—hydrostatic and colloid osmotic pressures.

Hydrostatic Pressures

Hydrostatic pressure (HP) is the force exerted by a fluid pressing against a wall. In capillaries, hydrostatic pressure is the same as *capillary blood pressure*—the pressure exerted by blood on capillary walls. **Capillary hydrostatic pressure (HP_c)** tends to force fluids through capillary walls (a process called *filtration*), leaving behind cells and most proteins. Blood pressure drops as blood flows along a capillary bed, so HP_c is higher at the arterial end of the bed (35 mm Hg) than at the venous end (17 mm Hg).

In theory, blood pressure—which forces fluid out of the capillaries—is opposed by the **interstitial fluid hydrostatic pressure (HP_{if})** acting outside the capillaries and pushing fluid in. However, there is usually very little fluid in the interstitial space because the lymphatic vessels constantly withdraw it. HP_{if} may vary from slightly negative to slightly positive, but traditionally it is assumed to be zero.

Colloid Osmotic Pressures

Colloid osmotic pressure (OP), the force opposing hydrostatic pressure, is created by large nondiffusible molecules, such as plasma proteins, that are unable to cross the capillary wall (◀ p. 644). Such molecules draw water toward themselves. In other words, they encourage osmosis. This is because water moves to make the solute more dilute. A quick and dirty way to remember this is "hydrostatic pressure pushes and osmotic pressure sucks."

The abundant plasma proteins in capillary blood (primarily albumin molecules) develop a **capillary colloid osmotic pressure (OP_c)**, also called *oncotic pressure*, of approximately 26 mm Hg. The **interstitial fluid colloid osmotic pressure (OP_{if})** is substantially lower—from 0.1 to 5 mm Hg—because interstitial fluid contains few proteins. Unlike HP, OP does not vary significantly from one end of the capillary bed to the other.

Hydrostatic-Osmotic Pressure Interactions

We are now ready to calculate the **net filtration pressure (NFP)**, which considers all the forces acting at the capillary bed. As you work your way through the right-hand page of Focus Figure 19.1, notice that while net *filtration* is occurring at the arteriolar end of the capillary, a negative value for NFP at the venous end of the capillary indicates that fluid is moving *into* the capillary bed (a process called *reabsorption*). As a result, net fluid flow is *out* of the circulation at the arterial ends of capillary beds and *into* the circulation at the venous ends.

However, more fluid enters the tissue spaces than returns to the blood, resulting in a net loss of fluid from the circulation of about 1.5 ml/min. Lymphatic vessels pick up this fluid and any leaked proteins and return it to the vascular system, which accounts for the relatively low levels of both fluid and proteins in the interstitial space. Were this not so, this "insignificant" fluid loss would empty your blood vessels of plasma in about 24 hours!

(Text continues on p. 734.)

FOCUS FIGURE 19.1 Bulk Flow across Capillary Walls

Bulk fluid flow across capillary walls causes continuous mixing of fluid between the plasma and the interstitial fluid compartments, and maintains the interstitial environment.

The big picture

Each day, 20 L of fluid filters from capillaries at their arteriolar end and flows through the interstitial space. Most (17 L) is reabsorbed at the venous end.

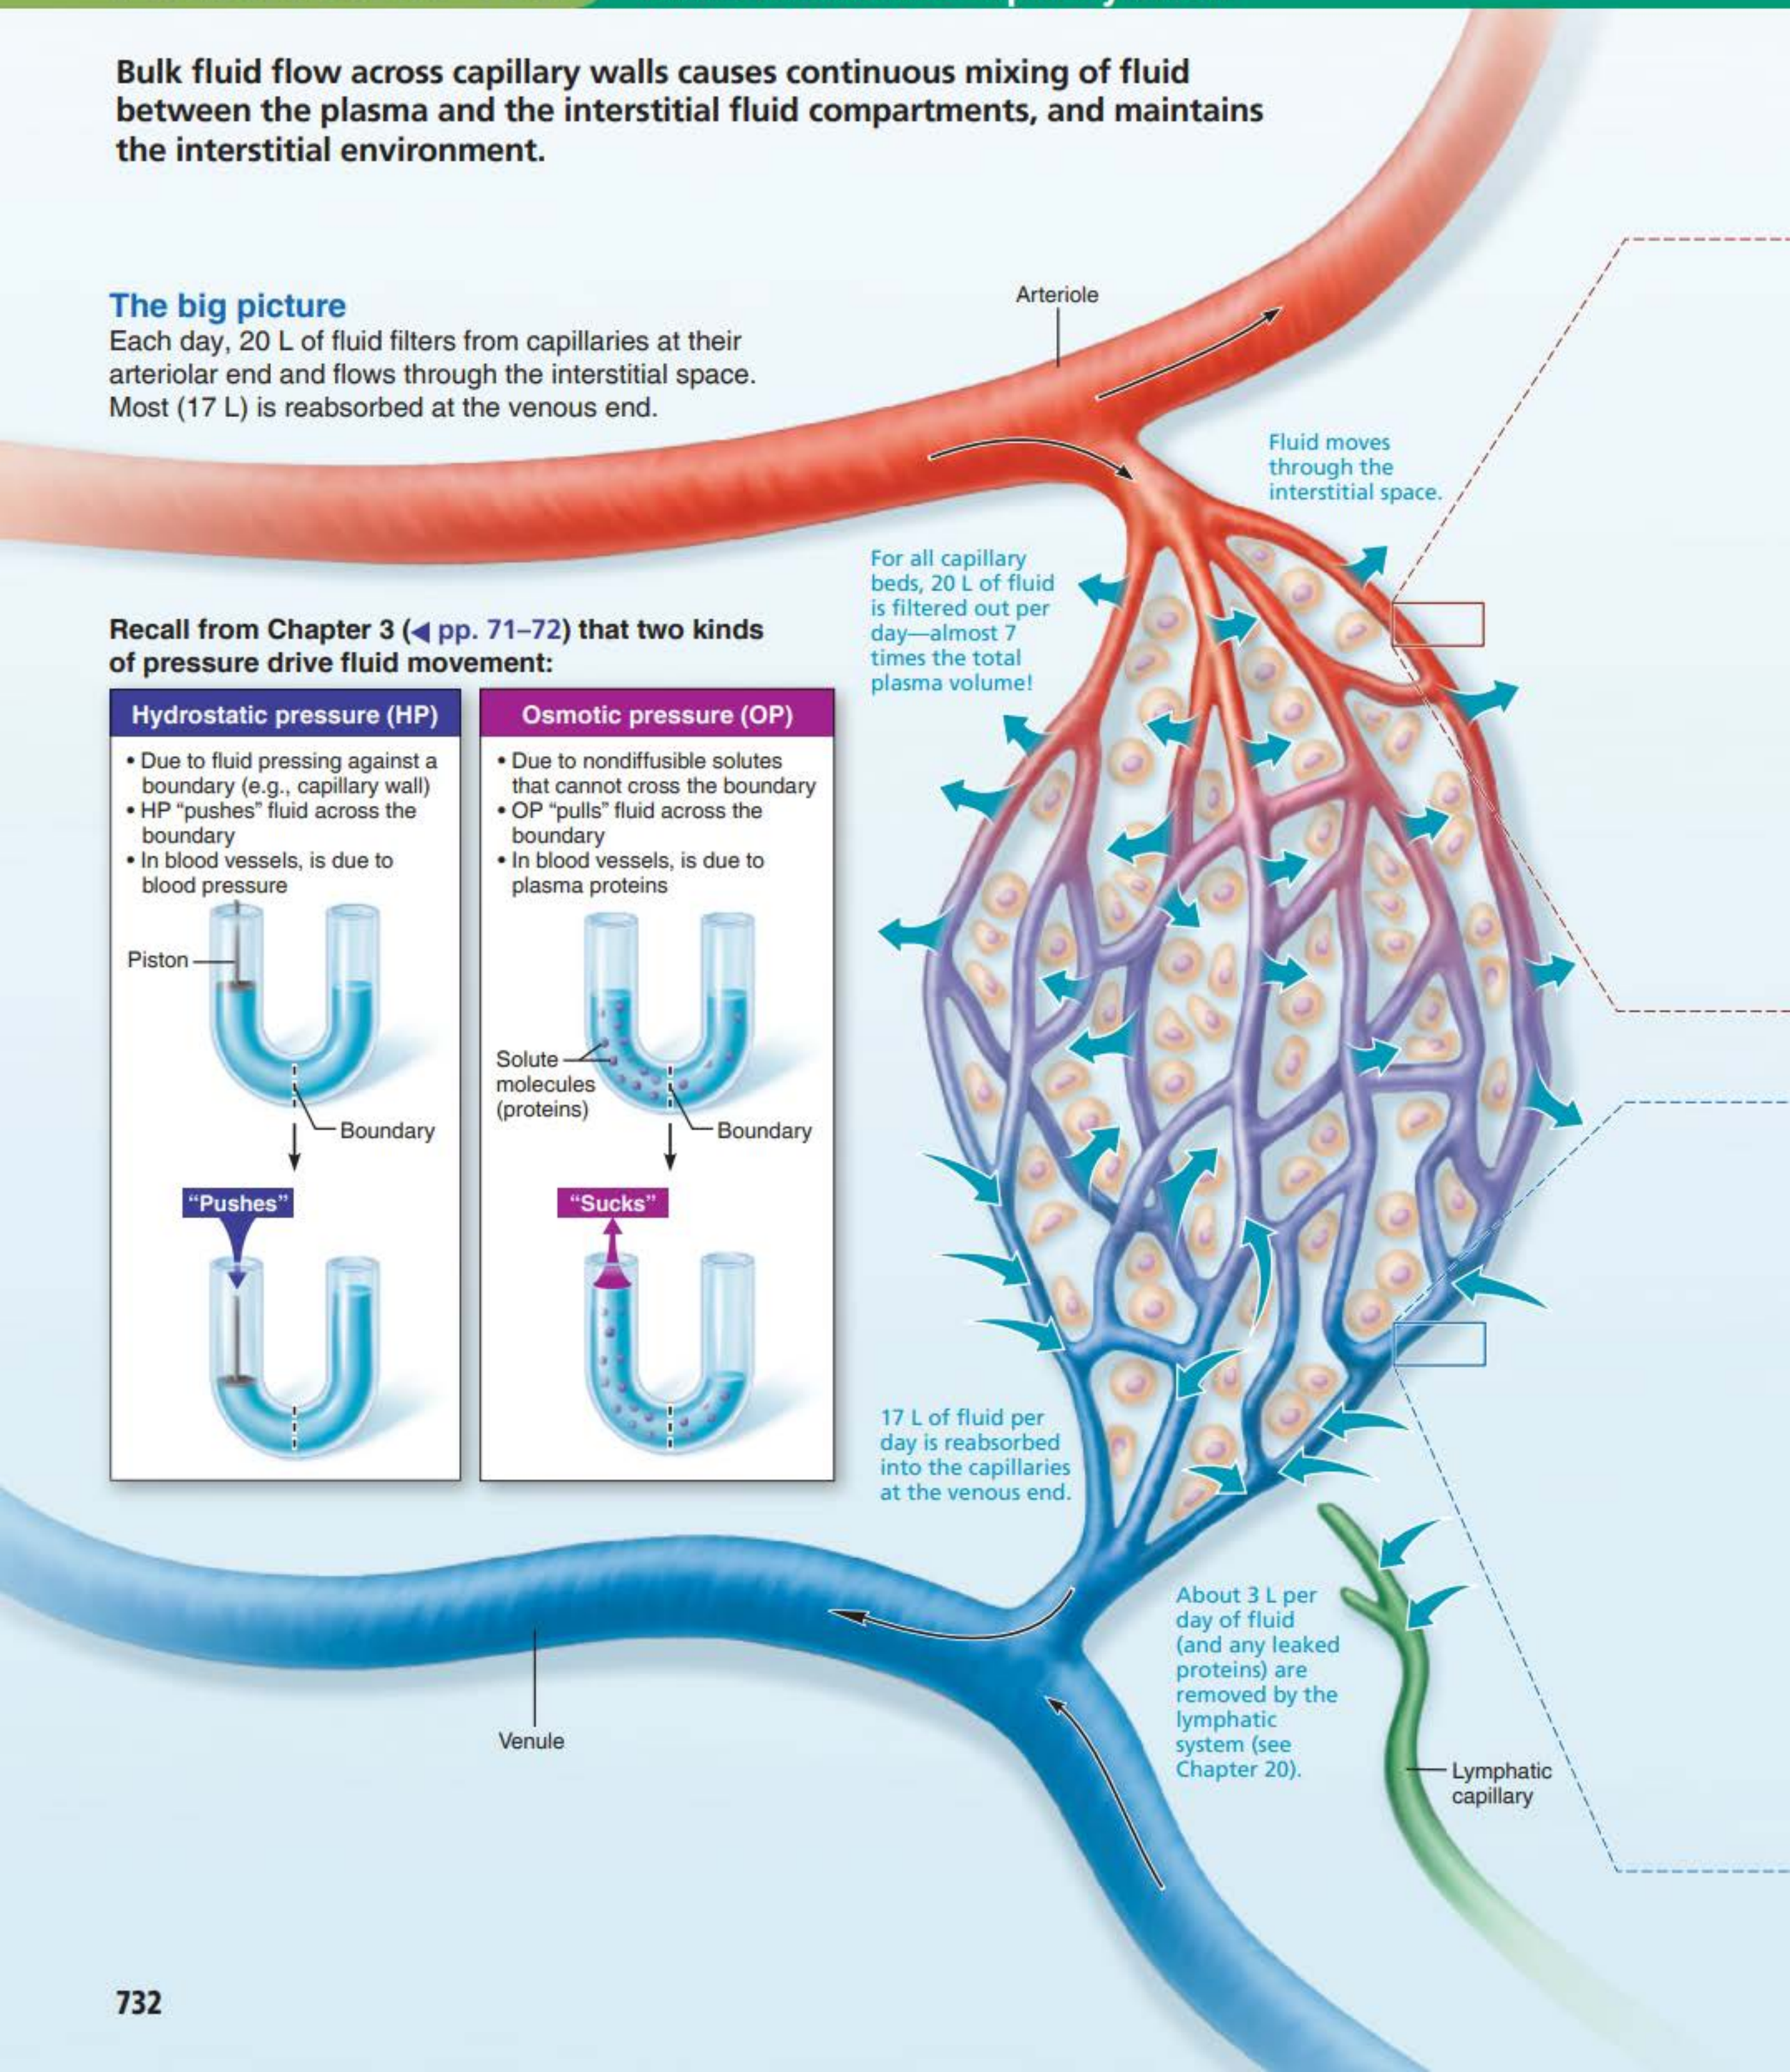
Recall from Chapter 3 (◀ pp. 71–72) that two kinds of pressure drive fluid movement:

Hydrostatic pressure (HP)

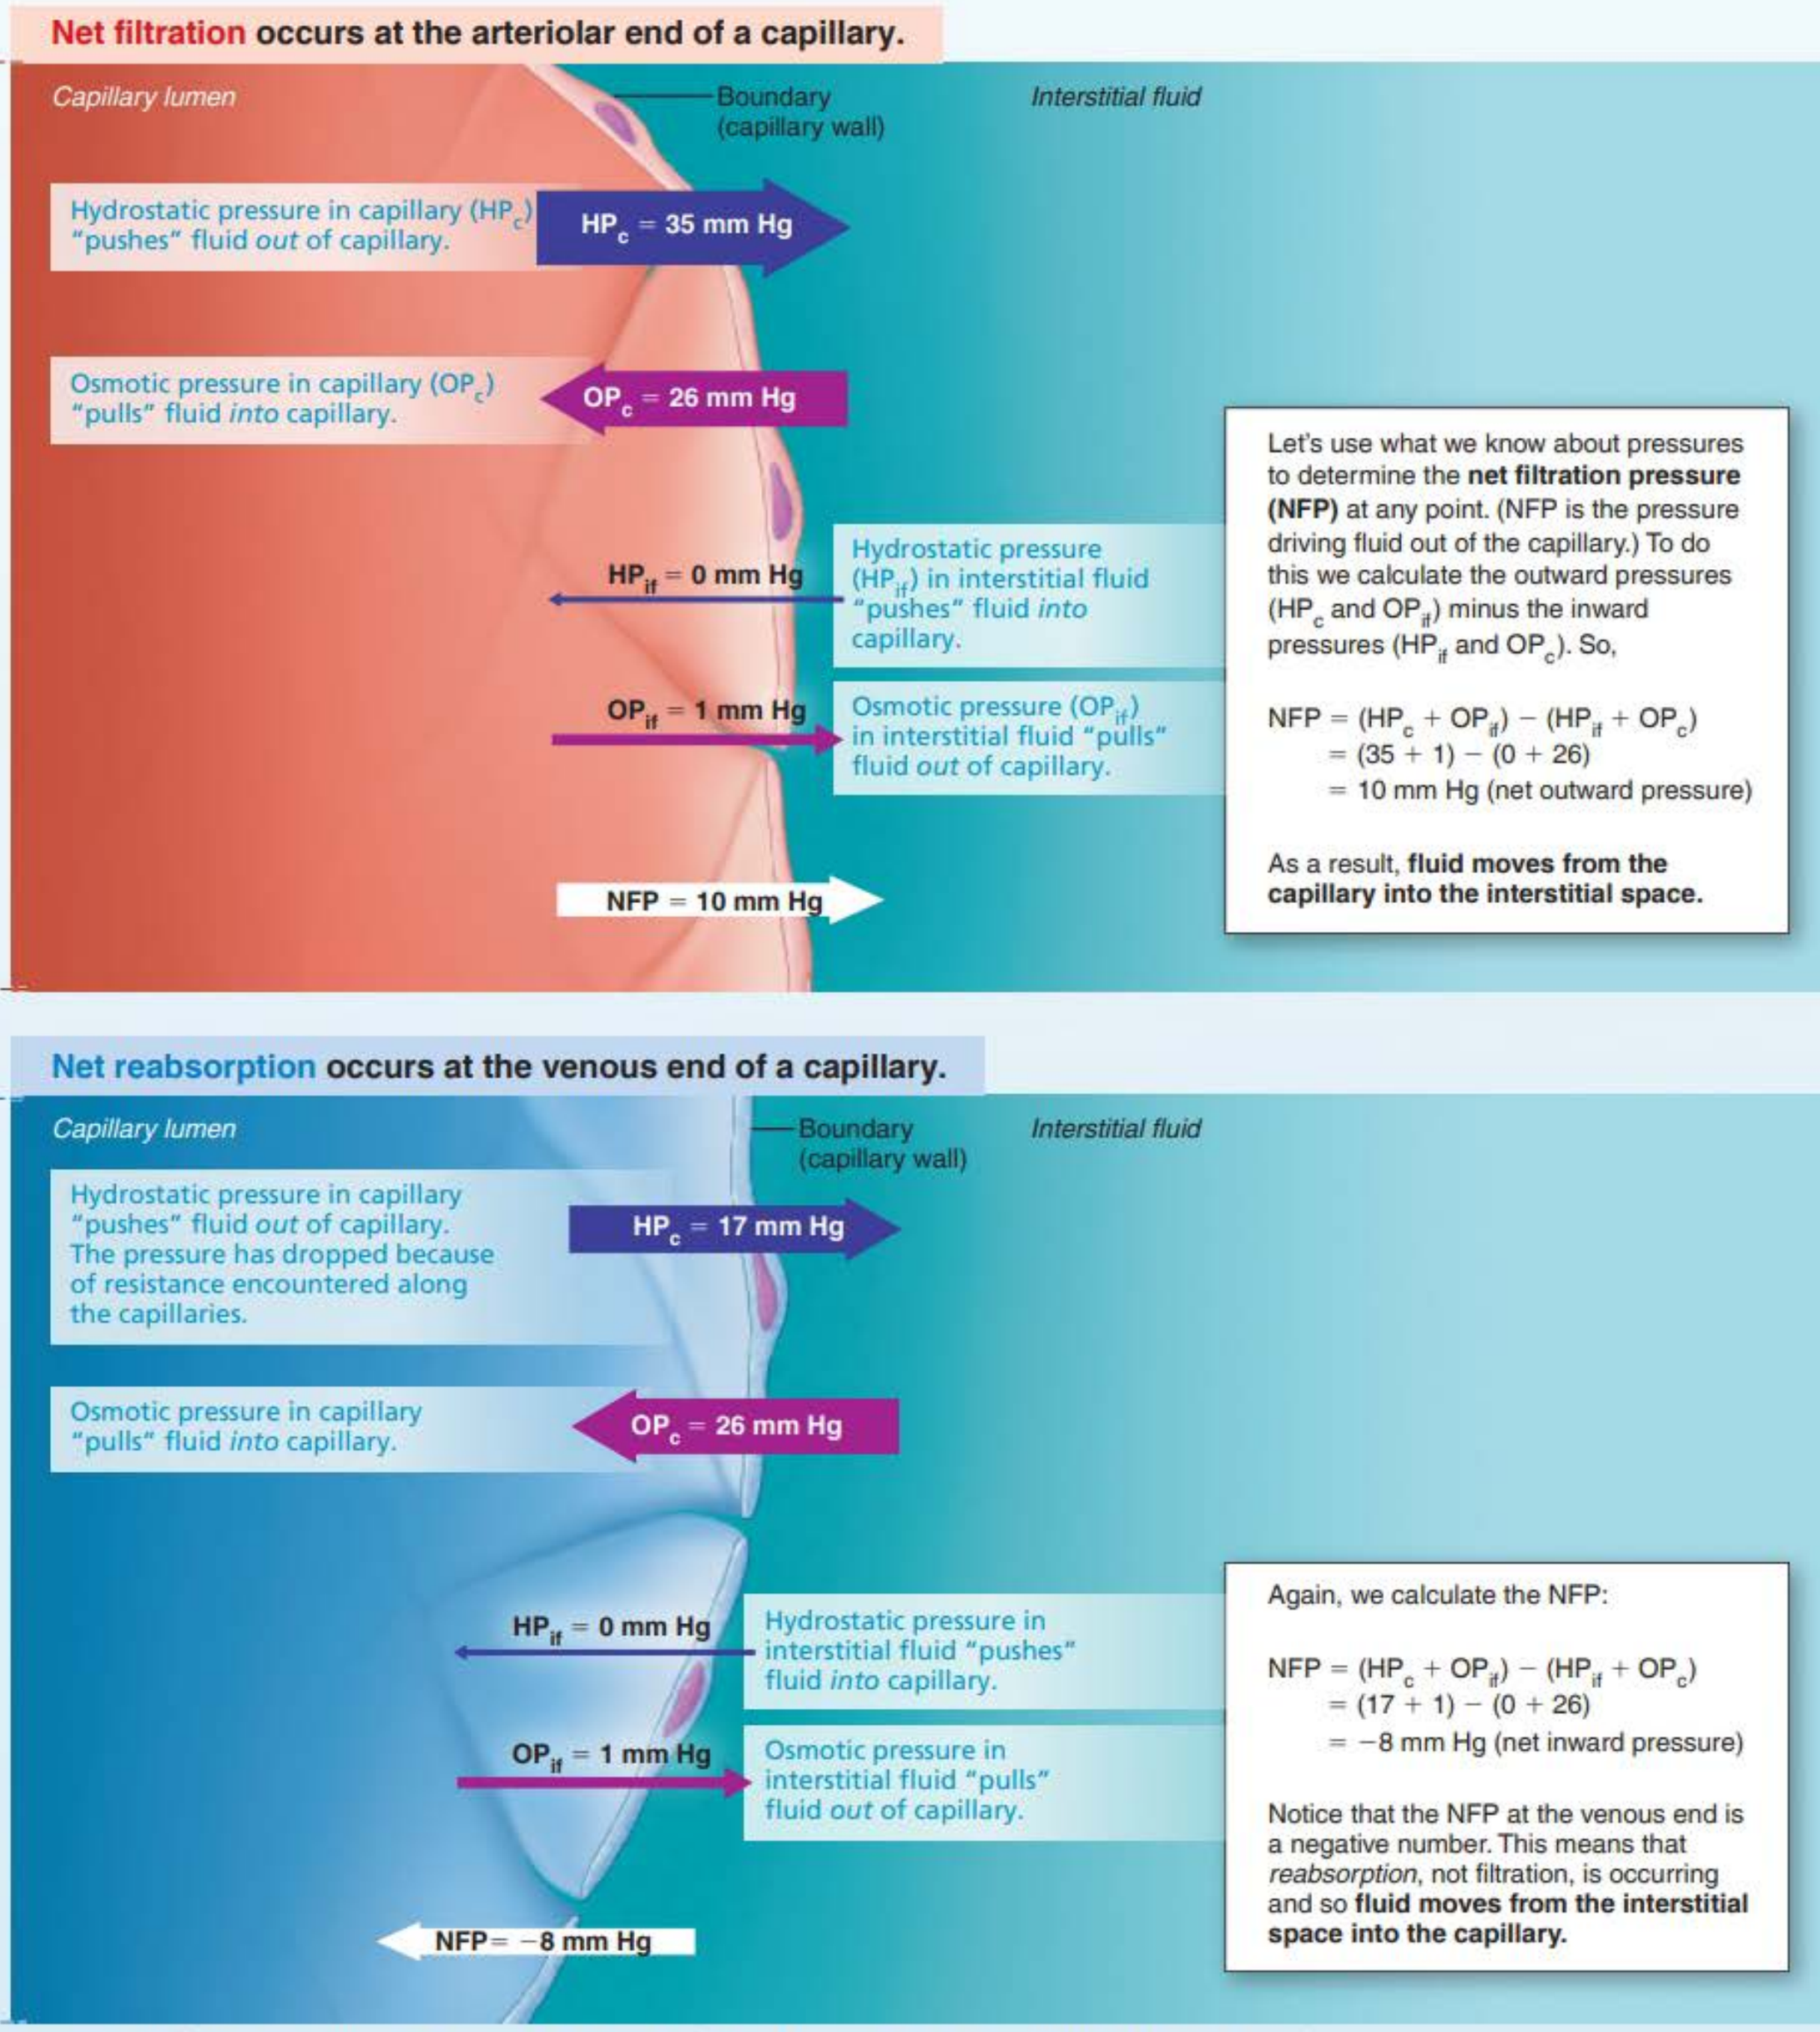
- Due to fluid pressing against a boundary (e.g., capillary wall)
- HP "pushes" fluid across the boundary
- In blood vessels, is due to blood pressure

Osmotic pressure (OP)

- Due to nondiffusible solutes that cannot cross the boundary
- OP "pulls" fluid across the boundary
- In blood vessels, is due to plasma proteins



How do the pressures drive fluid flow across a capillary?



When bulk flow goes wrong, *edema* can result (see Homeostatic Imbalance 19.2, p. 734).

HOMEOSTATIC IMBALANCE 19.2 — CLINICAL

Edema is an abnormal increase in the amount of interstitial fluid. You will encounter it frequently in the clinic because it occurs in diverse clinical scenarios. However, it will be easy for you to discern the underlying cause of edema in any given situation if you think of it in terms of the pressures that drive bulk flow. Either an increase in outward pressure (driving fluid out of the capillaries) or a decrease in inward pressure could be the cause.

- An increase in *capillary hydrostatic pressure* accelerates fluid loss from the blood. This could result from incompetent venous valves, localized blood vessel blockage, congestive heart failure, or high blood volume. It could also result from the enlarged uterus of a pregnant woman pressing on veins that return blood to the heart. Whatever the cause, the abnormally high capillary hydrostatic pressure intensifies filtration.
- Increased *interstitial fluid osmotic pressure* can result from an inflammatory response. Inflammation increases capillary permeability, allowing plasma proteins to leak into the interstitial fluid. Together, the more porous capillaries and the increased osmolality of the interstitial fluid draw large amounts of fluid out of the capillaries, accounting for the localized swelling seen in inflammation. In an anaphylactic response (see p. 813), edema results from the massive release of the inflammatory chemical histamine.
- Decreased *capillary colloid osmotic pressure* hinders fluid return to the blood. Since plasma proteins are largely responsible for OP_c, **hypoproteinemia** (hi″po-pro″te-ĭ-ne′me-ah), a condition of unusually low levels of plasma proteins, results in tissue edema. Fluids are forced out of the capillary beds at the arteriolar ends by blood pressure as usual, but fail to return to the blood at the venous ends. As a result, the interstitial spaces become congested with fluid. Hypoproteinemia may result from liver disease, protein malnutrition, or glomerulonephritis (in which plasma proteins pass through "leaky" renal filtration membranes and are lost in urine).
- Theoretically, a decrease in *interstitial fluid hydrostatic pressure* should also be a potential cause of edema. However, this does not occur because HP_{if} is too low to decrease to any extent.
- A fourth cause of edema is decreased drainage of interstitial fluid through *lymphatic vessels* that have been blocked (e.g., by parasitic worms; see elephantiasis in the Chapter 20 Related Clinical Terms on p. 777) or surgically removed (for example, during cancer surgery).

Edema can occur anywhere in the body but is most easily visible in the skin. Excess interstitial fluid in the subcutaneous tissues generally causes *pitting edema* (**Figure 19.20**). Gravity determines where edematous fluid accumulates, so involvement of the legs and feet is common.

Edema can impair tissue function because excess fluid in the interstitial space increases the distance nutrients and oxygen must diffuse between the blood and the cells. Usually edema develops slowly, and so the fluid losses from the blood are compensated for by renal mechanisms that maintain blood volume and pressure. However, rapid onset of edema such as that in anaphylaxis may have serious effects on the efficiency of the circulation due to a decrease in blood volume and blood pressure.

Figure 19.20 Pitting edema. Applying pressure with a thumb leaves an indentation that remains for some time.

Check Your Understanding

19. DRAW At a given point in a capillary, suppose that capillary hydrostatic pressure is 32 mm Hg, interstitial fluid hydrostatic pressure is 1 mm Hg, capillary colloid osmotic pressure is 25 mm Hg, and interstitial fluid osmotic pressure is 2 mm Hg. Draw a line representing the capillary wall and label the compartments on either side as "capillary lumen" and "interstitial fluid." For each of the four pressures, draw an arrow across the capillary wall pointing in the correct direction, and label it with the appropriate name and value. Calculate the net filtration pressure. Would you expect to find this point at the venous or arterial end of the capillary?

20. PREDICT Suppose OP_{if} rises dramatically—say because of a severe bacterial infection in the surrounding tissue. (a) Predict how fluid flow will change in this situation. (b) Now calculate the NFP at the venous end of the capillary in Focus Figure 19.1 if OP_{if} increases to 10 mm Hg. (c) In which direction does fluid flow at the venous end of the capillary now—in or out?

21. MAKE CONNECTIONS Your patient in right heart failure is experiencing peripheral edema. Which of the four pressures that drive bulk fluid flow at capillaries has been changed as a result of the heart failure and in which direction?

For answers, see Answers Appendix.

PART 3
CIRCULATORY PATHWAYS: BLOOD VESSELS OF THE BODY

Learning Outcomes

- **Trace the pathway of blood through the pulmonary circuit, and state the importance of this special circulation.**

▶ **Describe the general functions of the systemic circuit.**

The term **vascular system** is often used to describe the body's complex network of blood vessels. However, as we saw in Chapter 18, the heart is actually a double pump that serves two distinct circulations, each with its own set of arteries, capillaries, and veins. The *pulmonary circulation* is the short loop that runs from the heart to the lungs and back to the heart. The *systemic circulation* routes blood through a long loop to all parts of the body before returning it to the heart. **Table 19.3** on pp. 736–737 shows both circuits schematically.

The heart pumps all of its blood into a single systemic artery—the aorta. In contrast, blood returning to the heart is delivered largely by two terminal systemic veins, the superior and inferior venae cavae. The single exception to this is the blood draining from the myocardium of the heart, which is collected by the cardiac veins and reenters the right atrium via the coronary sinus.

In addition to these differences between arteries and veins connecting to the heart, there are three important differences between systemic arteries and veins:

- **Arteries run deep while veins are both deep and superficial.** Deep veins parallel the course of the systemic arteries and both are protected by body tissues along most of their course. With a few exceptions, these veins are named identically to their companion arteries. Superficial veins run just beneath the skin and are readily seen, especially in the limbs, face, and neck. Because there are no superficial arteries, the names of the superficial veins do not correspond to the names of any of the arteries.
- **Venous pathways are more interconnected.** Unlike the fairly distinct arterial pathways, venous pathways tend to have numerous interconnections, and many veins are represented by not one but two similarly named vessels. As a result, venous pathways are more difficult to follow.
- **The brain and digestive systems have unique venous drainage systems.** Most body regions have a similar pattern for their arterial supply and venous drainage. However, the venous drainage patterns in at least two important body areas are unique. First, venous blood draining from the brain enters large *dural venous sinuses* (◀ pp. 464–465) rather than typical veins. Second, blood draining from the digestive organs enters a special subcirculation, the *hepatic portal system*, and perfuses through the liver before it reenters the general systemic circulation (see Table 19.12).

19.11 The vessels of the systemic circulation transport blood to all body tissues

Learning Outcomes

▶ **Name and give the location of the major arteries and veins in the systemic circulation.**
▶ **Describe the structure and special function of the hepatic portal system.**

The principal arteries and veins of the systemic circulation are described in **Tables 19.4** through **19.13**. (The fetal circulation is described later in the Developmental Aspects section of this chapter and in Chapter 28.)

Notice that by convention, oxygen-rich blood is shown red, while blood that is relatively oxygen-poor is depicted blue, regardless of vessel type. The schematic flowcharts (pipe diagrams) that accompany each table show the vessels that would be closer to the viewer in brighter, more intense colors than vessels deeper or farther from the viewer. For example, darker blue veins would be closer to the viewer than lighter blue veins in the body region shown.

As you examine the tables that follow and locate the various systemic arteries and veins in the illustrations, be aware of cues that make your memorization task easier. Also notice that:

- In many cases, the name of a vessel reflects the body region traversed (axillary, brachial, femoral, etc.), the organ served (renal, hepatic, gonadal), or the bone followed (vertebral, radial, tibial).
- Arteries and veins tend to run side by side and, in many places, they also run with nerves.
- The systemic vessels do not always match on the right and left sides of the body. Thus, while almost all vessels in the head and limbs are bilaterally symmetrical, some of the large, deep vessels of the trunk region are asymmetrical or unpaired.

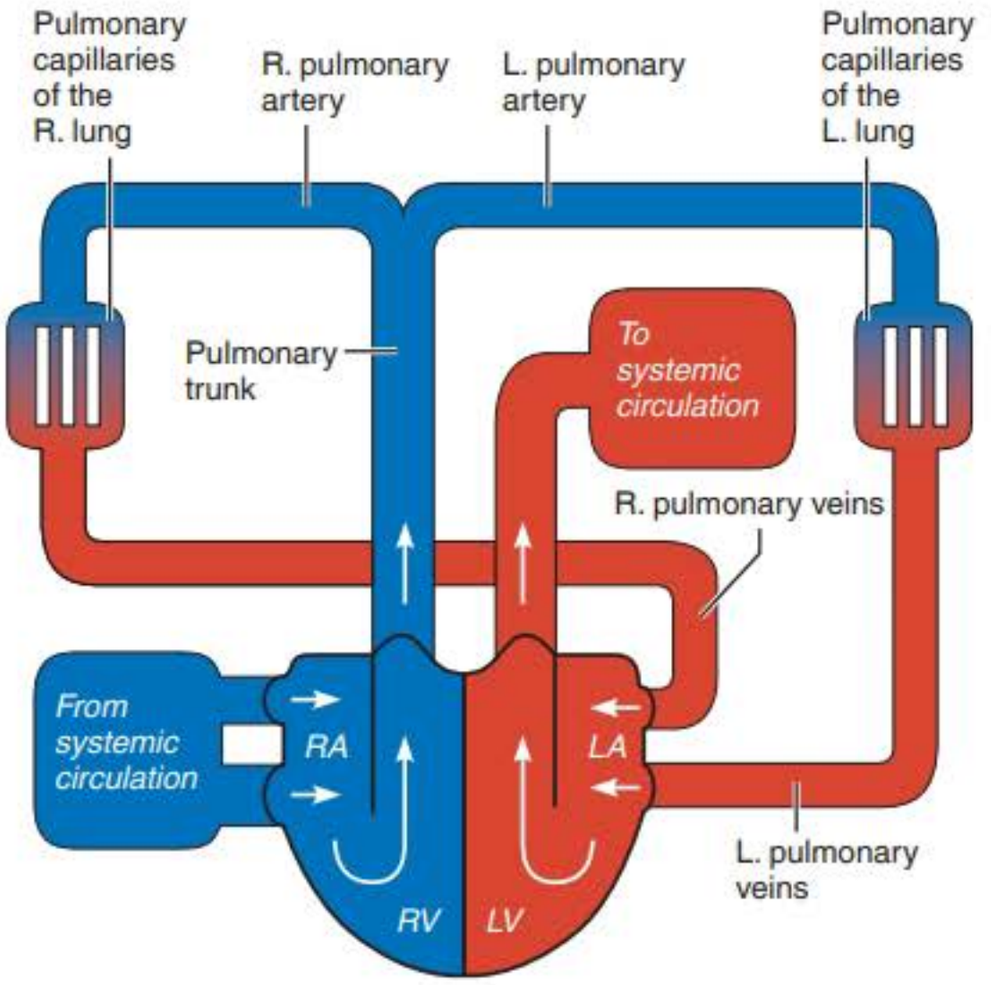
(Text continues on p. 747.)

Table 19.3 Pulmonary and Systemic Circulations

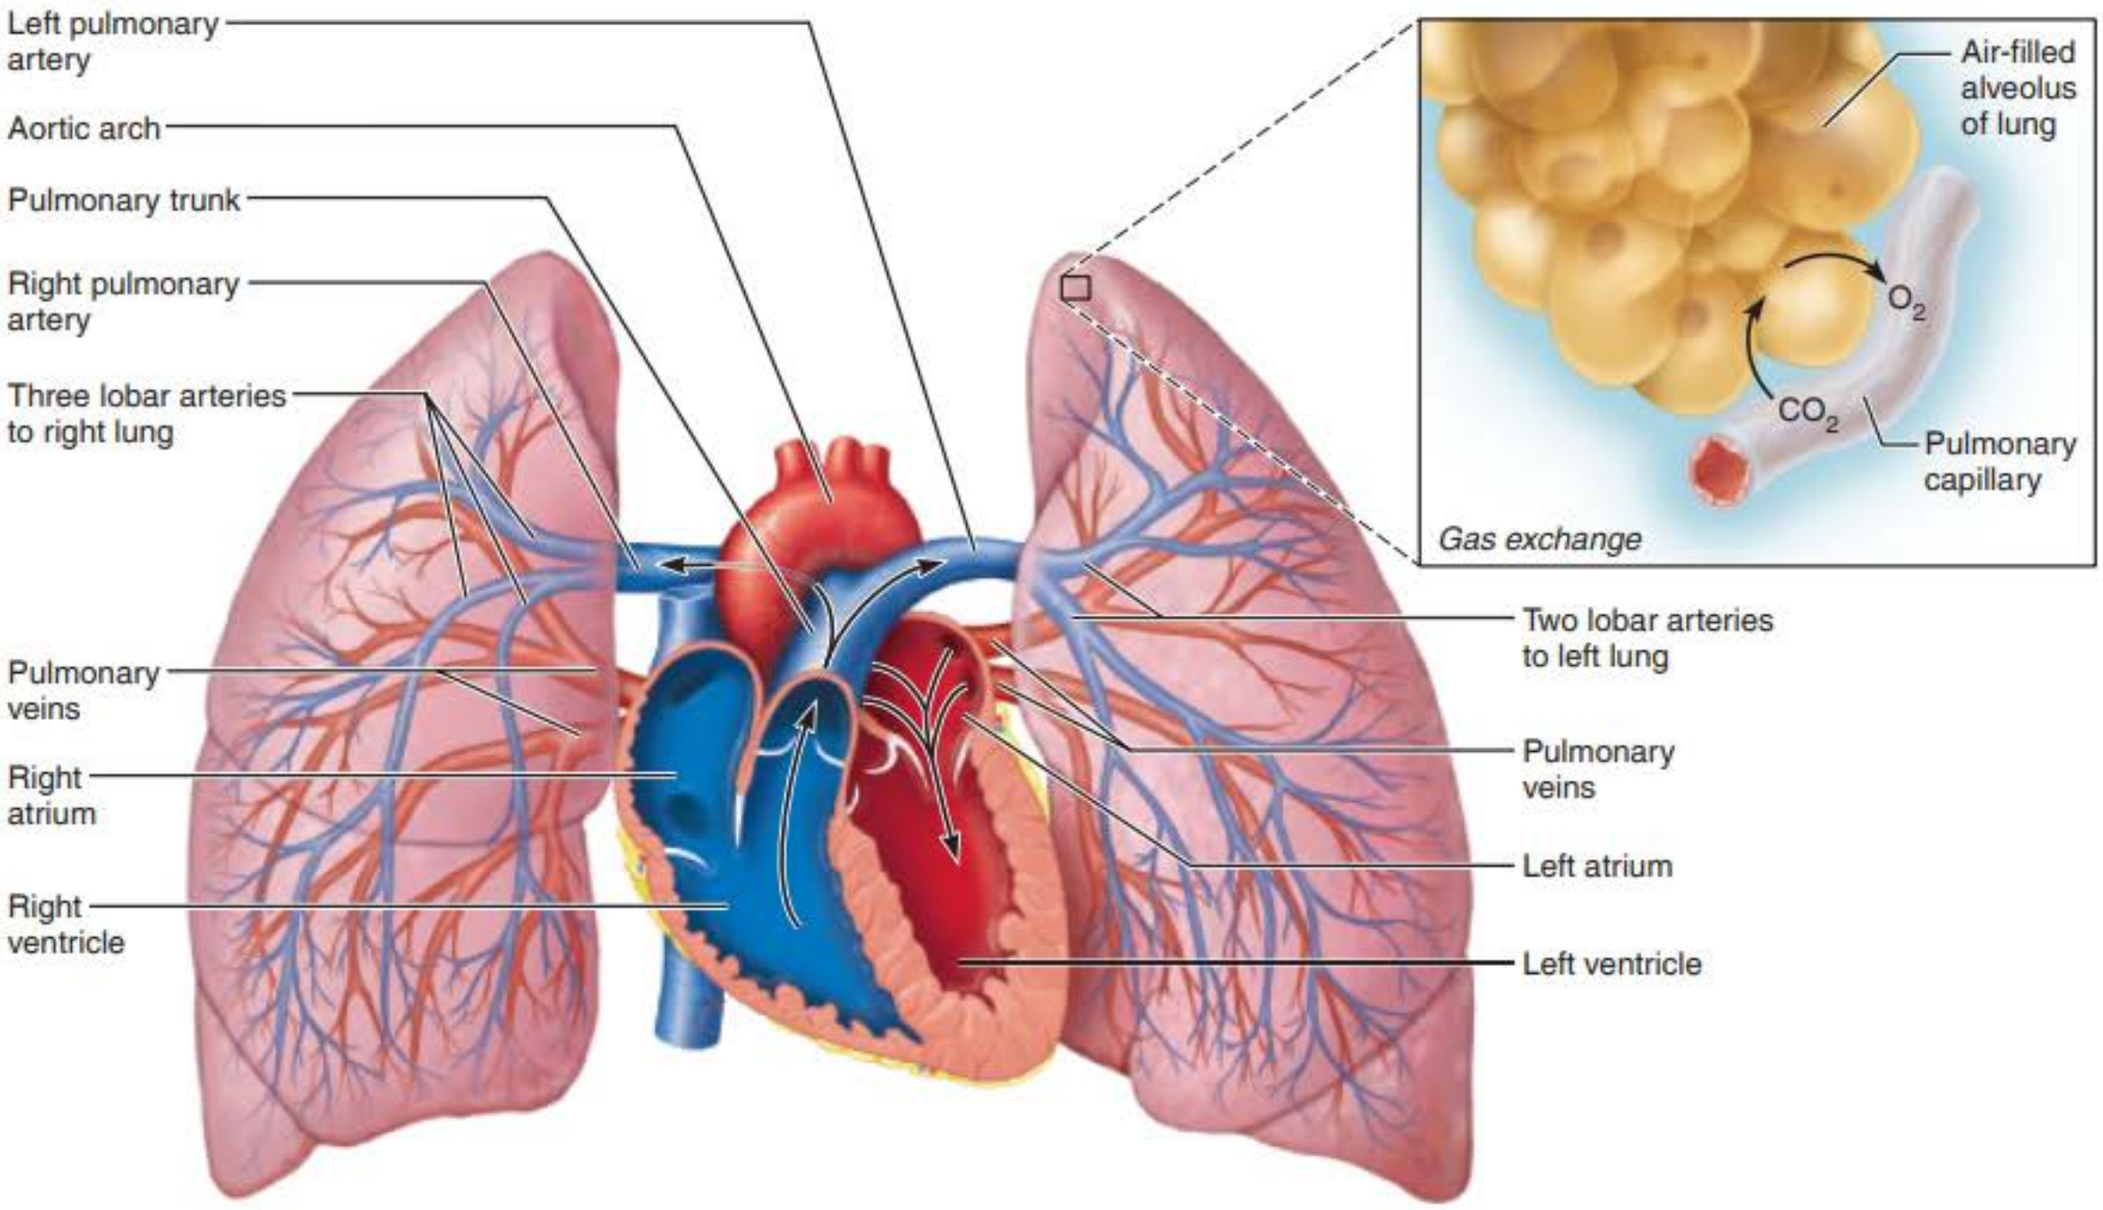
Pulmonary Circulation

The pulmonary circulation (**Figure 19.21a**) functions only to bring blood into close contact with the alveoli (air sacs) of the lungs so that gases can be exchanged. It does not directly serve the metabolic needs of body tissues.

Oxygen-poor, dark red blood enters the pulmonary circulation as it is pumped from the right ventricle into the large **pulmonary trunk** (Figure 19.21b), which runs diagonally upward for about 8 cm and then divides abruptly to form the **right** and **left pulmonary arteries**. In the lungs, the pulmonary arteries subdivide into the **lobar arteries** (lo′bar) (three in the right lung and two in the left lung), each of which serves one lung lobe. The lobar arteries accompany the main bronchi into the lungs and then branch profusely, forming first arterioles and then the dense networks of **pulmonary capillaries** that surround and cling to the delicate air sacs. It is here that oxygen moves from the alveolar air to the blood and carbon dioxide moves from the blood to the alveolar air. As gases are exchanged and the oxygen content of the blood rises, the blood becomes bright red. The pulmonary capillary beds drain into venules, which join to form the two **pulmonary veins** exiting from each lung. The four pulmonary veins complete the circuit by unloading their precious cargo into the left atrium of the heart.



(a) Schematic flowchart.



(b) Illustration. The pulmonary arterial system is shown in blue to indicate that the blood it carries is oxygen-poor. The pulmonary venous drainage is shown in red to indicate that the blood it transports is oxygen-rich.

Figure 19.21 Pulmonary circulation. (RA = right atrium, RV = right ventricle, LA = left atrium, LV = left ventricle)

Table 19.3 *(continued)*

Note that any vessel with the term *pulmonary* or *lobar* in its name is part of the pulmonary circulation. All others are part of the systemic circulation.

Pulmonary arteries carry oxygen-poor, carbon dioxide–rich blood, and pulmonary veins carry oxygen-rich blood.* This is opposite to the systemic circulation, where arteries carry oxygen-rich blood and veins carry carbon dioxide–rich, relatively oxygen-poor blood.

Systemic Circulation

The systemic circulation provides the *functional blood supply* to all body tissues; that is, it delivers oxygen, nutrients, and other needed substances while carrying away carbon dioxide and other metabolic wastes. Freshly oxygenated blood* returning from the pulmonary circuit is pumped out of the left ventricle into the aorta (**Figure 19.22**).

From the aorta, blood can take various routes, because essentially all systemic arteries branch from this single great vessel. The aorta arches upward from the heart and then curves and runs downward along the body midline to its terminus in the pelvis, where it splits to form the two large arteries serving the lower extremities. The branches of the aorta continue to subdivide to produce the arterioles and, finally, the capillaries that spread throughout the organs. Venous blood draining from organs inferior to the diaphragm ultimately enters the inferior vena cava.† Except for some coronary and thoracic venous drainage (which enters the azygos system of veins), the superior vena cava drains body regions above the diaphragm. The venae cavae empty the carbon dioxide–laden blood into the right atrium of the heart.

Two important points concerning the two major circulations:

- Blood passes from systemic veins to systemic arteries only after first moving through the pulmonary circuit (Figure 19.21a).
- Although the entire cardiac output of the right ventricle passes through the pulmonary circulation, only a small fraction of the output of the left ventricle flows through any single organ (Figure 19.22).

The systemic circulation can be viewed as multiple circulatory channels functioning in parallel to distribute blood to all body organs.

*By convention, oxygen-rich blood is shown red and oxygen-poor blood is shown blue.

†Venous blood from the digestive viscera passes through the hepatic portal circulation (liver and associated veins) before entering the inferior vena cava.

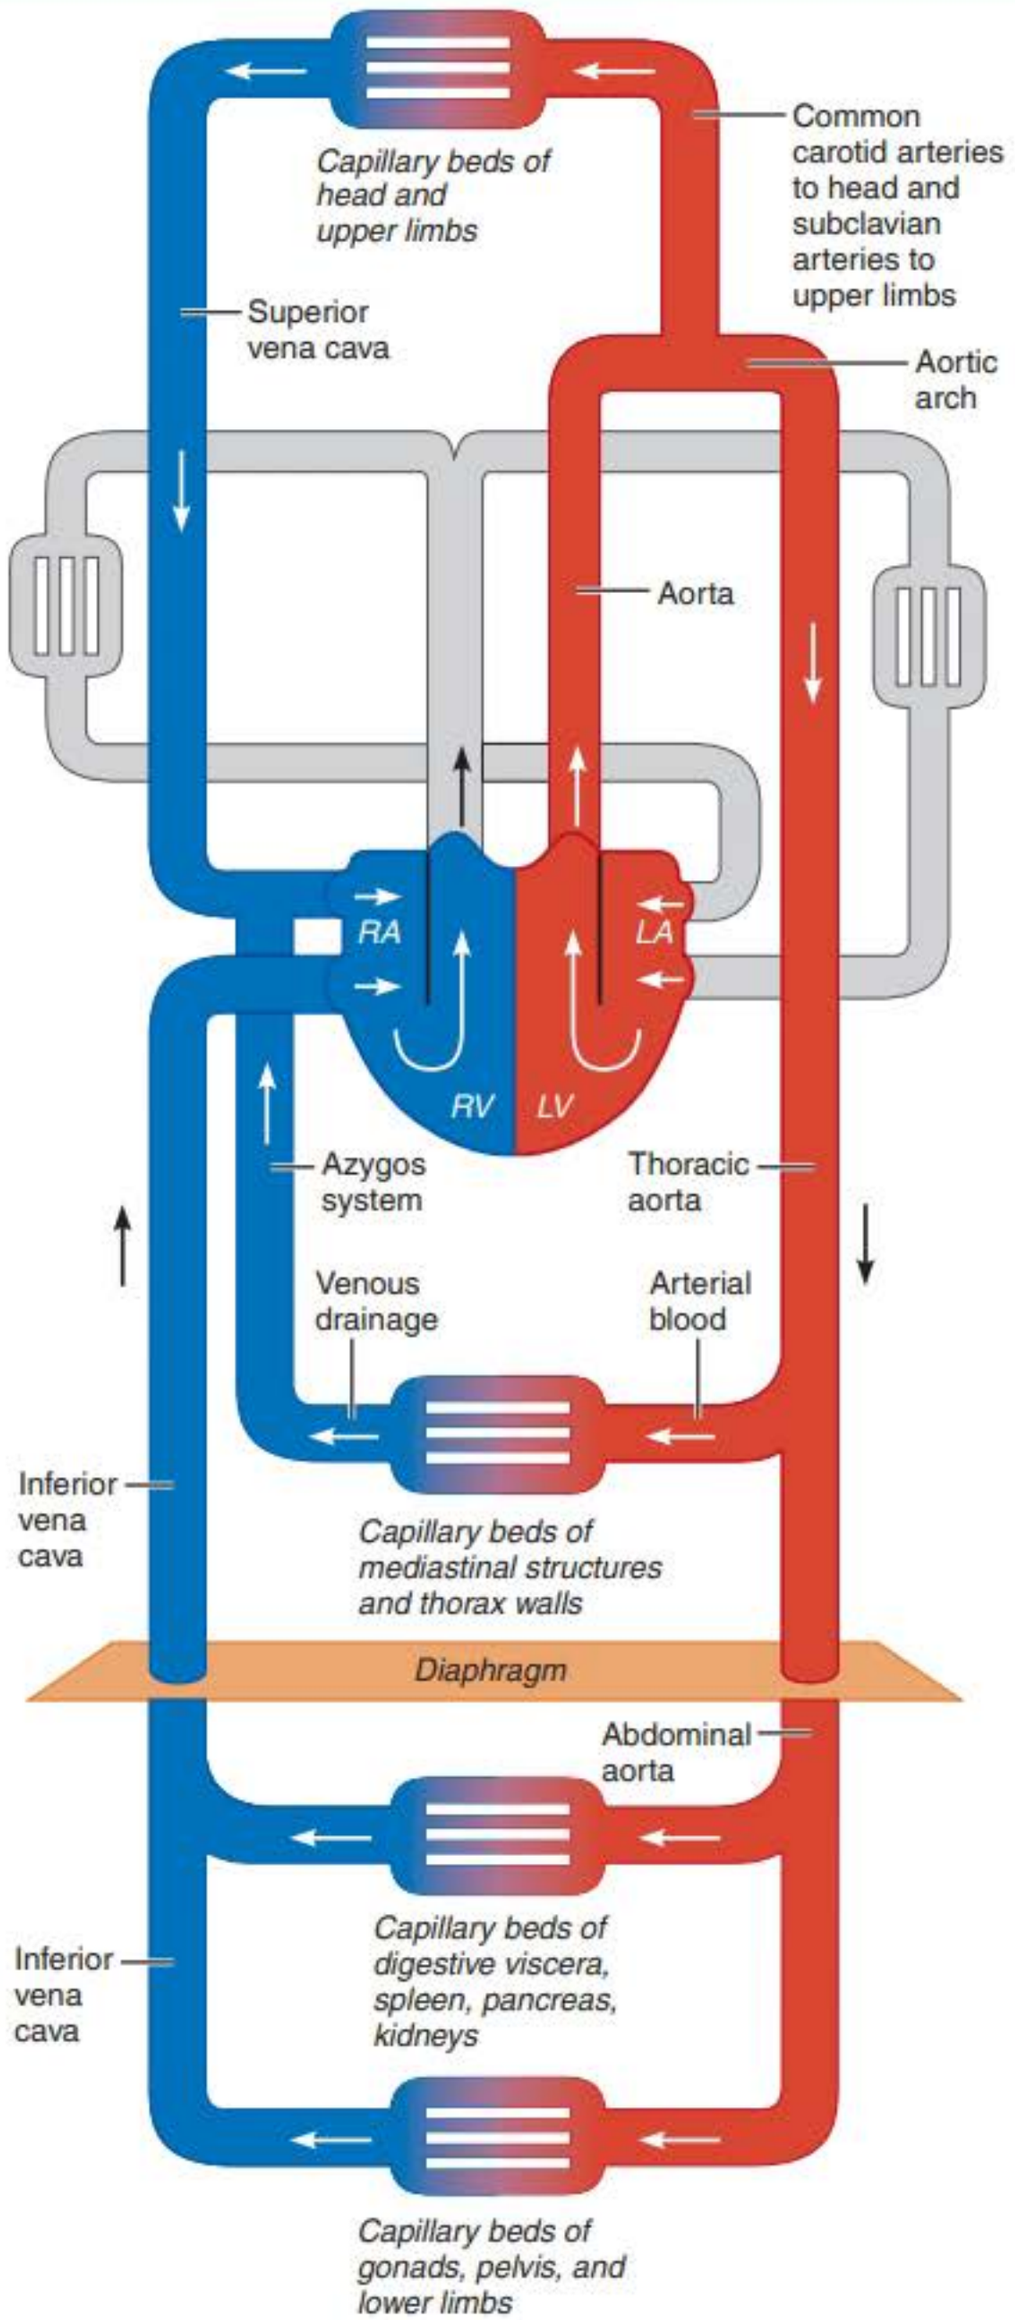


Figure 19.22 Schematic flowchart showing an overview of the systemic circulation. The pulmonary circulation is shown in gray for comparison. (RA = right atrium, RV = right ventricle, LA = left atrium, LV = left ventricle)

Table 19.4 The Aorta and Major Arteries of the Systemic Circulation

Figure 19.23a diagrams the distribution of the aorta and major arteries of the systemic circulation in flowchart form, and Figure 19.23b illustrates them. See Tables 19.5 through 19.8 for fine points about the vessels arising from the aorta.

The **aorta** (a-or′tah) is the largest artery in the body. In adults, the aorta is approximately the size of a garden hose where it issues from the left ventricle of the heart. Its internal diameter is 2.5 cm, and its wall is about 2 mm thick. It decreases in size slightly as it runs to its terminus. The aortic valve guards the base of the aorta and prevents backflow of blood during diastole. Opposite each aortic valve cusp is an *aortic sinus*, which contains baroreceptors important in reflex regulation of blood pressure.

Different portions of the aorta are named according to shape or location. The first portion, the **ascending aorta**, runs posteriorly and to the right of the pulmonary trunk. It persists for only about 5 cm before curving to the left as the aortic arch. The only branches of the ascending aorta are the **right** and **left coronary arteries**, which supply the myocardium. The **aortic arch**, deep to the sternum, begins and ends at the sternal angle (T_4 level). Its three major branches (R to L) are: (1) the **brachiocephalic trunk** (bra′ke-o-sĕ-fal″ik; "armhead"), which passes superiorly under the right sternoclavicular joint and branches into the **right common carotid artery** (kah-rot′id) and the **right subclavian artery**, (2) the **left common carotid artery**, and (3) the **left subclavian artery**. These three vessels provide the arterial supply of the head, neck, upper limbs, and part of the thorax wall.

The **descending aorta** runs along the anterior spine. Called the **thoracic aorta** from T_5 to T_{12}, it sends off numerous small arteries to the thorax wall and viscera before piercing the diaphragm. As it enters the abdominal cavity, it becomes the **abdominal aorta**. This portion supplies the abdominal walls and viscera and ends at the L_4 level, where it splits into the **right** and **left common iliac arteries**, which supply the pelvis and lower limbs.

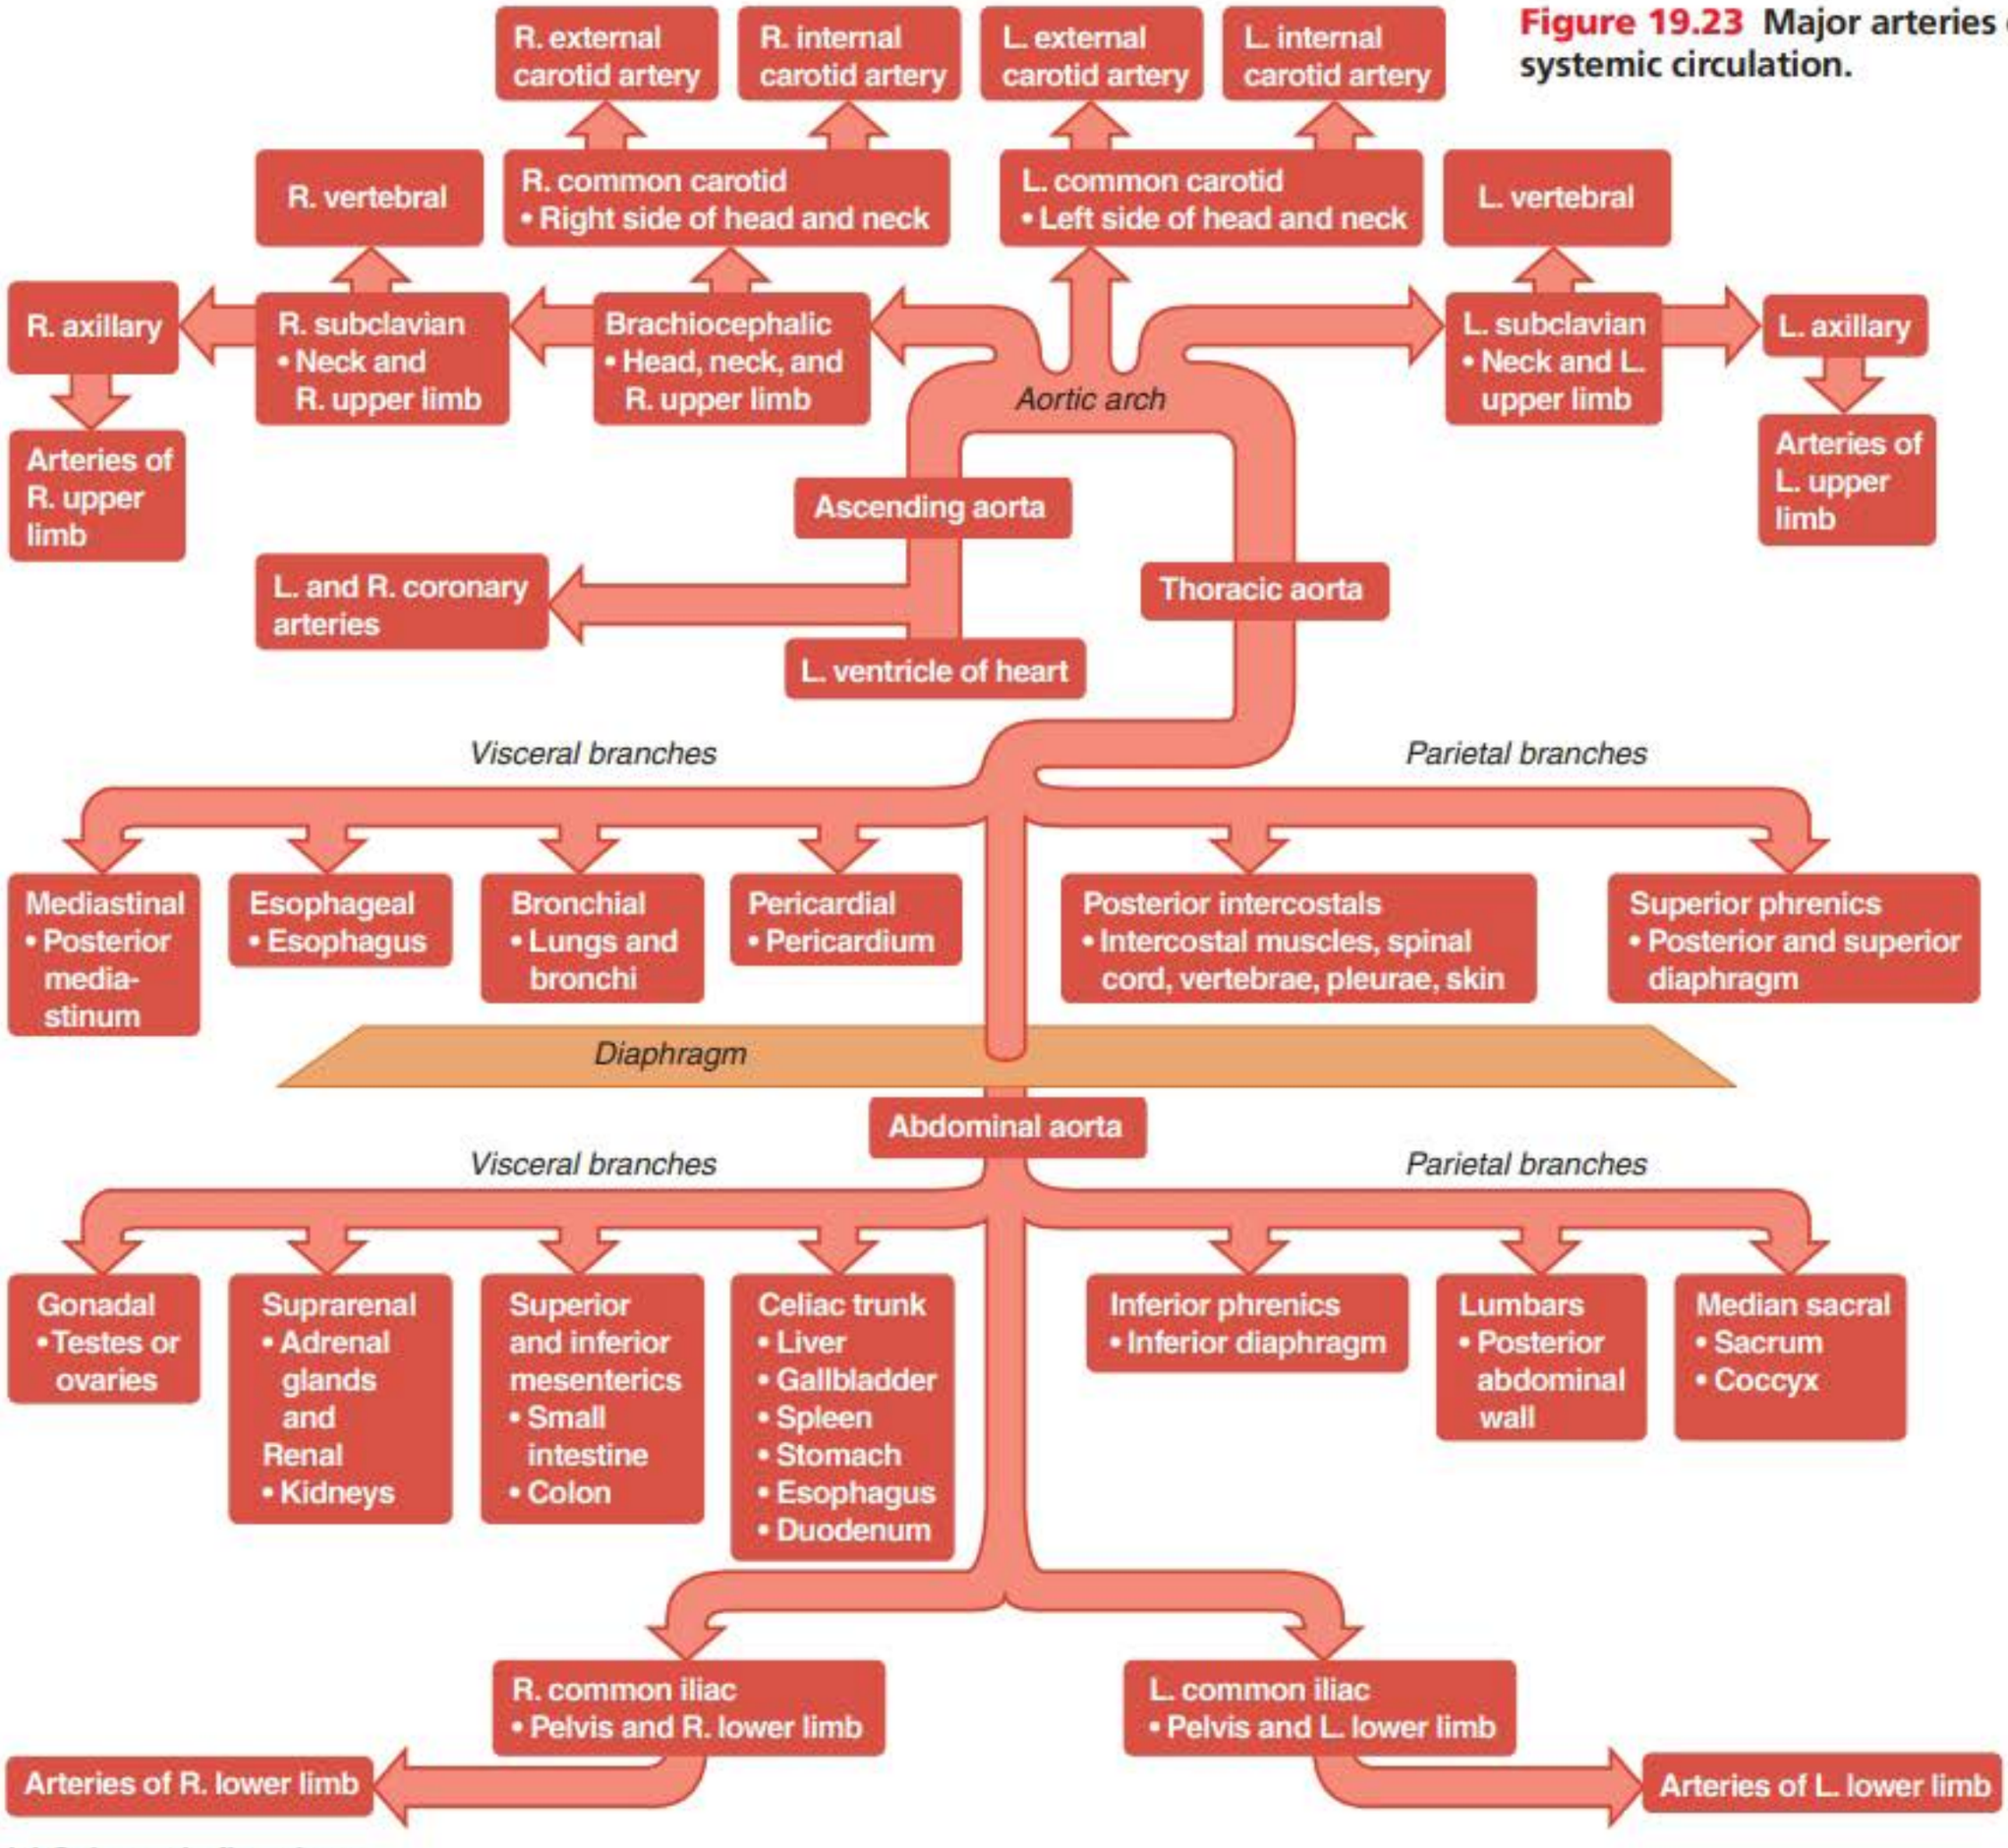

Figure 19.23 Major arteries of the systemic circulation.

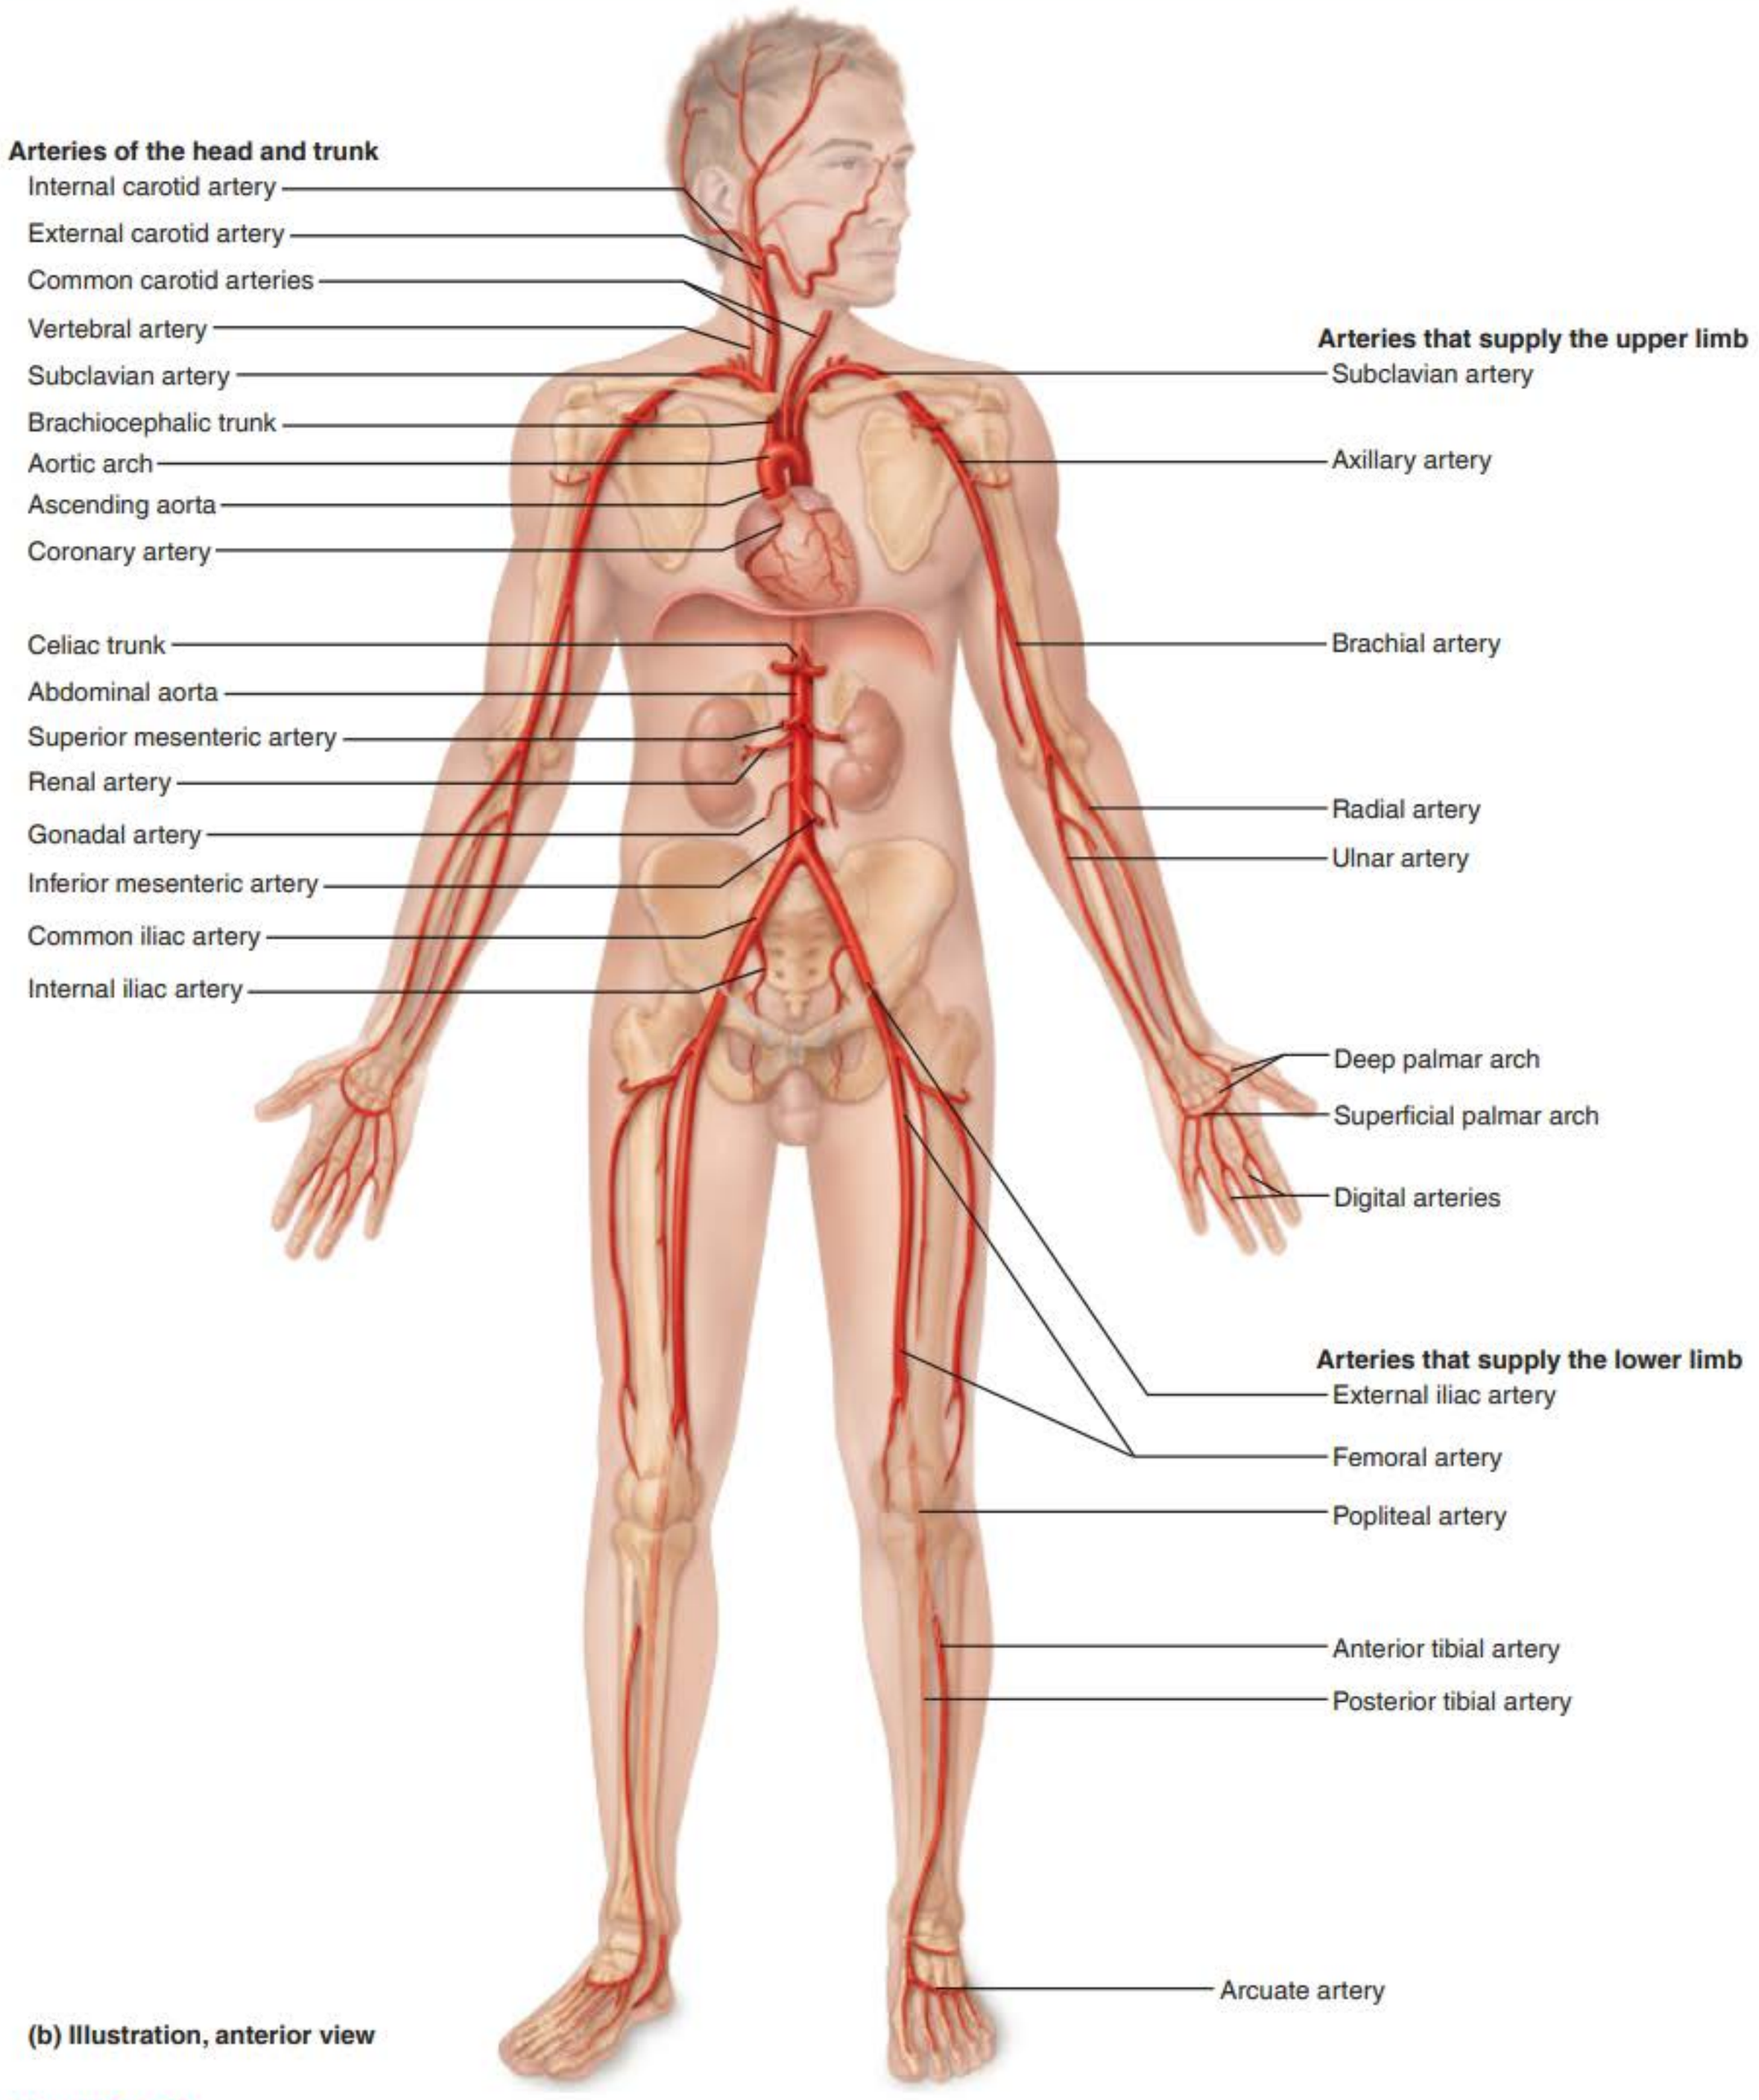
(a) Schematic flowchart

Table 19.4 *(continued)*

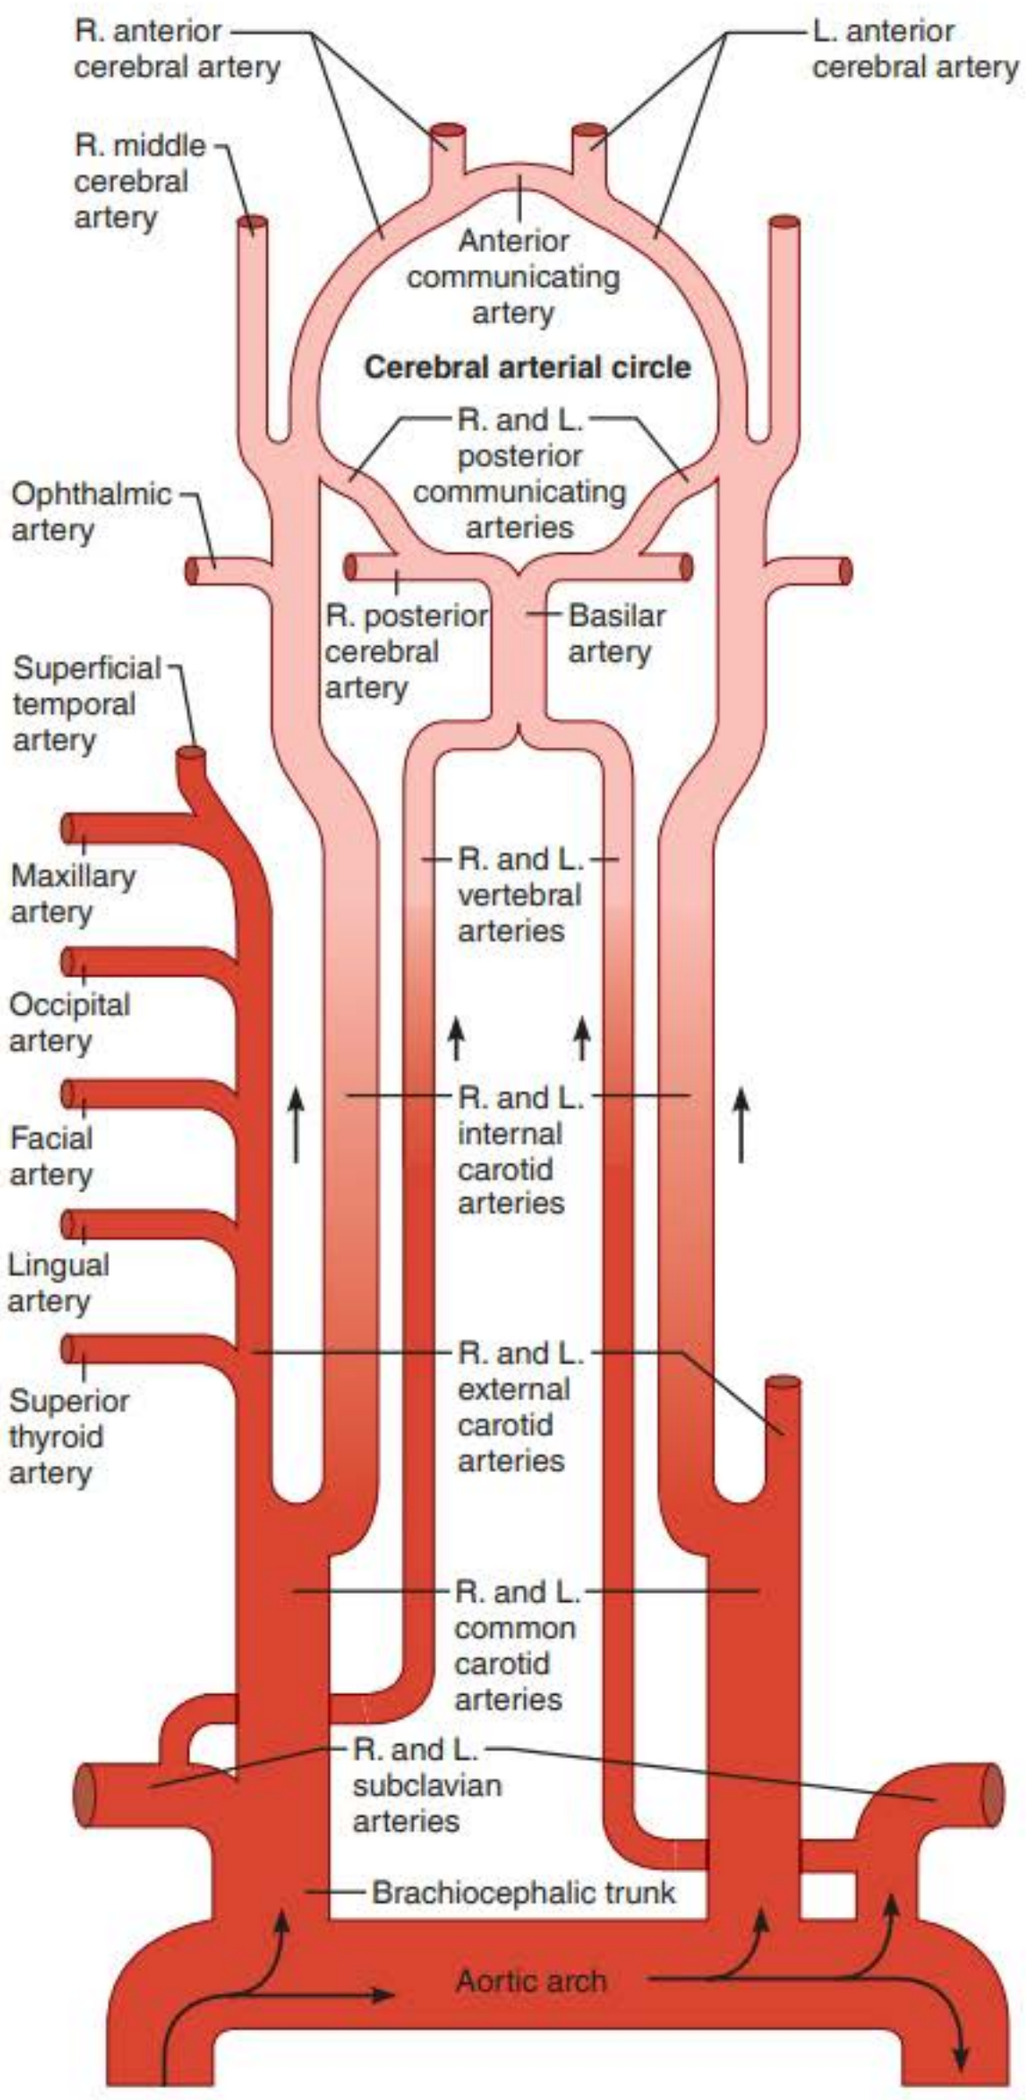


(b) Illustration, anterior view

Figure 19.23 *(continued)*

Table 19.5 Arteries of the Head and Neck

Four paired arteries supply the head and neck. These are the common carotid arteries, plus three branches from each subclavian artery: the vertebral arteries, the thyrocervical trunks, and the costocervical trunks (**Figure 19.24b**). Of these, the common carotid arteries have the broadest distribution (Figure 19.24a).



(a) Schematic flowchart

Figure 19.24 Arteries of the head, neck, and brain.

Each common carotid divides into two major branches (the internal and external carotid arteries). At the division point, each internal carotid artery has a slight dilation, the **carotid sinus**, that contains baroreceptors that assist in reflex blood pressure control. The **carotid bodies**, chemoreceptors involved in controlling respiratory rate, are located close by. Pressing on the neck in the area of the carotid sinuses can cause unconsciousness (*carot* = stupor) because the pressure created mimics high blood pressure, eliciting vasodilation, which interferes with blood delivery to the brain.

Description and Distribution

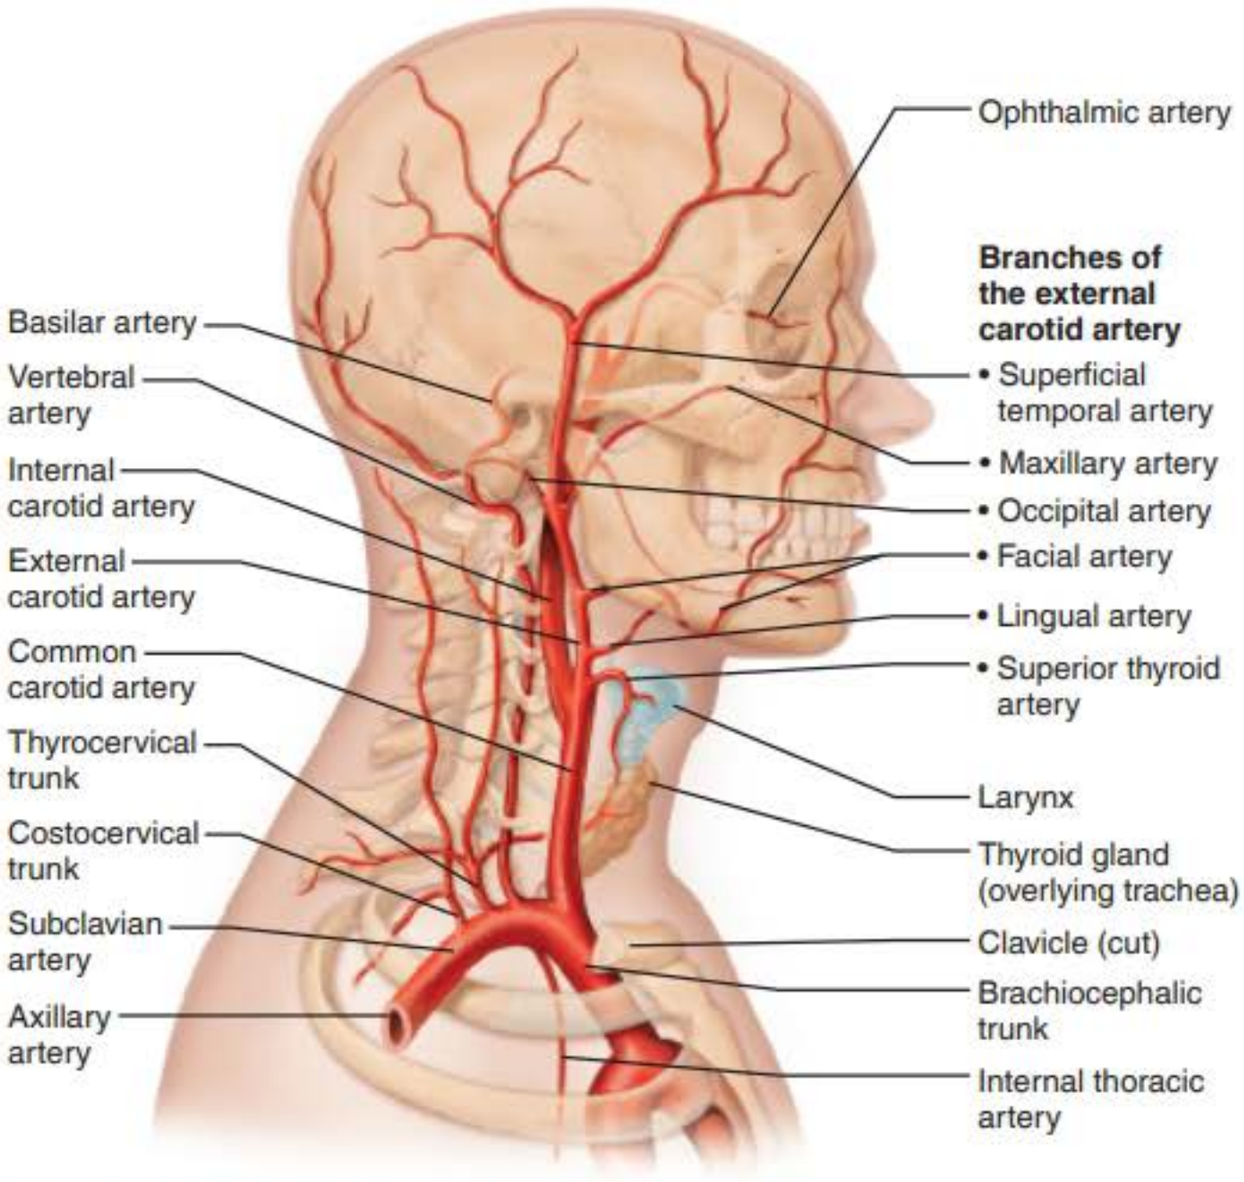
Common carotid arteries. The origins of these two arteries differ: The right common carotid artery arises from the brachiocephalic trunk; the left is the second branch of the aortic arch. The common carotid arteries ascend through the lateral neck, and at the superior border of the larynx (the level of the "Adam's apple"), each divides into its two major branches, the *external* and *internal carotid arteries*.

The **external carotid arteries** supply most tissues of the head except for the brain and orbit. As each artery runs superiorly, it sends branches to the thyroid gland and larynx (**superior thyroid artery**), the tongue (**lingual artery**), the skin and muscles of the anterior face (**facial artery**), and the posterior scalp (**occipital artery**). Each external carotid artery terminates by splitting into a **superficial temporal artery**, which supplies the parotid salivary gland and most of the scalp, and a **maxillary artery**, which supplies the upper and lower jaws and chewing muscles, the teeth, and the nasal cavity. A clinically important branch of the maxillary artery is the *middle meningeal artery* (not illustrated). It enters the skull through the foramen spinosum and supplies the inner surface of the parietal bone, squamous part of the temporal bone, and the underlying dura mater.

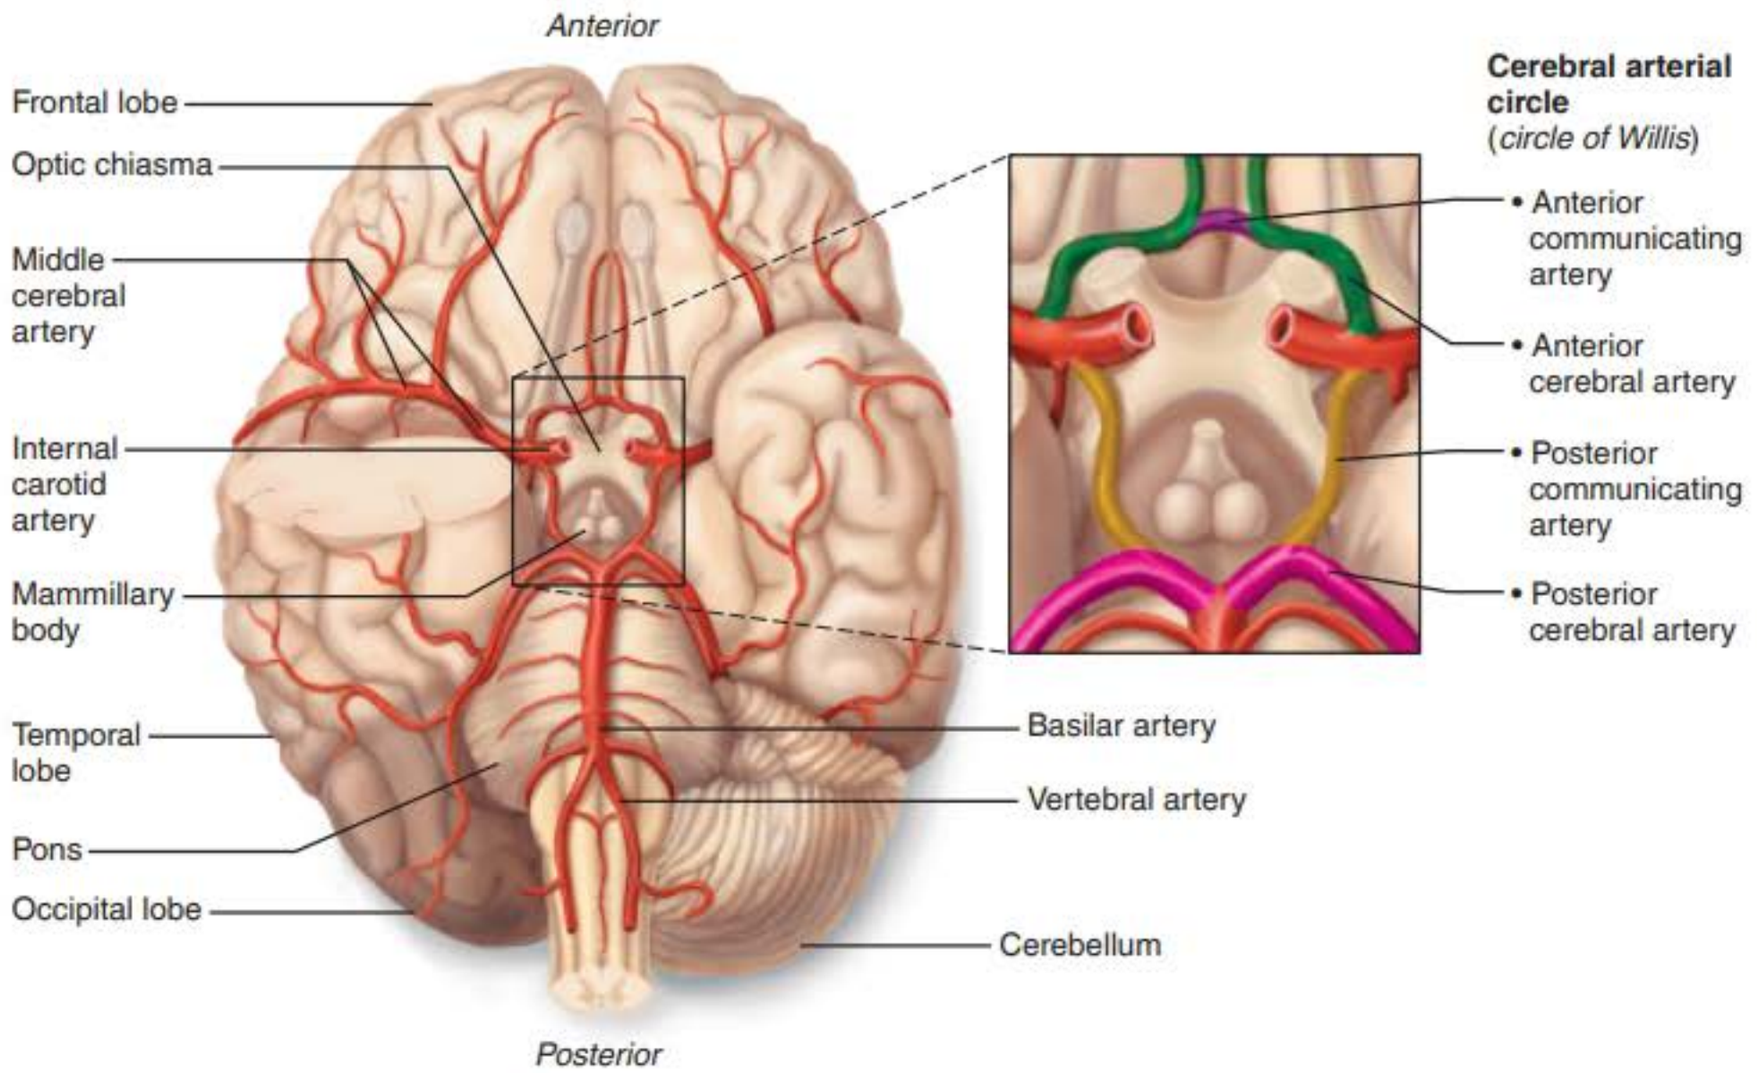
The larger **internal carotid arteries** supply the orbits and more than 80% of the cerebrum. They assume a deep course and enter the skull through the carotid canals of the temporal bones (Figure 7.6a and b, ◀ p. 206). Once inside the cranium, each artery gives off one main branch, the ophthalmic artery, and then divides into the anterior and middle cerebral arteries. The **ophthalmic arteries** (of-thal′mik) supply the eyes, orbits, forehead, and nose. Each **anterior cerebral artery** supplies the medial surface of the frontal and parietal lobes of the cerebral hemisphere on its side and also anastomoses with its partner on the opposite side via a short arterial shunt called the **anterior communicating artery** (Figure 19.24c). The **middle cerebral arteries** run in the lateral sulci of their respective cerebral hemispheres and supply the lateral parts of the temporal, parietal, and frontal lobes.

Vertebral arteries. The vertebral arteries spring from the subclavian arteries at the root of the neck and ascend through foramina in the transverse processes of the cervical vertebrae to enter the skull through the foramen magnum. En route, they

Table 19.5 *(continued)*



(b) Arteries of the head and neck, right aspect



(c) Major arteries serving the brain (inferior view, right side of cerebellum and part of right temporal lobe removed)

Figure 19.24 *(continued)*

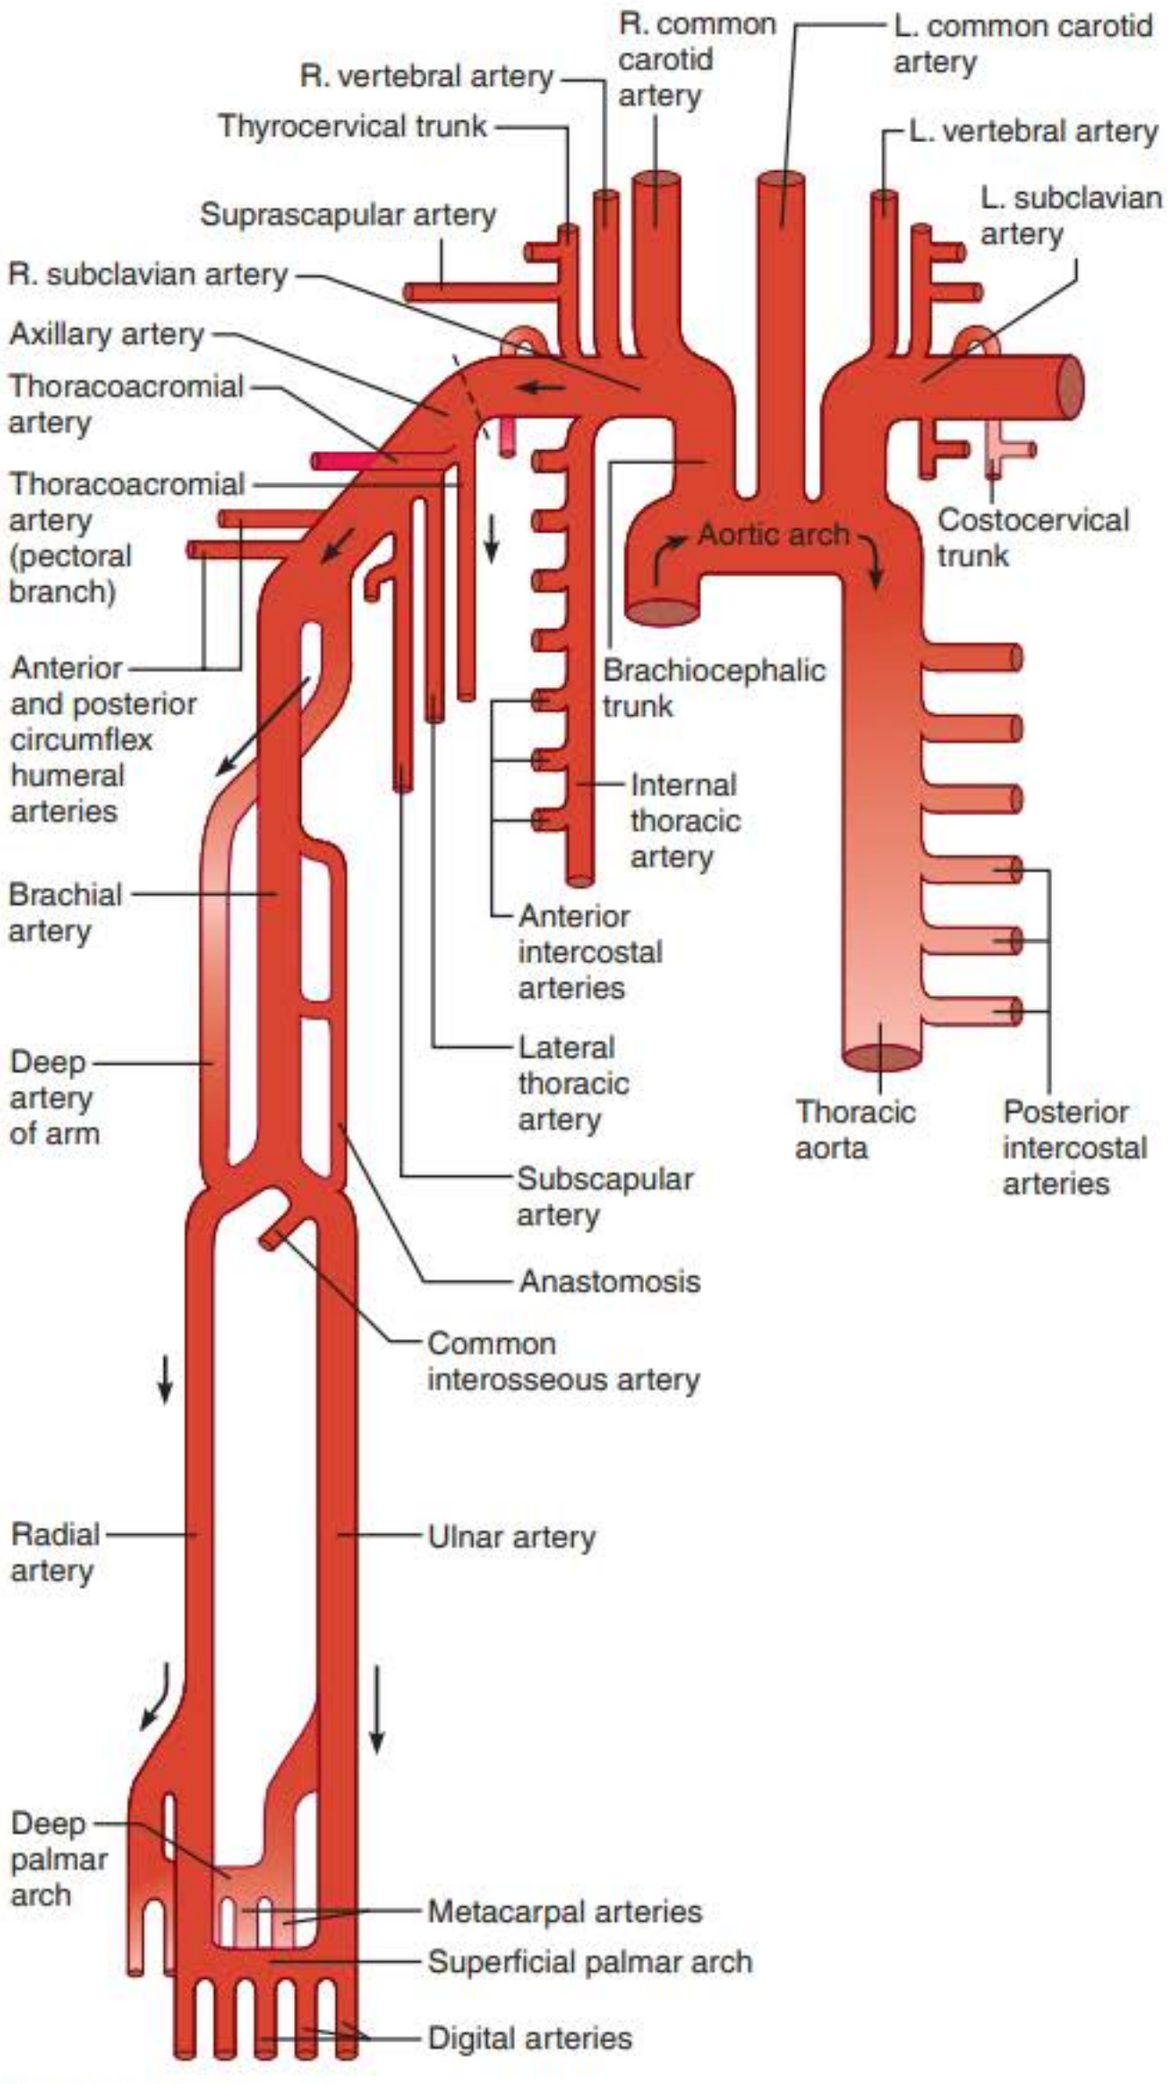
send branches to the vertebrae and cervical spinal cord and to some deep structures of the neck. Within the cranium, the right and left vertebral arteries join to form the **basilar artery** (bas′ĭ-lar), which ascends along the anterior aspect of the brain stem, giving off branches to the cerebellum, pons, and inner ear (Figure 19.24b and c). At the pons-midbrain border, the basilar artery divides into a pair of **posterior cerebral arteries**, which supply the occipital lobes and the inferior parts of the temporal lobes.

Arterial shunts called **posterior communicating arteries** connect the posterior cerebral arteries to the middle cerebral arteries anteriorly. The two posterior arteries and a single **anterior communicating artery** complete the formation of an arterial anastomosis called the **cerebral arterial circle** (*circle of Willis*). This structure encircles the pituitary gland and optic chiasma and unites the brain's anterior and posterior blood supplies. It also equalizes blood pressure in the two brain areas and provides alternate routes for blood to reach the brain tissue if a carotid or vertebral artery becomes occluded.

Thyrocervical and costocervical trunks. These short vessels arise from the subclavian artery just lateral to the vertebral arteries on each side (Figure 19.24b and Figure 19.25). The thyrocervical trunk mainly supplies the thyroid gland, portions of the cervical vertebrae and spinal cord, and some scapular muscles. The costocervical trunk serves deep neck and superior intercostal muscles.

Table 19.6 Arteries of the Upper Limbs and Thorax

The upper limbs are supplied entirely by arteries arising from the **subclavian arteries** (Figure 19.25a). After giving off branches to the neck, each subclavian artery courses laterally between the clavicle and first rib to enter the axilla, where its name changes to axillary artery. The thorax wall is supplied by an array of vessels that arise either directly from the thoracic aorta or from branches of the subclavian arteries. Most visceral organs of the thorax receive their functional blood supply from small branches issuing from the thoracic aorta. Because these vessels are so small and tend to vary in number (except for the bronchial arteries), Figure 19.25a and b does not illustrate them, but several are listed at the end of this table.



(a) Schematic flowchart

Figure 19.25 Arteries of the right upper limb and thorax.

Description and Distribution

Arteries of the Upper Limb

Axillary artery. As it runs through the axilla accompanied by cords of the brachial plexus, each axillary artery gives off branches to the axilla, chest wall, and shoulder girdle. These branches include the **thoracoacromial artery** (tho″rah-ko-ah-kro′me-al), which supplies the deltoid muscle and pectoral region; the **lateral thoracic artery**, which serves the lateral chest wall and breast; the **subscapular artery** to the scapula, dorsal thorax wall, and part of the latissimus dorsi muscle; and the **anterior** and **posterior circumflex humeral arteries**, which wrap around the humeral neck and help supply the shoulder joint and the deltoid muscle. As the axillary artery emerges from the axilla, it becomes the brachial artery.

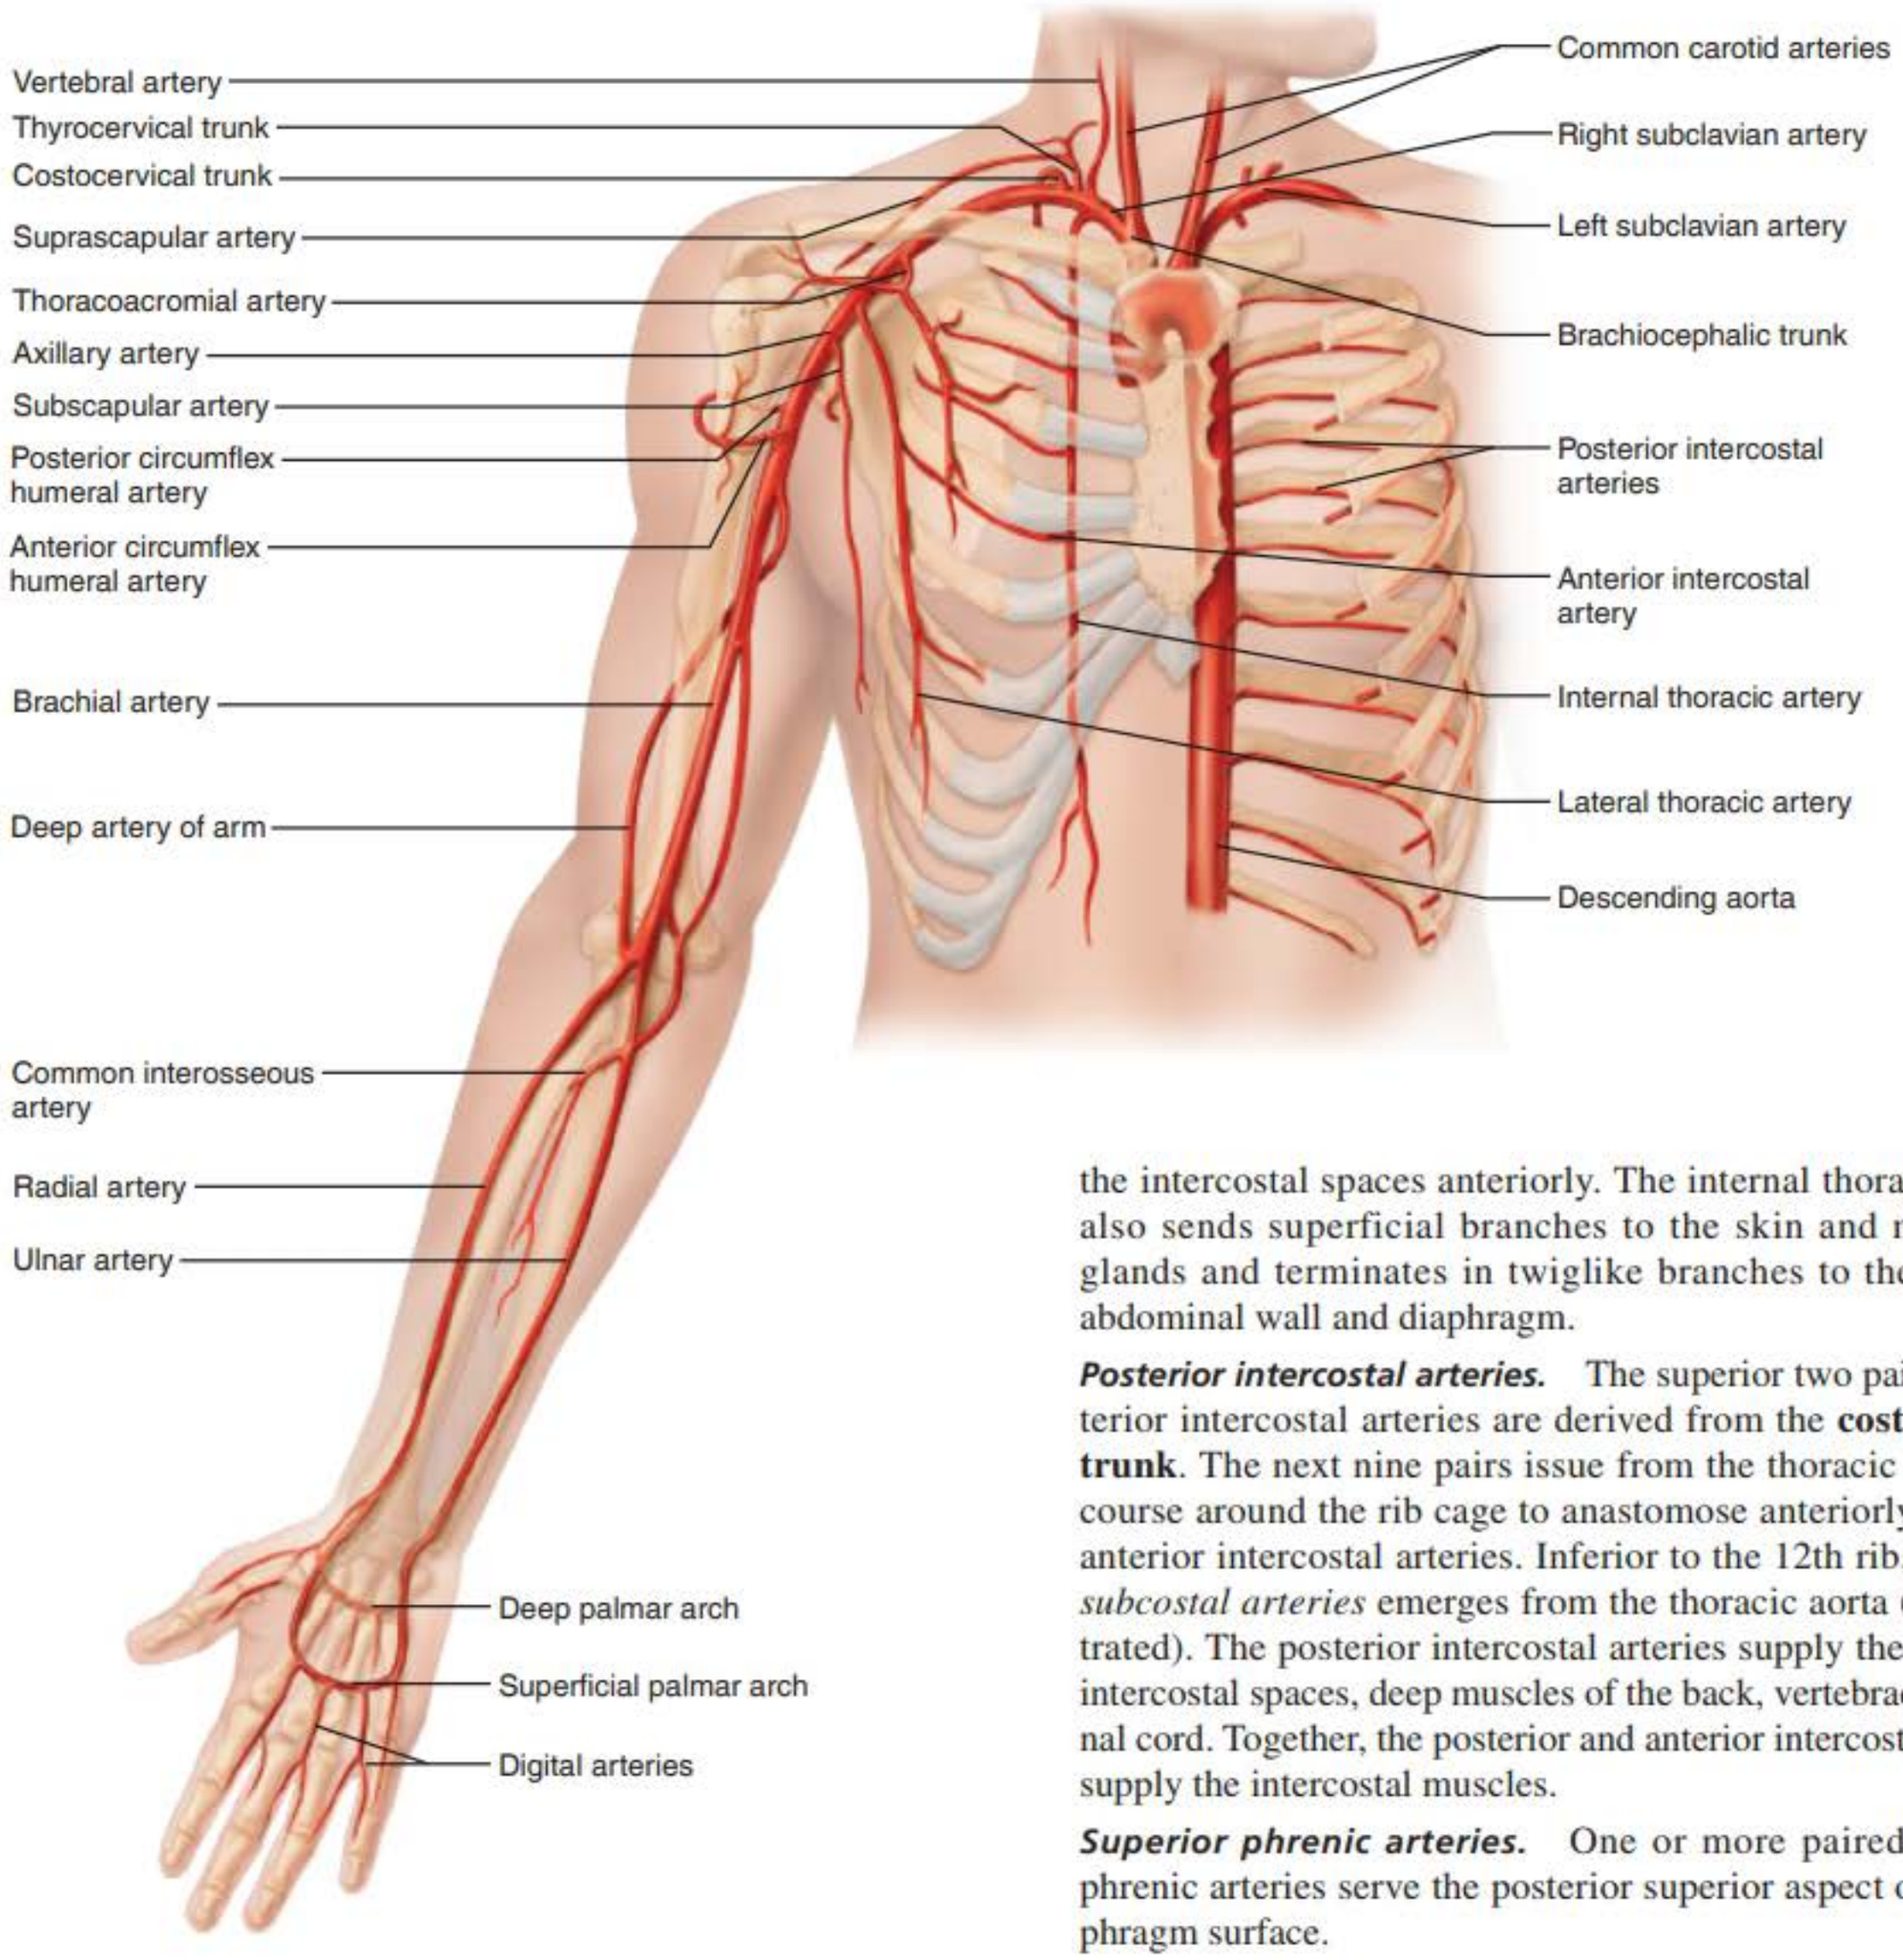
Brachial artery. The brachial artery runs down the medial aspect of the humerus and supplies the anterior flexor muscles of the arm. One major branch, the **deep artery of the arm**, serves the posterior triceps brachii muscle. As it nears the elbow, the brachial artery gives off several small branches that contribute to an anastomosis serving the elbow joint and that connect to the arteries of the forearm. As the brachial artery crosses the anterior midline aspect of the elbow, it provides an easily palpated pulse point (brachial pulse) (see Figure 19.8). Immediately beyond the elbow, the brachial artery splits to form the radial and ulnar arteries, which more or less follow the course of similarly named bones down the anterior forearm.

Radial artery. The radial artery runs from the median line of the cubital fossa to the styloid process of the radius. It supplies the lateral muscles of the forearm, the wrist, and the thumb and index finger. Proximal to the carpal bones, the radial artery provides a convenient site for taking the radial pulse.

Ulnar artery. The ulnar artery supplies the medial aspect of the forearm, fingers 3–5, and the medial aspect of the index finger. Proximally, the ulnar artery gives off a short branch, the **common interosseous artery** (in″ter-os′e-us), which runs between the radius and ulna to serve the deep flexors and extensors of the forearm.

Palmar arches. In the palm, branches of the radial and ulnar arteries anastomose to form the **superficial** and **deep palmar arches**. The **metacarpal arteries** and **digital arteries** that supply the fingers arise from these palmar arches.

Table 19.6 *(continued)*



(b) Illustration, anterior view

Figure 19.25 *(continued)*

Arteries of the Thorax Wall

Internal thoracic arteries. The internal thoracic arteries (formerly called the internal mammary arteries) arise from the subclavian arteries and supply blood to most of the anterior thorax wall. Each of these arteries descends lateral to the sternum and gives off **anterior intercostal arteries**, which supply the intercostal spaces anteriorly. The internal thoracic artery also sends superficial branches to the skin and mammary glands and terminates in twiglike branches to the anterior abdominal wall and diaphragm.

Posterior intercostal arteries. The superior two pairs of posterior intercostal arteries are derived from the **costocervical trunk**. The next nine pairs issue from the thoracic aorta and course around the rib cage to anastomose anteriorly with the anterior intercostal arteries. Inferior to the 12th rib, a pair of *subcostal arteries* emerges from the thoracic aorta (not illustrated). The posterior intercostal arteries supply the posterior intercostal spaces, deep muscles of the back, vertebrae, and spinal cord. Together, the posterior and anterior intercostal arteries supply the intercostal muscles.

Superior phrenic arteries. One or more paired superior phrenic arteries serve the posterior superior aspect of the diaphragm surface.

Arteries of the Thoracic Viscera

Pericardial arteries. Several tiny branches supply the posterior pericardium.

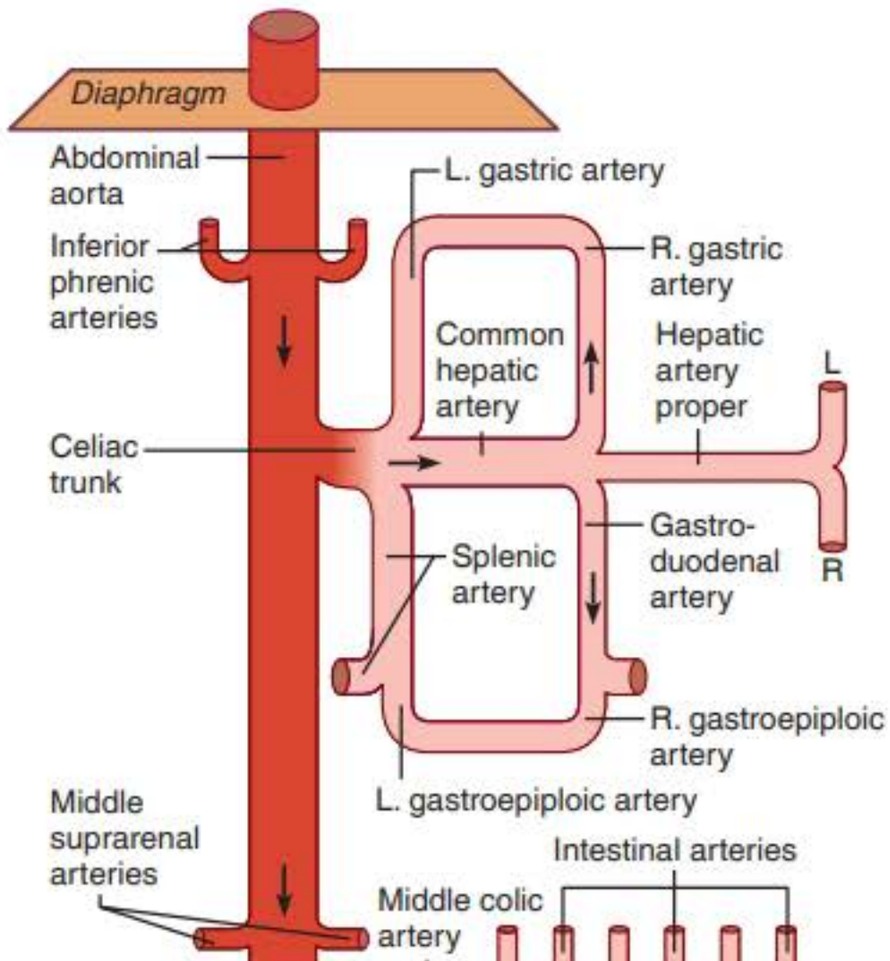
Bronchial arteries. Two left and one right bronchial arteries supply systemic (oxygen-rich) blood to the lungs, bronchi, and pleurae.

Esophageal arteries. Four to five esophageal arteries supply the esophagus.

Mediastinal arteries. Many small mediastinal arteries serve the posterior mediastinum.

Table 19.7 Arteries of the Abdomen

The arterial supply to the abdominal organs arises from the abdominal aorta (**Figure 19.26a**). Under resting conditions, about half of the entire arterial flow moves through these vessels. Except for the celiac trunk, the superior and inferior mesenteric arteries, and the median sacral artery, all are paired vessels. These arteries supply the abdominal wall, diaphragm, and visceral organs of the abdominopelvic cavity. We discuss the branches in the order of their issue.



(a) Schematic flowchart.

Figure 19.26 Arteries of the abdomen.

Table 19.7 *(continued)*

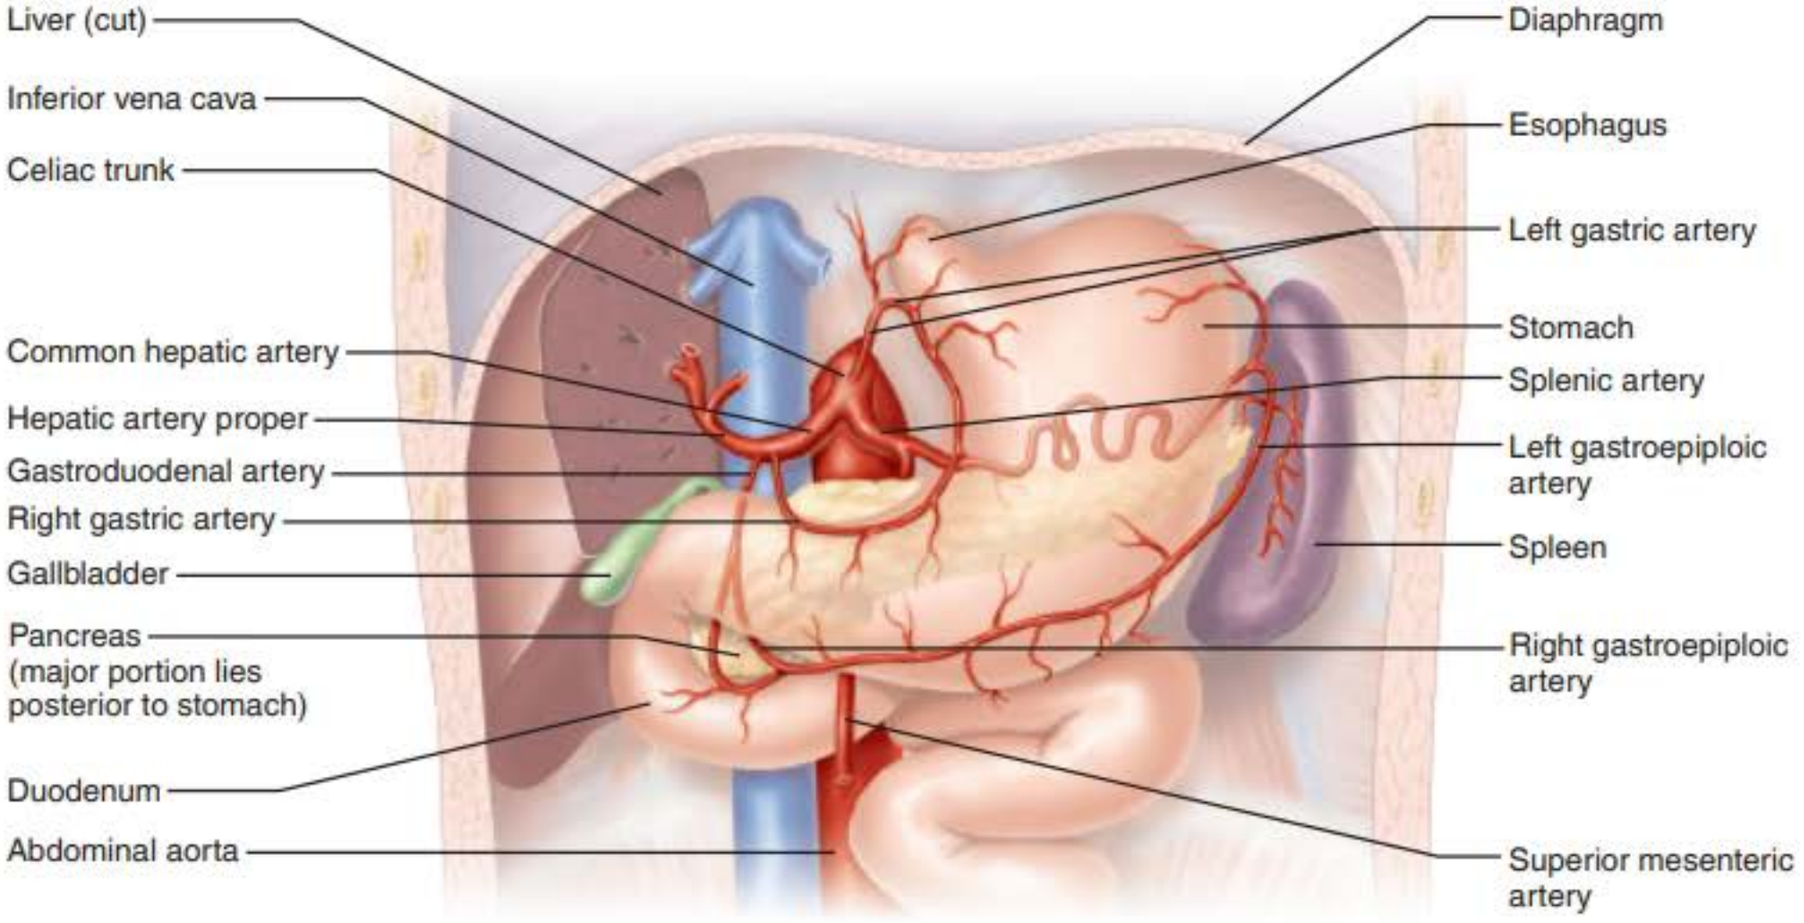
Description and Distribution

Inferior phrenic arteries. The inferior phrenics emerge from the aorta at T_{12}, just inferior to the diaphragm (Figure 19.26c). They serve the inferior diaphragm surface.

Celiac trunk. This very large unpaired branch of the abdominal aorta divides almost immediately into three branches (Figure 19.26b):

- **Common hepatic artery.** The **common hepatic artery** (hĕ-pat′ik) gives off branches to the stomach, duodenum, and pancreas. Where the **gastroduodenal artery** branches off, the common hepatic becomes the **hepatic artery proper**, which splits into right and left branches that serve the liver.
- **Splenic artery.** As the **splenic artery** (splen′ik) passes deep to the stomach, it sends branches to the pancreas and stomach and terminates in branches to the spleen.
- **Left gastric artery.** The **left gastric artery** (*gaster* = stomach) supplies part of the stomach and the inferior esophagus.

The **right** and **left gastroepiploic arteries** (gas″tro-ep″ĭ-plo′ik)—branches of the gastroduodenal and splenic arteries, respectively—serve the greater curvature of the stomach. A **right gastric artery**, which supplies the stomach's lesser curvature, may arise from the common hepatic artery or from the hepatic artery proper.



(b) The celiac trunk and its major branches. The left half of the liver has been removed.

Figure 19.26 *(continued)*

Table 19.7 Arteries of the Abdomen *(continued)*

Superior mesenteric artery (mes-en-ter′ik). This large, unpaired artery arises from the abdominal aorta at the L_1 level immediately below the celiac trunk (Figure 19.26d). It runs deep to the pancreas and then enters the mesentery (a drapelike membrane that supports the small intestine), where its numerous anastomosing branches serve virtually all of the small intestine via the **intestinal arteries**, most of the large intestine—the appendix, cecum, ascending colon (via the **ileocolic** and **right colic arteries**)— and part of the transverse colon (via the **middle colic artery**).

Suprarenal arteries (soo″prah-re′nal). The **middle suprarenal arteries** flank the origin of the superior mesenteric artery as they emerge from the abdominal aorta (Figure 19.26c). They supply blood to the adrenal (suprarenal) glands overlying the kidneys. The adrenal glands also receive two sets of branches not illustrated: *superior suprarenal* branches from the nearby inferior phrenic arteries, and *inferior suprarenal* branches from the nearby renal arteries.

Renal arteries. The short but wide renal arteries, right and left, issue from the lateral surfaces of the aorta slightly below the superior mesenteric artery (between L_1 and L_2). Each serves the kidney on its side.

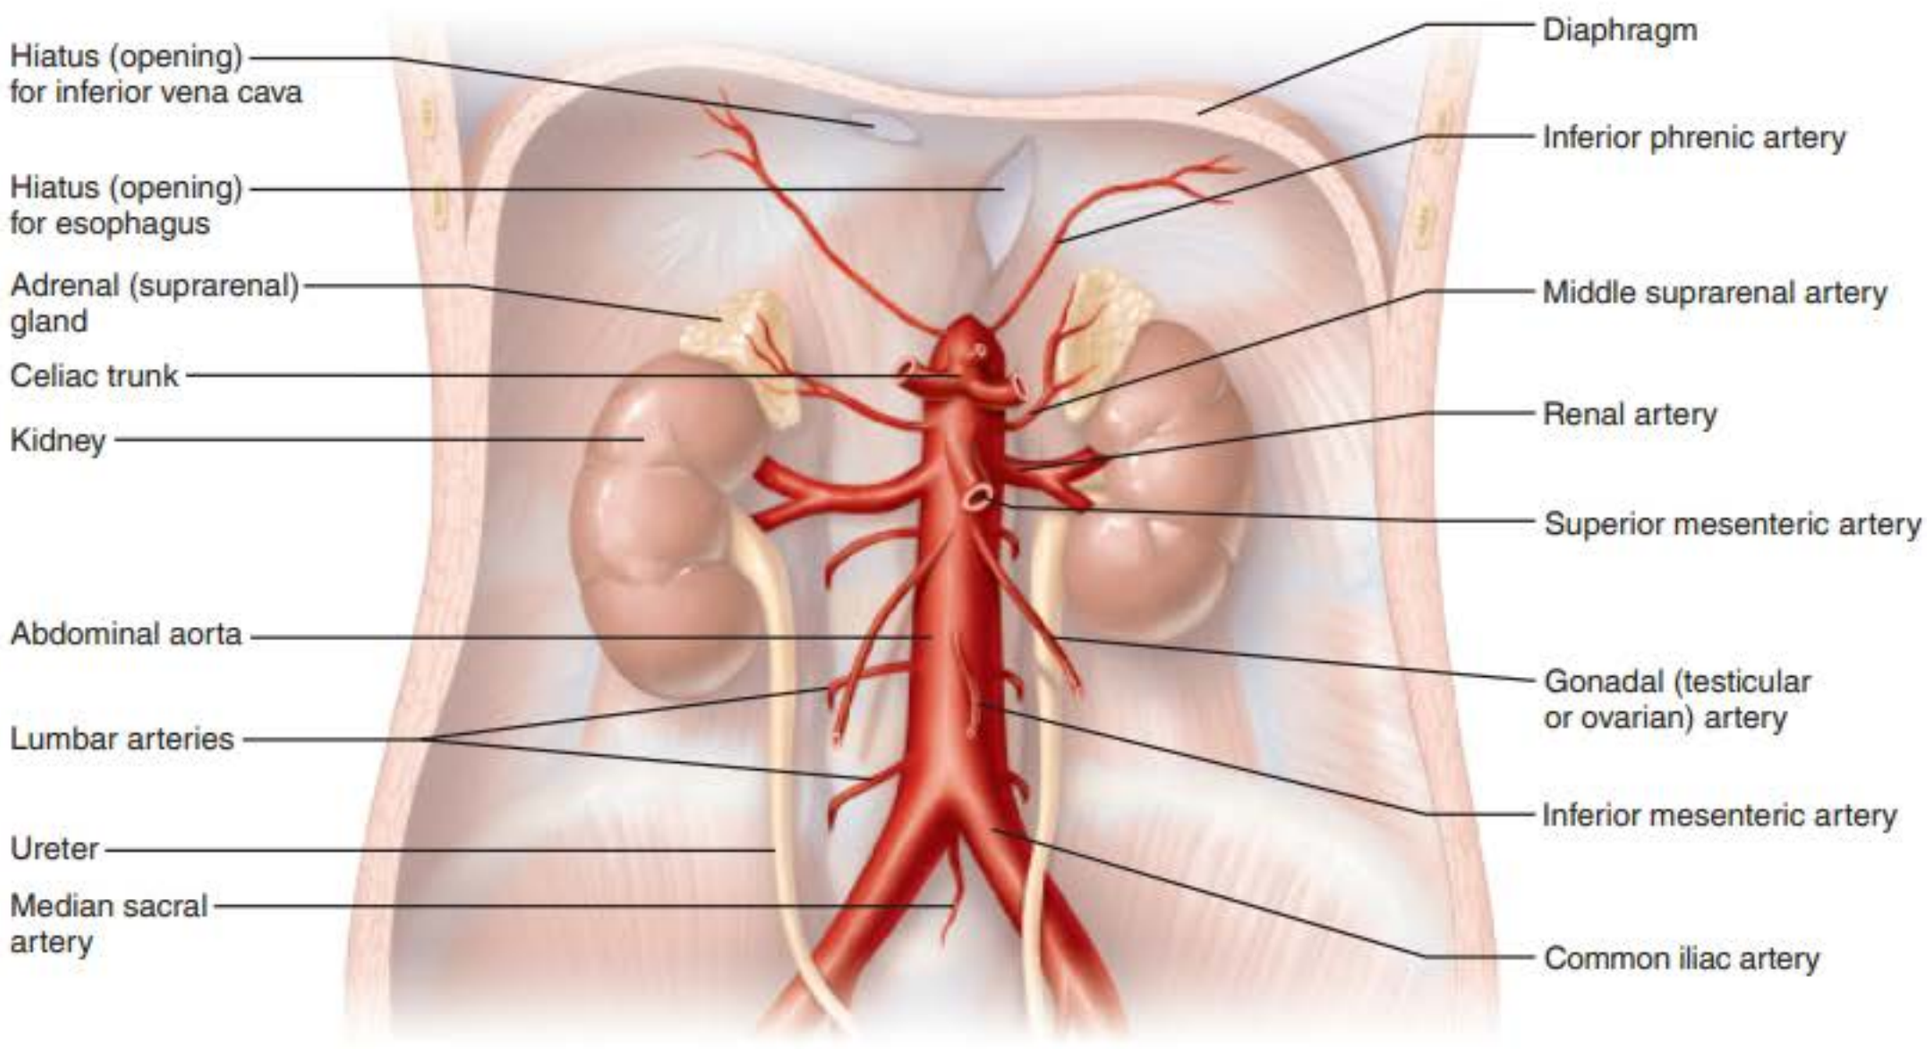
Gonadal arteries (go-nă′dul). The paired gonadal arteries are called **ovarian arteries** in females and **testicular arteries** in males. The ovarian arteries extend into the pelvis to serve the ovaries and part of the uterine tubes. The much longer testicular arteries descend through the pelvis and inguinal canals to enter the scrotum, where they serve the testes.

Inferior mesenteric artery. This final major branch of the abdominal aorta is unpaired and arises from the anterior aortic surface at the L_3 level. It serves the distal part of the large intestine—from the midpart of the transverse colon to the midrectum—via its **left colic**, **sigmoidal**, and **superior rectal branches** (Figure 19.26d). Looping anastomoses between the superior and inferior mesenteric arteries help ensure that blood will continue to reach the digestive viscera in cases of trauma to one of these abdominal arteries.

Lumbar arteries. Four pairs of lumbar arteries arise from the posterolateral surface of the aorta in the lumbar region (Figure 19.26c). These segmental arteries supply the posterior abdominal wall.

Median sacral artery. The unpaired median sacral artery issues from the posterior surface of the abdominal aorta at its terminus. This tiny artery supplies the sacrum and coccyx.

Common iliac arteries. At the L_4 level, the aorta splits into the right and left common iliac arteries, which supply blood to the lower abdominal wall, pelvic organs, and lower limbs.



(c) Major branches of the abdominal aorta.

Figure 19.26 *(continued)* **Arteries of the abdomen.**

22. Which paired artery supplies most of the tissues of the head except for the brain and orbits?

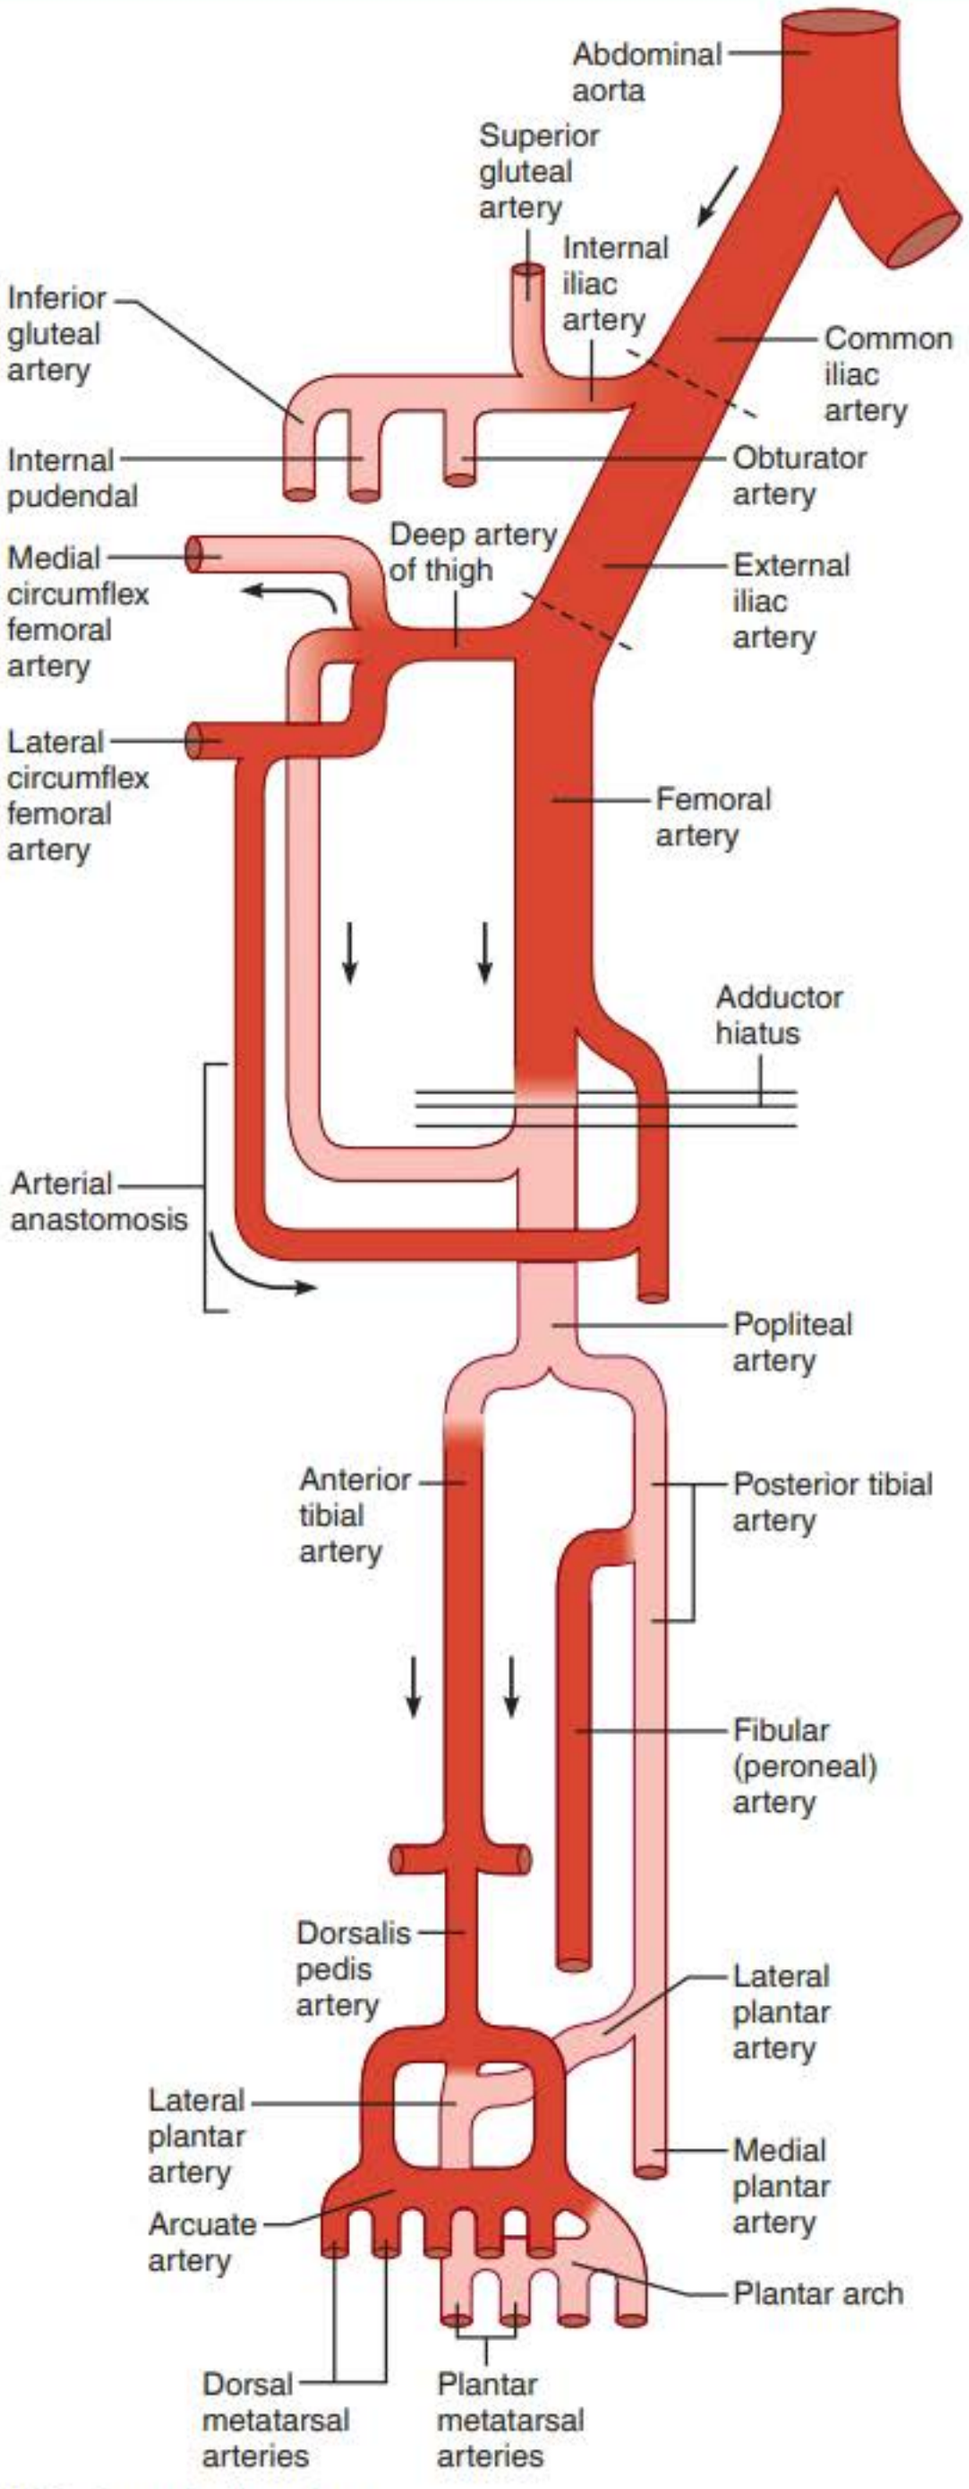
23. Name the arterial anastomosis at the base of the cerebrum.

24. Name the four unpaired arteries that emerge from the abdominal aorta.

For answers, see Answers Appendix.

(Text continues on p. 749.)

Table 19.8 Arteries of the Pelvis and Lower Limbs



(a) Schematic flowchart

At the level of the sacroiliac joints, the **common iliac arteries** divide into two major branches, the internal and external iliac arteries (**Figure 19.27a**). The internal iliacs distribute blood mainly to the pelvic region. The external iliacs primarily serve the lower limbs but also send branches to the abdominal wall.

Description and Distribution

Internal iliac arteries. These paired arteries run into the pelvis and distribute blood to the pelvic walls and viscera (bladder and rectum, plus the uterus and vagina in the female and the prostate and ductus deferens in the male). Additionally they serve the gluteal muscles via the **superior** and **inferior gluteal arteries**, adductor muscles of the medial thigh via the **obturator artery**, and external genitalia and perineum via the **internal pudendal artery** (not illustrated).

External iliac arteries. These arteries supply the lower limbs (Figure 19.27b). As they course through the pelvis, they give off branches to the anterior abdominal wall. After passing under the inguinal ligaments to enter the thigh, they become the femoral arteries.

Femoral arteries. As each of these arteries passes down the anteromedial thigh, it gives off several branches to the thigh muscles. The largest of the deep branches is the **deep artery of the thigh** (also called the *deep femoral artery*), which is the main supply to the thigh muscles (hamstrings, quadriceps, and adductors). Proximal branches of the deep femoral artery, the **lateral** and **medial circumflex femoral arteries**, encircle the neck of the femur. The medial circumflex artery is the major vessel to the head of the femur. If it is torn in a hip fracture, the bone tissue of the head of the femur dies. A long descending branch of the lateral circumflex artery supplies the vastus lateralis muscle. Near the knee the femoral artery passes posteriorly and through a gap in the adductor magnus muscle, the *adductor hiatus*, to enter the popliteal fossa, where its name changes to popliteal artery.

Popliteal artery. This posterior vessel contributes to an arterial anastomosis that supplies the knee region and then splits into the anterior and posterior tibial arteries of the leg.

Anterior tibial artery. The anterior tibial artery runs through the anterior compartment of the leg, supplying the extensor muscles along the way. At the ankle, it becomes the **dorsalis pedis artery**, which supplies the ankle and dorsum of the foot, and gives off a branch, the **arcuate artery**, which issues the **dorsal metatarsal arteries** to the metatarsus of the foot. The superficial dorsalis pedis ends by penetrating into the sole where it forms the medial part of the **plantar arch**. The dorsalis pedis artery provides a clinically important pulse point, the pedal pulse. If the pedal pulse is easily felt, it is fairly certain that the blood supply to the leg is good.

Figure 19.27 Arteries of the right pelvis and lower limb.

Table 19.8 *(continued)*

Posterior tibial artery. This large artery courses through the posteromedial part of the leg and supplies the flexor muscles. Proximally, it gives off a large branch, the **fibular (peroneal) artery**, which supplies the lateral fibularis muscles of the leg. On the medial side of the foot, the posterior tibial artery divides into **lateral** and **medial plantar arteries** that serve the plantar surface of the foot. The lateral plantar artery forms the lateral end of the plantar arch. **Plantar metatarsal arteries** and digital arteries to the toes arise from the plantar arch.

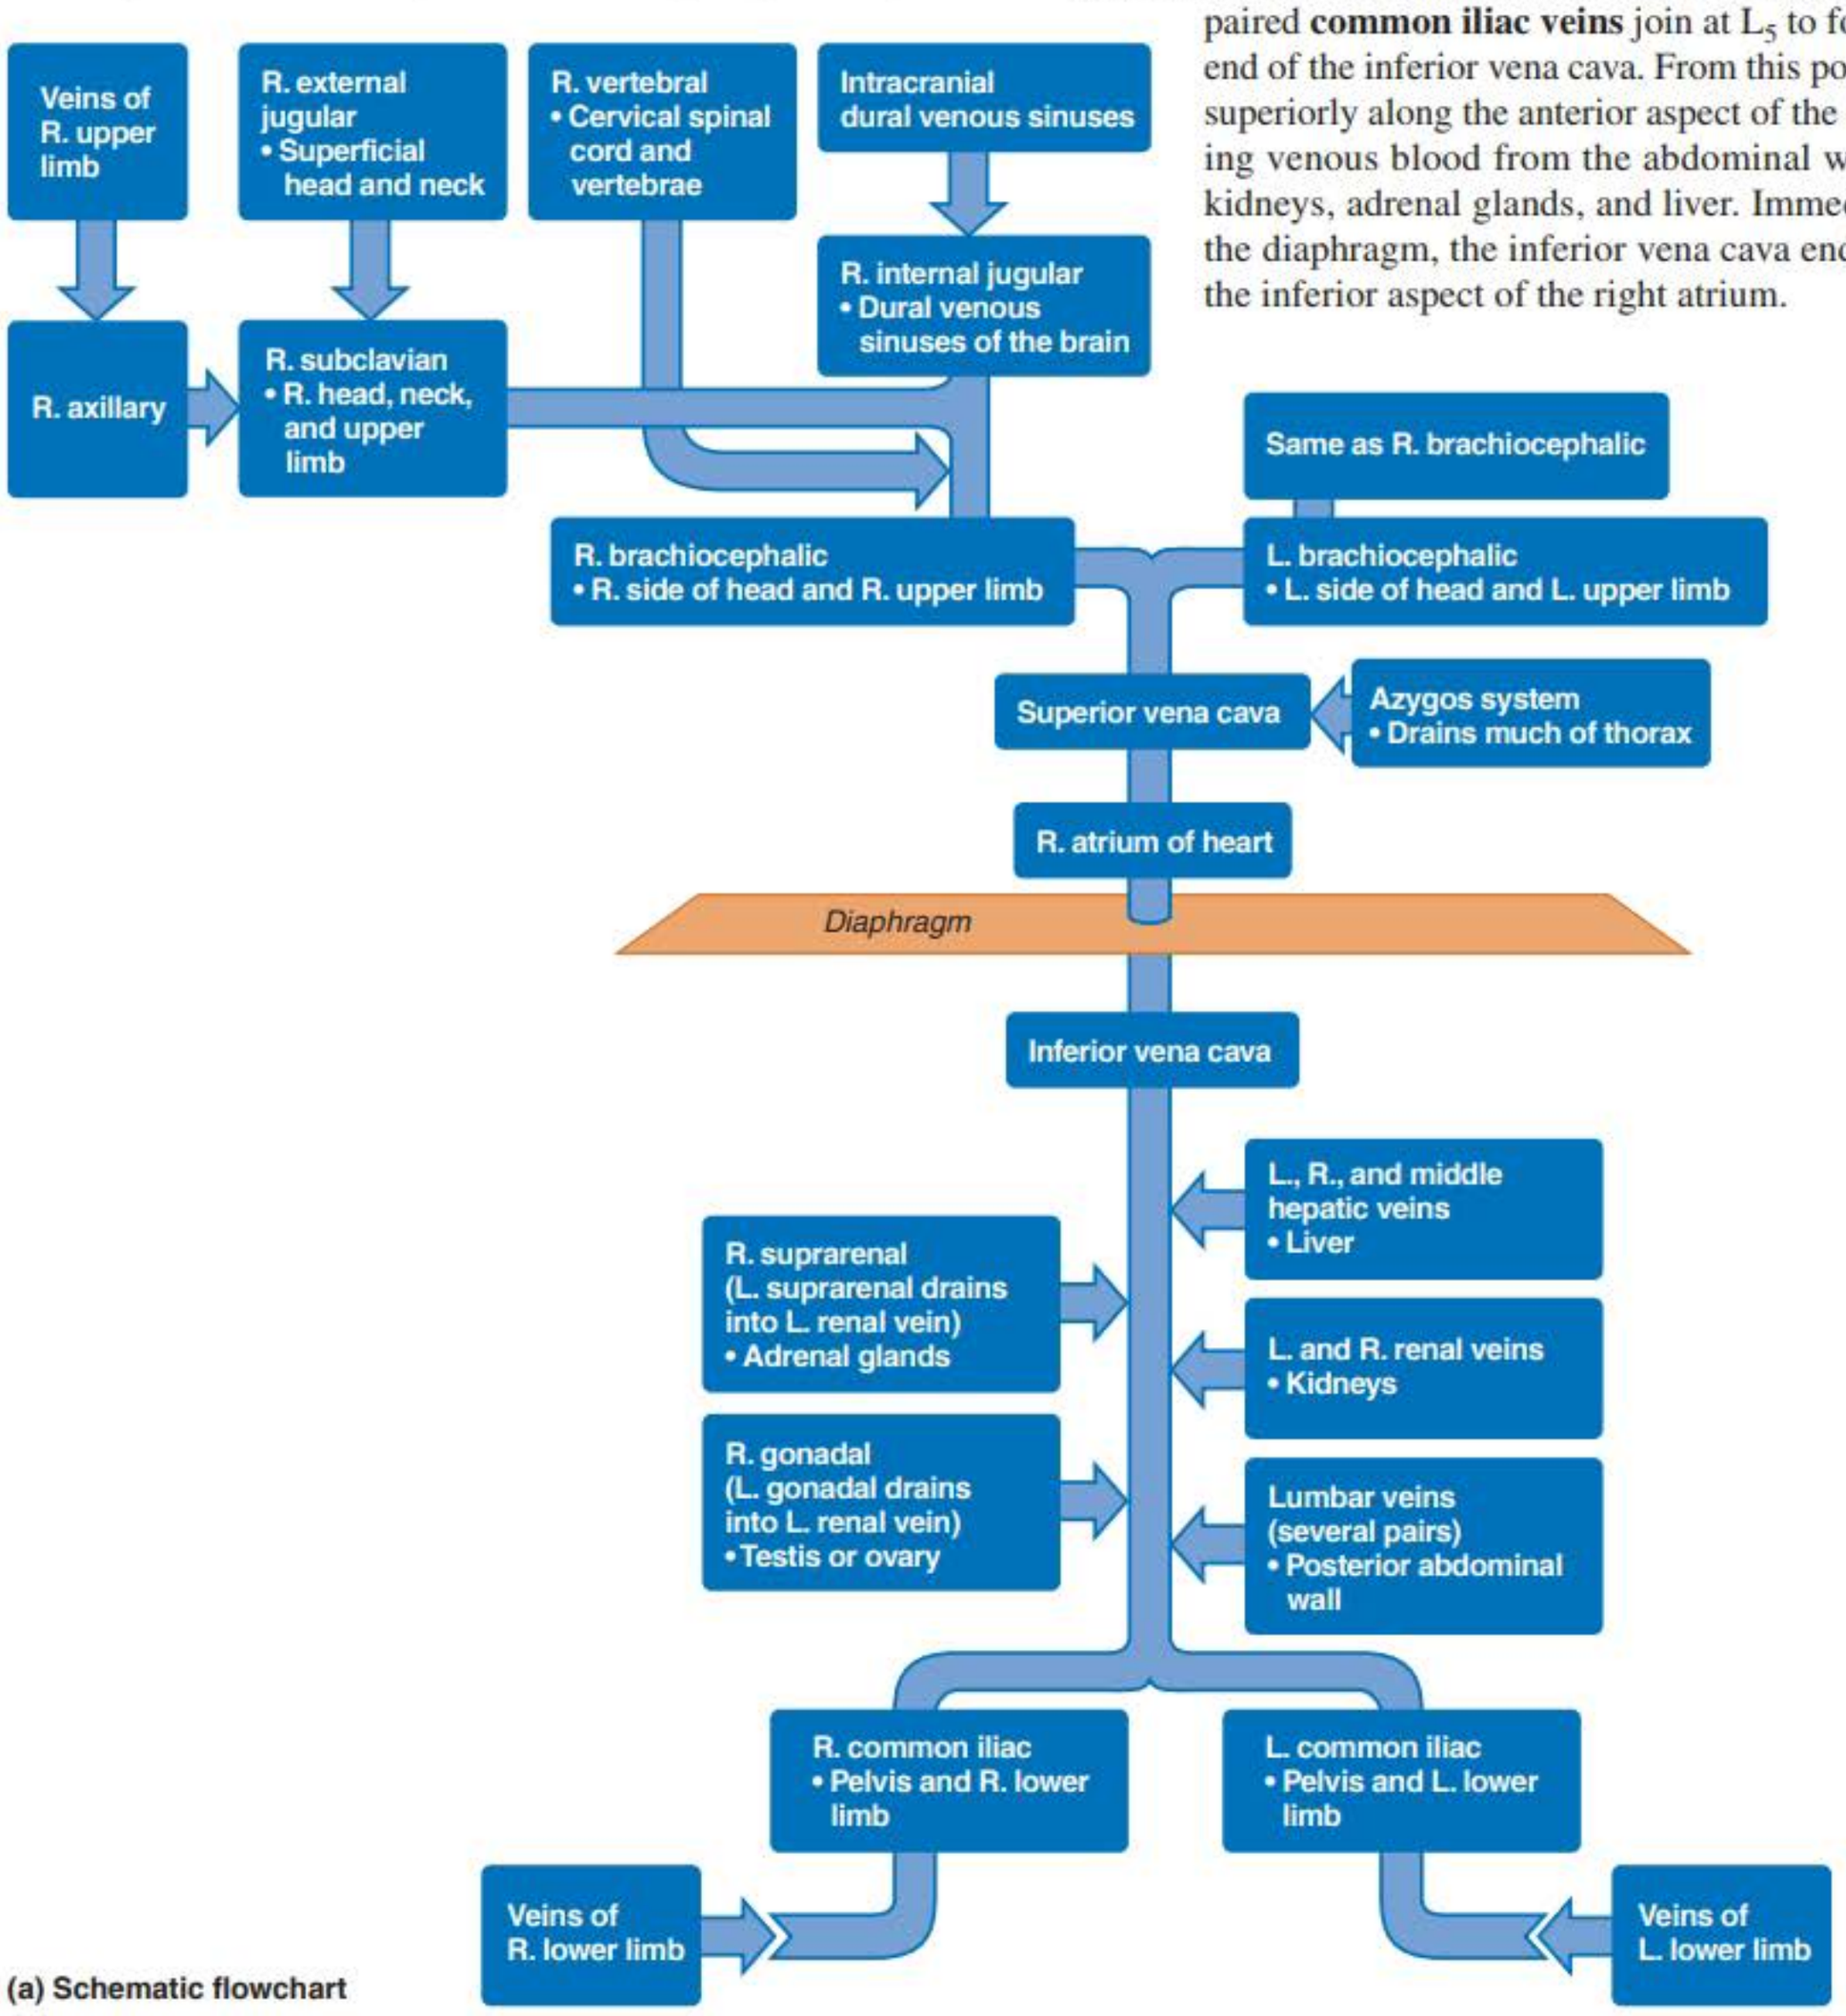
Table 19.9 The Venae Cavae and the Major Veins of the Systemic Circulation

In our survey of the systemic veins, the major tributaries (branches) of the venae cavae are noted first in **Figure 19.28**, followed by a description in Tables 19.10 through 19.13 of the venous pattern of the various body regions. Because veins run toward the heart, the most distal veins are named first and those closest to the heart last. Deep veins generally drain the same areas served by their companion arteries, so they are not described in detail.

Description and Areas Drained

Superior vena cava. This great vein receives systemic blood draining from all areas superior to the diaphragm, except the heart wall. It is formed by the union of the **right** and **left brachiocephalic veins** and empties into the right atrium (Figure 19.28b). Notice that there are two brachiocephalic veins, but only one brachiocephalic artery (trunk). Each brachiocephalic vein is formed by the joining of the **internal jugular** and **subclavian veins** on its side. In most of the flowcharts that follow, only the vessels draining blood from the right side of the body are shown (except for the azygos circulation of the thorax).

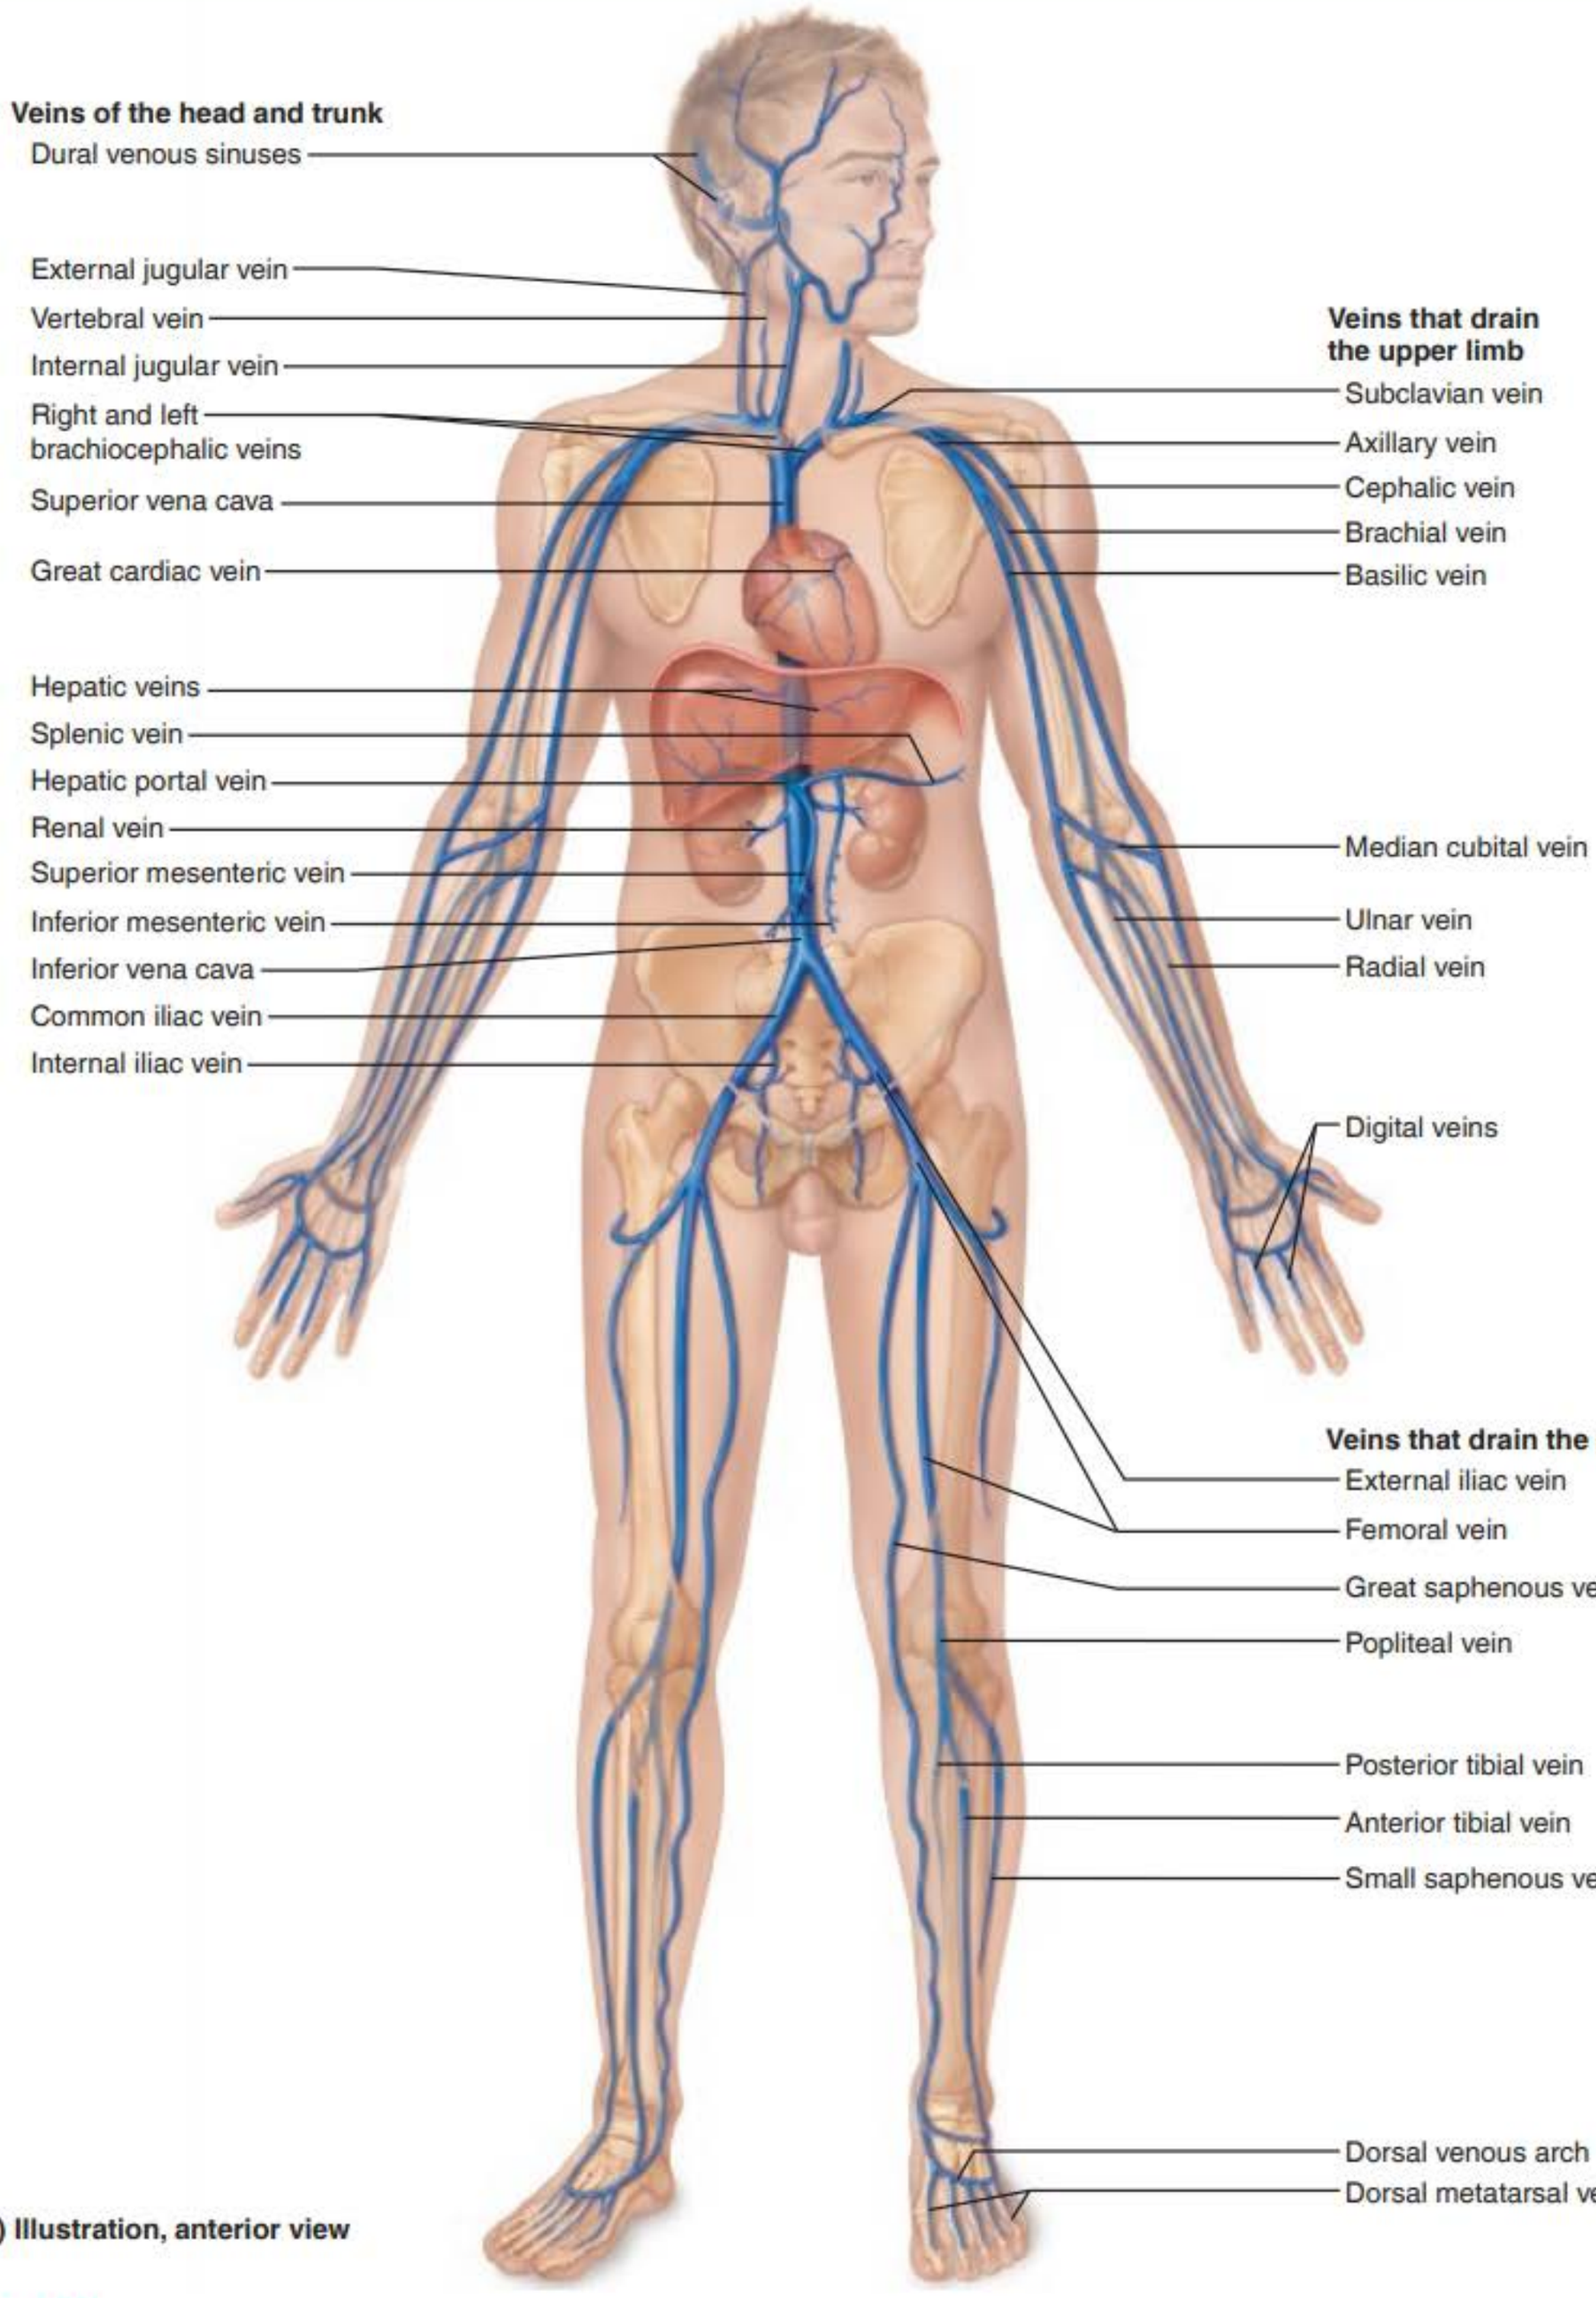
Inferior vena cava. The widest blood vessel in the body, this vein returns blood to the heart from all body regions below the diaphragm. The abdominal aorta lies directly to its left. The paired **common iliac veins** join at L_5 to form the distal end of the inferior vena cava. From this point, it courses superiorly along the anterior aspect of the spine, receiving venous blood from the abdominal walls, gonads, kidneys, adrenal glands, and liver. Immediately above the diaphragm, the inferior vena cava ends as it enters the inferior aspect of the right atrium.



(a) Schematic flowchart

Figure 19.28 Major veins of the systemic circulation.

Table 19.9 *(continued)*



(b) Illustration, anterior view

Figure 19.28 *(continued)*

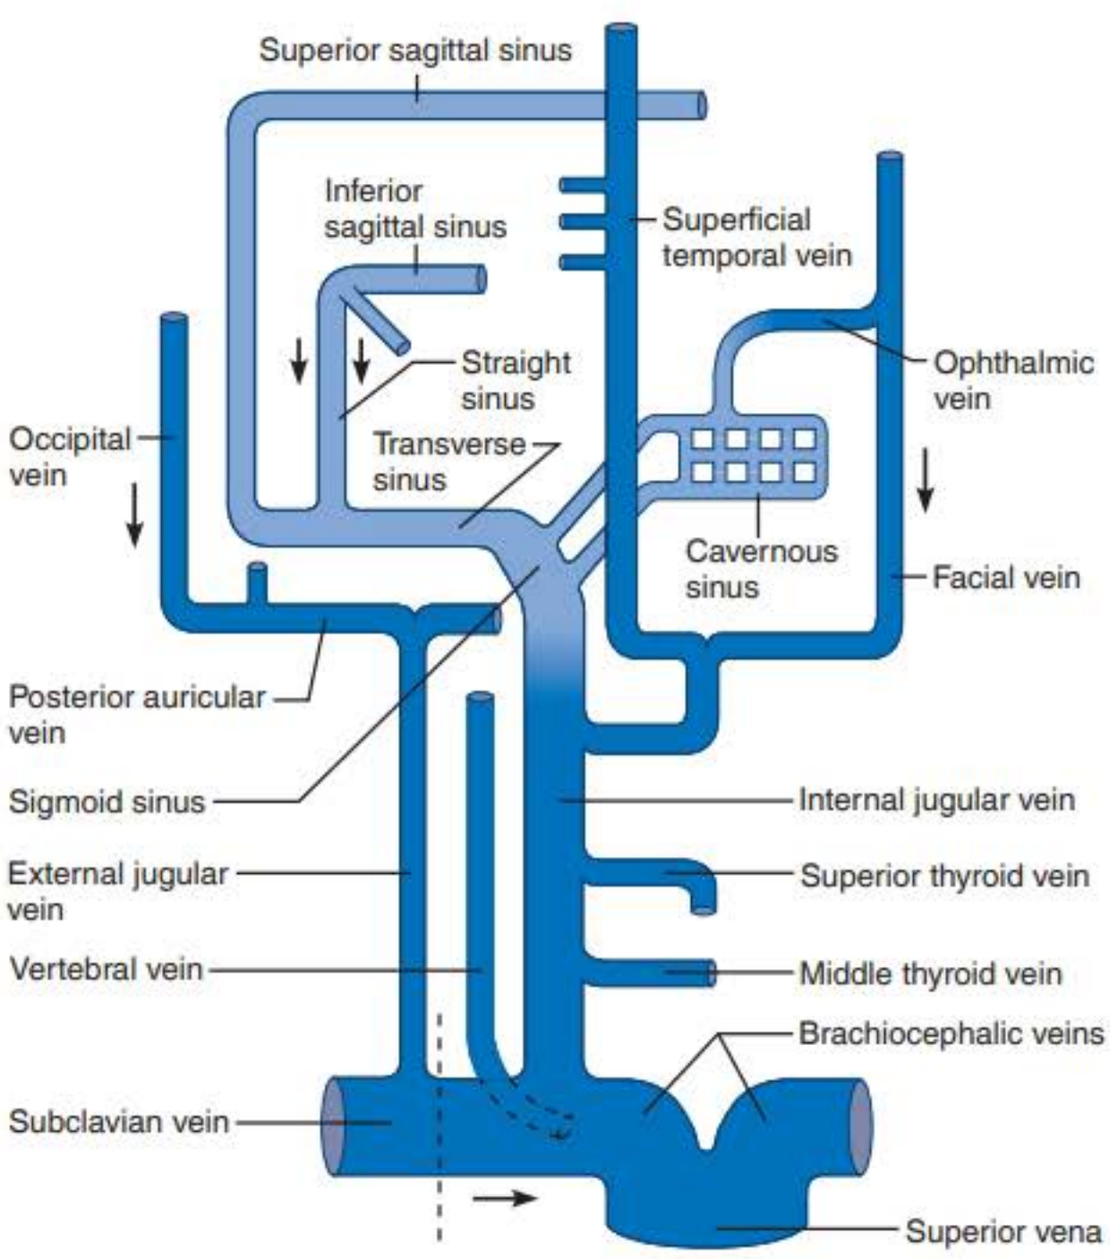
Table 19.10 Veins of the Head and Neck

Three pairs of veins collect most of the blood draining from the head and neck (**Figure 19.29a**):

- The external jugular veins, which empty into the subclavians
- The internal jugular veins, which join with the subclavians
- The vertebral veins, which drain into the brachiocephalic veins

Although most extracranial veins have the same names as the extracranial arteries, their courses and interconnections differ substantially.

Most veins of the brain drain into the **dural venous sinuses**, an interconnected series of enlarged chambers located between the dura mater layers (◀ p. 464). The **superior** and **inferior sagittal sinuses** are in the falx cerebri, which dips down between the cerebral hemispheres. The inferior sagittal sinus drains into the **straight sinus** posteriorly (Figure 19.29a and c). The superior sagittal and straight sinuses then empty into the **transverse sinuses**, which run in shallow grooves on the internal surface of the occipital bone. These drain into the S-shaped **sigmoid sinuses**, which become the *internal jugular veins* as they leave the skull through the jugular foramen. The **cavernous sinuses**, which flank the sphenoid body, receive venous blood from the **ophthalmic veins** of the orbits and the facial veins, which drain the nose and upper lip area. The internal carotid artery and cranial nerves III, IV, VI, and part of V all run *through* the cavernous sinus on their way to the orbit and face.



(a) Schematic flowchart

Figure 19.29 Venous drainage of the head, neck, and brain.

Description and Area Drained

External jugular veins. The right and left external jugular veins drain superficial scalp and face structures served by the external carotid arteries. However, their tributaries anastomose frequently, and some of the superficial drainage from these regions enters the internal jugular veins as well. As the external jugular veins descend through the lateral neck, they pass obliquely over the sternocleidomastoid muscles and then empty into the subclavian veins.

Vertebral veins. Unlike the vertebral arteries, the vertebral veins do not serve much of the brain. Instead they drain the cervical vertebrae, the spinal cord, and some small neck muscles. They run inferiorly through the transverse foramina of the cervical vertebrae and join the brachiocephalic veins at the root of the neck.

Internal jugular veins. The paired internal jugular veins, which receive the bulk of blood draining from the brain, are the largest of the paired veins draining the head and neck. They arise from the dural venous sinuses, exit the skull via the *jugular foramina* (◀ Figure 7.6a and b, p. 206), and then descend through the neck alongside the internal carotid arteries. As they move inferiorly, they receive blood from some of the deep veins of the face and neck—branches of the **facial** and **superficial temporal veins** (Figure 19.29b). At the base of the neck, each internal jugular vein joins the subclavian vein on its own side to form a brachiocephalic vein. As already noted, the two brachiocephalic veins unite to form the **superior vena cava**.

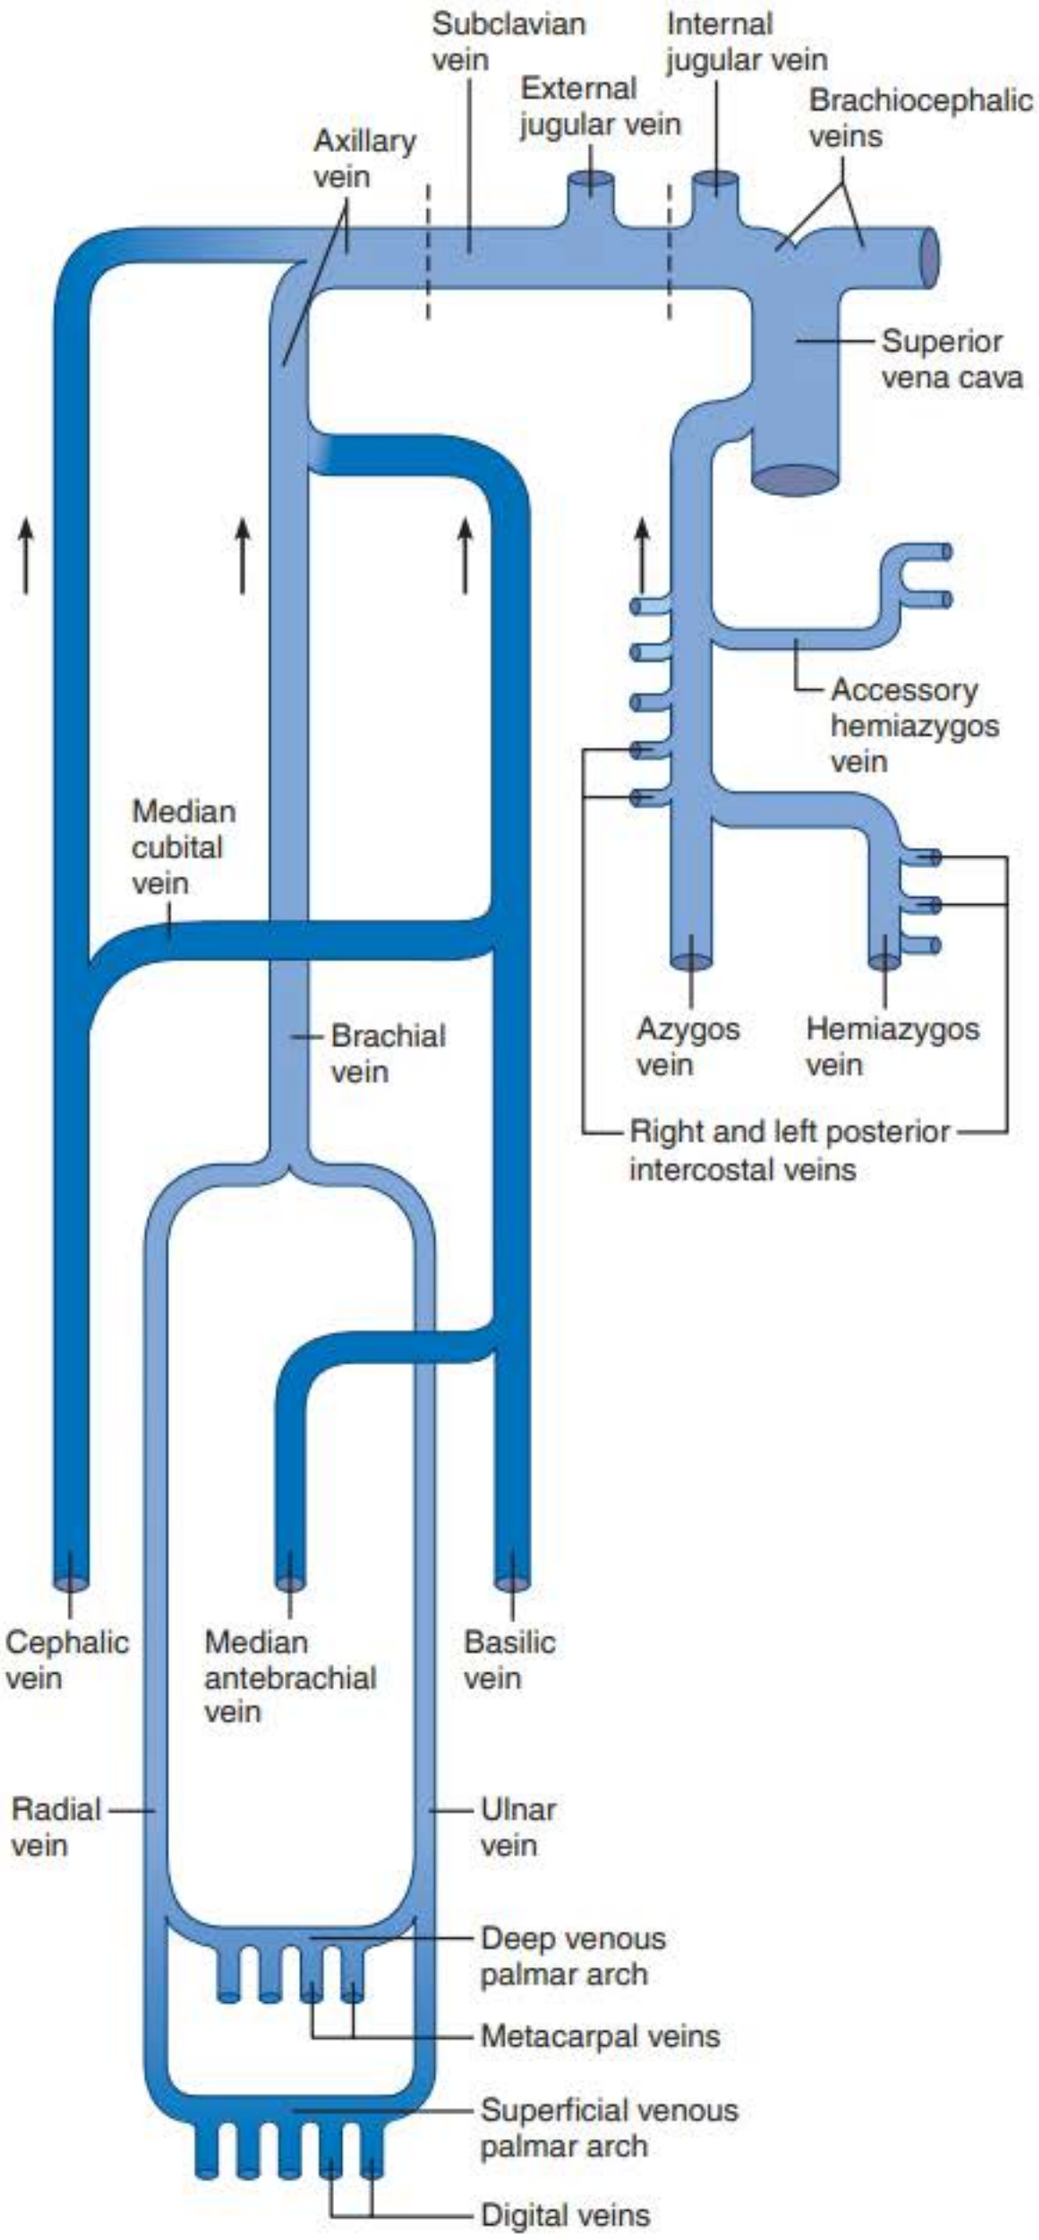
Table 19.11 Veins of the Upper Limbs and Thorax



(a) Schematic flowchart

Figure 19.30 Veins of the thorax and right upper limb. For clarity, the abundant branching and anastomoses of the superficial veins are not shown.

The deep veins of the upper limbs follow the paths of their companion arteries and have the same names (**Figure 19.30a**). However, except for the largest, most are paired veins that flank their artery. The superficial veins of the upper limbs are larger than the deep veins and are easily seen just beneath the skin. The median cubital vein, crossing the anterior aspect of the elbow, is commonly used to obtain blood samples or administer intravenous medications.

Blood draining from the mammary glands and the first two to three intercostal spaces enters the **brachiocephalic veins**. However, the vast majority of thoracic tissues and the thorax wall are drained by a complex network of veins called the **azygos system** (a-zi′gos). The branching nature of the azygos system provides a collateral circulation for draining the abdominal wall and other areas served by the inferior vena cava, and there are numerous anastomoses between the azygos system and the inferior vena cava.

Description and Areas Drained

Deep Veins of the Upper Limbs

The most distal deep veins of the upper limb are the radial and ulnar veins. The **deep** and **superficial venous palmar arches** of the hand empty into the **radial** and **ulnar veins** of the forearm, which then unite to form the **brachial vein** of the arm. As the brachial vein enters the axilla, it becomes the **axillary vein**, which becomes the **subclavian vein** at the level of the first rib.

Superficial Veins of the Upper Limbs

The superficial venous system begins with the *dorsal venous network* (not illustrated), a plexus of superficial veins in the dorsum of the hand. In the distal forearm, this plexus drains into two major superficial veins—the cephalic and basilic veins—which anastomose frequently as they course upward (Figure 19.30b). The **cephalic vein** bends around the radius as it travels superiorly and then continues up the lateral superficial aspect of the arm to the shoulder, where it runs in the groove between the deltoid and pectoralis muscles to join the axillary vein. The **basilic vein** courses along the posteromedial aspect of the forearm, crosses the elbow, and then joins the brachial vein in the axilla, forming the axillary vein. At the anterior aspect of the elbow, the **median cubital vein** connects the basilic and cephalic veins. The **median antebrachial vein** lies between the radial and ulnar veins in the forearm and terminates (variably) at the elbow by entering either the basilic or the cephalic vein.

The Azygos System

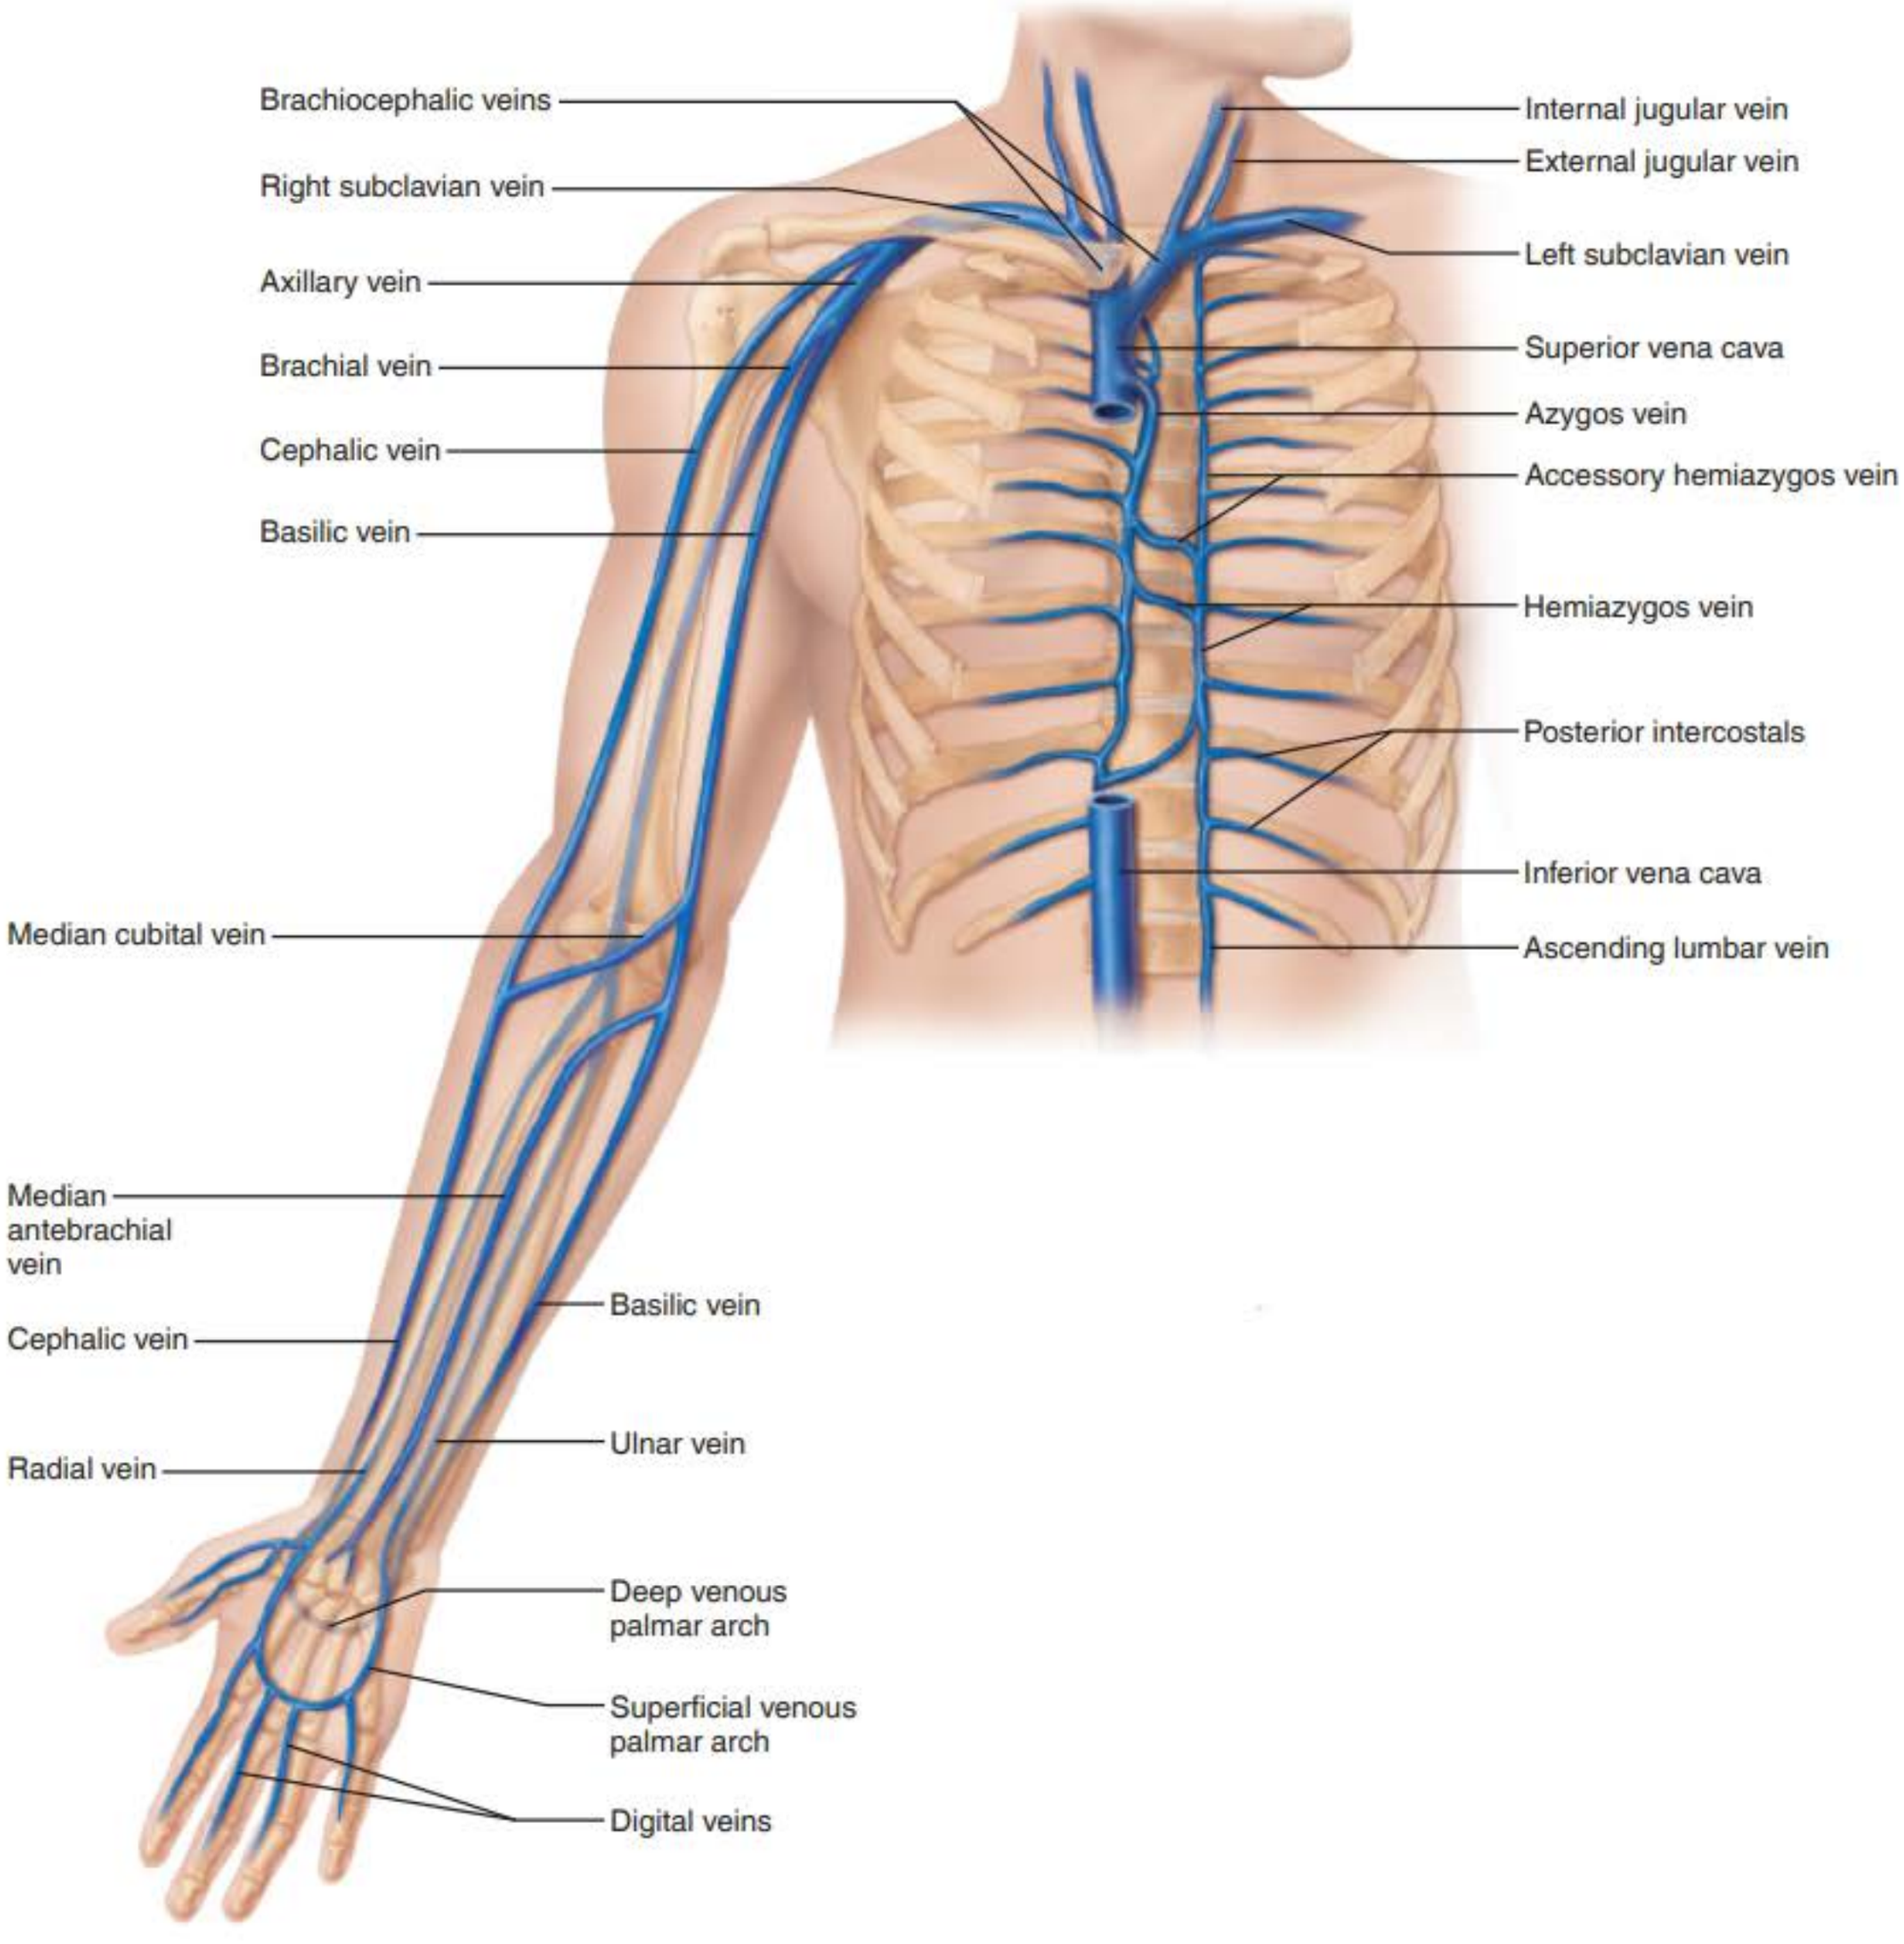
The azygos system consists of the following vessels, which flank the vertebral column laterally.

Azygos vein. Located against the right side of the vertebral column, the **azygos vein** (*azygos* = unpaired) originates in the abdomen, from the **right ascending lumbar vein** that drains most of the right abdominal cavity wall and from the **right posterior intercostal veins** (except the first) that drain the chest muscles. At the T_4 level, it arches over the great vessels that run to the right lung and empties into the superior vena cava.

Table 19.11 *(continued)*

Hemiazygos vein (hĕ″me-a-zi′gos; "half the azygos"). This vessel ascends on the left side of the vertebral column. Its origin, from the **left ascending lumbar vein** and the lower (9th–11th) **posterior intercostal veins**, mirrors that of the inferior portion of the azygos vein on the right. About midthorax, the hemiazygos vein passes in front of the vertebral column and joins the azygos vein.

Accessory hemiazygos vein. The accessory hemiazygos completes the venous drainage of the left (middle) thorax and can be thought of as a superior continuation of the hemiazygos vein. It receives blood from the 4th–8th posterior intercostal veins and then crosses to the right to empty into the azygos vein. Like the azygos, it receives oxygen-poor systemic blood from the bronchi of the lungs (*bronchial veins*).



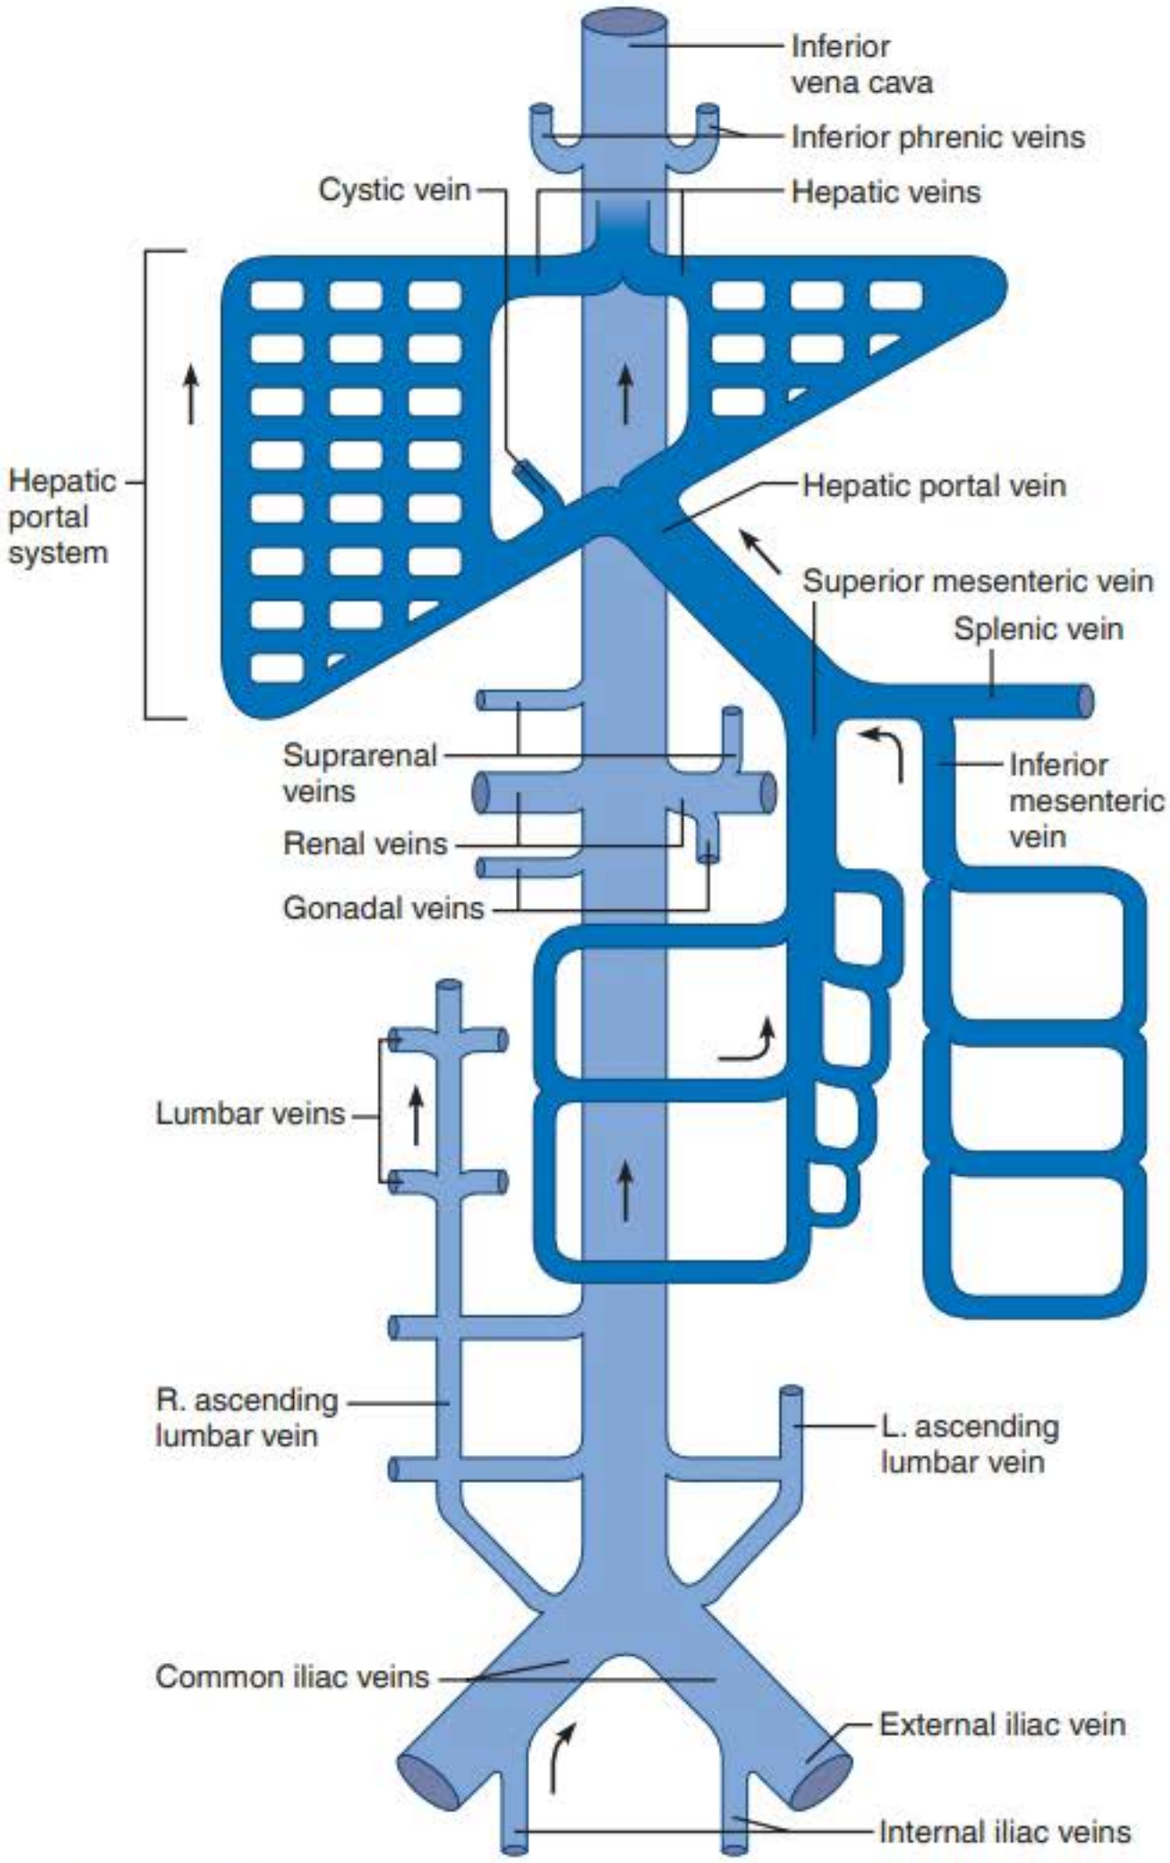
(b) Anterior view

Figure 19.30 *(continued)*

Table 19.12 Veins of the Abdomen

The **inferior vena cava** returns blood from the abdominopelvic viscera and abdominal walls to the heart (**Figure 19.31a**). Most of its venous tributaries have names that correspond to the arteries serving the abdominal organs.

Veins draining the digestive viscera empty into a common vessel, the *hepatic portal vein*, which transports this venous blood into the liver before it is allowed to enter the major systemic circulation via the hepatic veins (Figure 19.31c). Such a venous system—veins connecting two capillary beds together—is called a *portal system* and always serves very specific needs. The **hepatic portal system** carries nutrient-rich blood (which may also contain toxins and microorganisms) from the digestive organs to the liver, where it can be "treated" before it reaches the rest of the body. As the blood percolates slowly through the liver sinusoid capillaries, hepatocytes process nutrients and toxins, and phagocytic cells rid the blood of bacteria and other foreign matter.



(a) Schematic flowchart.

Figure 19.31 Veins of the abdomen.

Description and Areas Drained

The veins of the abdomen are listed in inferior to superior order.

Lumbar veins. Several pairs of lumbar veins drain the posterior abdominal wall. They empty both directly into the inferior vena cava and into the ascending lumbar veins of the azygos system of the thorax.

Gonadal (testicular or ovarian) veins. The right gonadal vein drains the ovary or testis on the right side of the body and empties into the inferior vena cava. The left gonadal vein drains into the left renal vein superiorly.

Renal veins. The right and left renal veins drain the kidneys.

Suprarenal veins. The right suprarenal vein drains the adrenal gland on the right and empties into the inferior vena cava. The left suprarenal vein drains into the left renal vein.

Hepatic portal system. Like all portal systems, the hepatic portal system is a series of vessels in which two separate capillary beds lie between the arterial supply and the final venous drainage. In this case, the first capillary beds are in the stomach and intestines and drain into tributaries of the hepatic portal vein, which brings them to the second capillary bed in the liver. The short **hepatic portal vein** begins at the L_2 level. Numerous tributaries from the stomach and pancreas contribute to the hepatic portal system (Figure 19.31c), but the major vessels are:

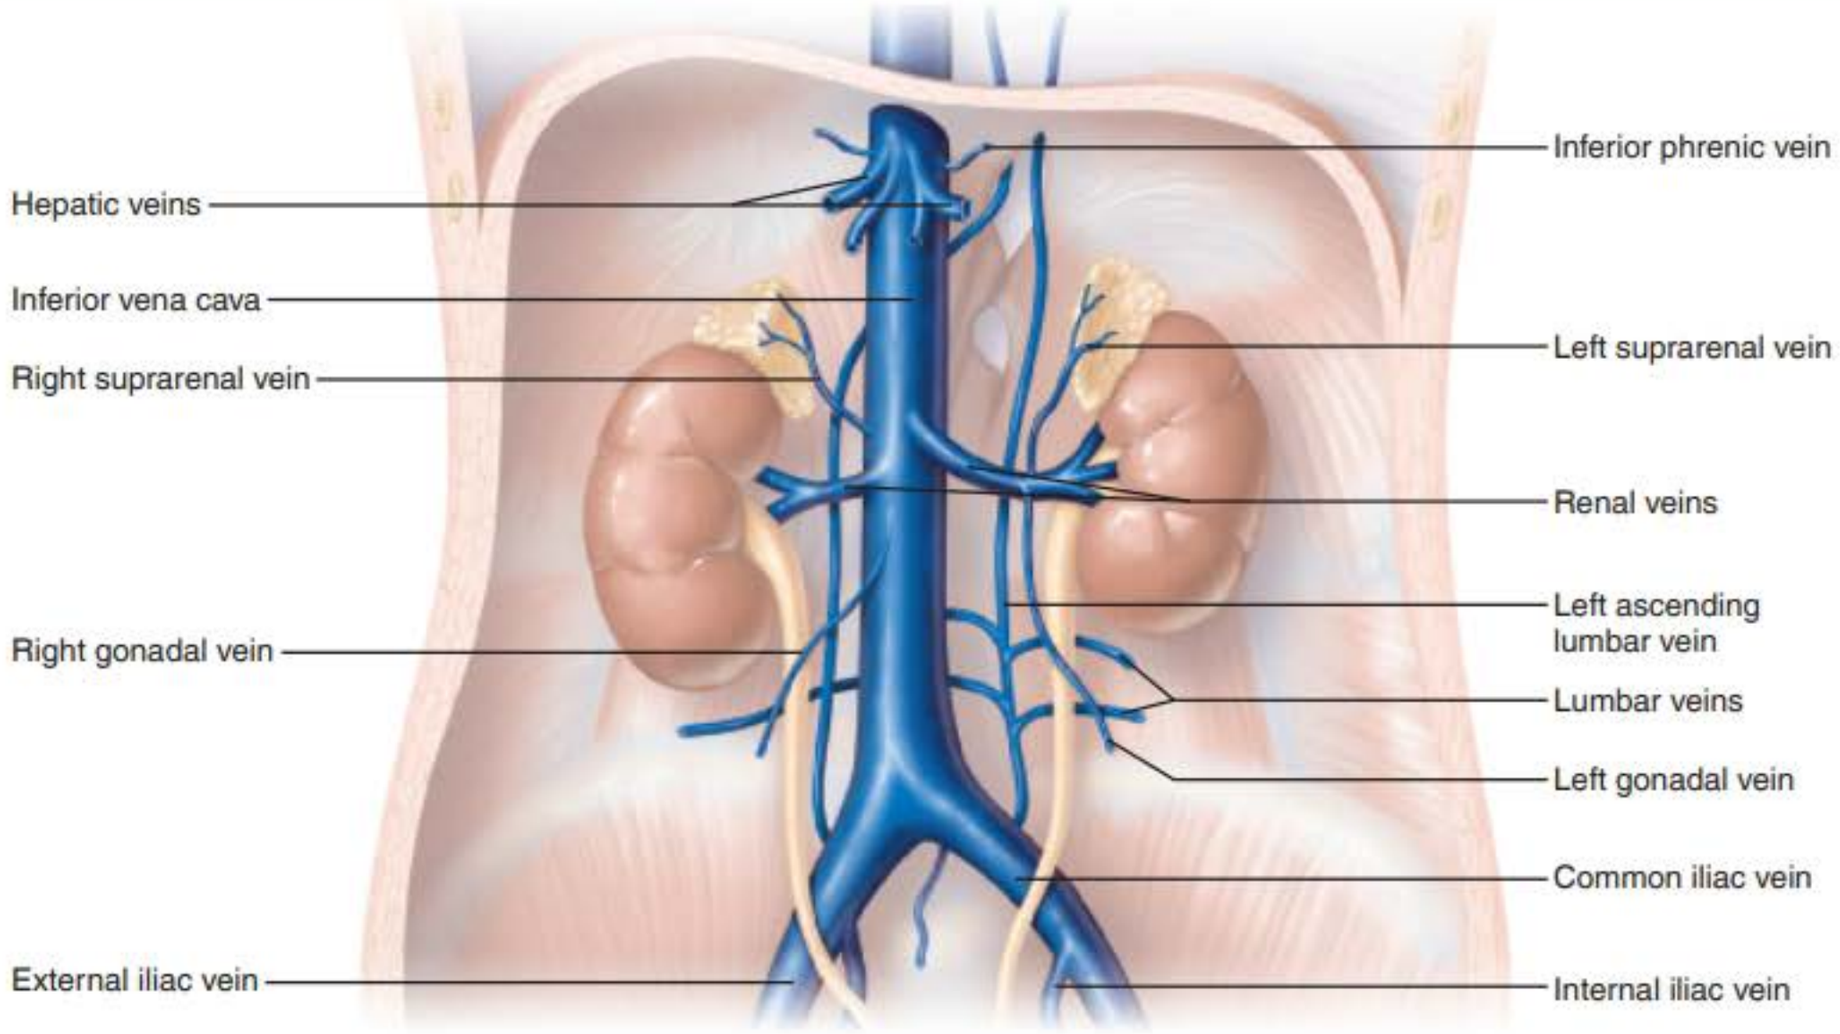
- **Superior mesenteric vein:** Drains the entire small intestine, part of the large intestine (ascending and transverse regions), and stomach.
- **Splenic vein:** Collects blood from the spleen, parts of the stomach and pancreas, and then joins the superior mesenteric vein to form the hepatic portal vein.
- **Inferior mesenteric vein:** Drains the distal portions of the large intestine and rectum and joins the splenic vein just before that vessel unites with the superior mesenteric vein to form the hepatic portal vein.

Hepatic veins. The right, left, and middle hepatic veins carry venous blood from the liver to the inferior vena cava.

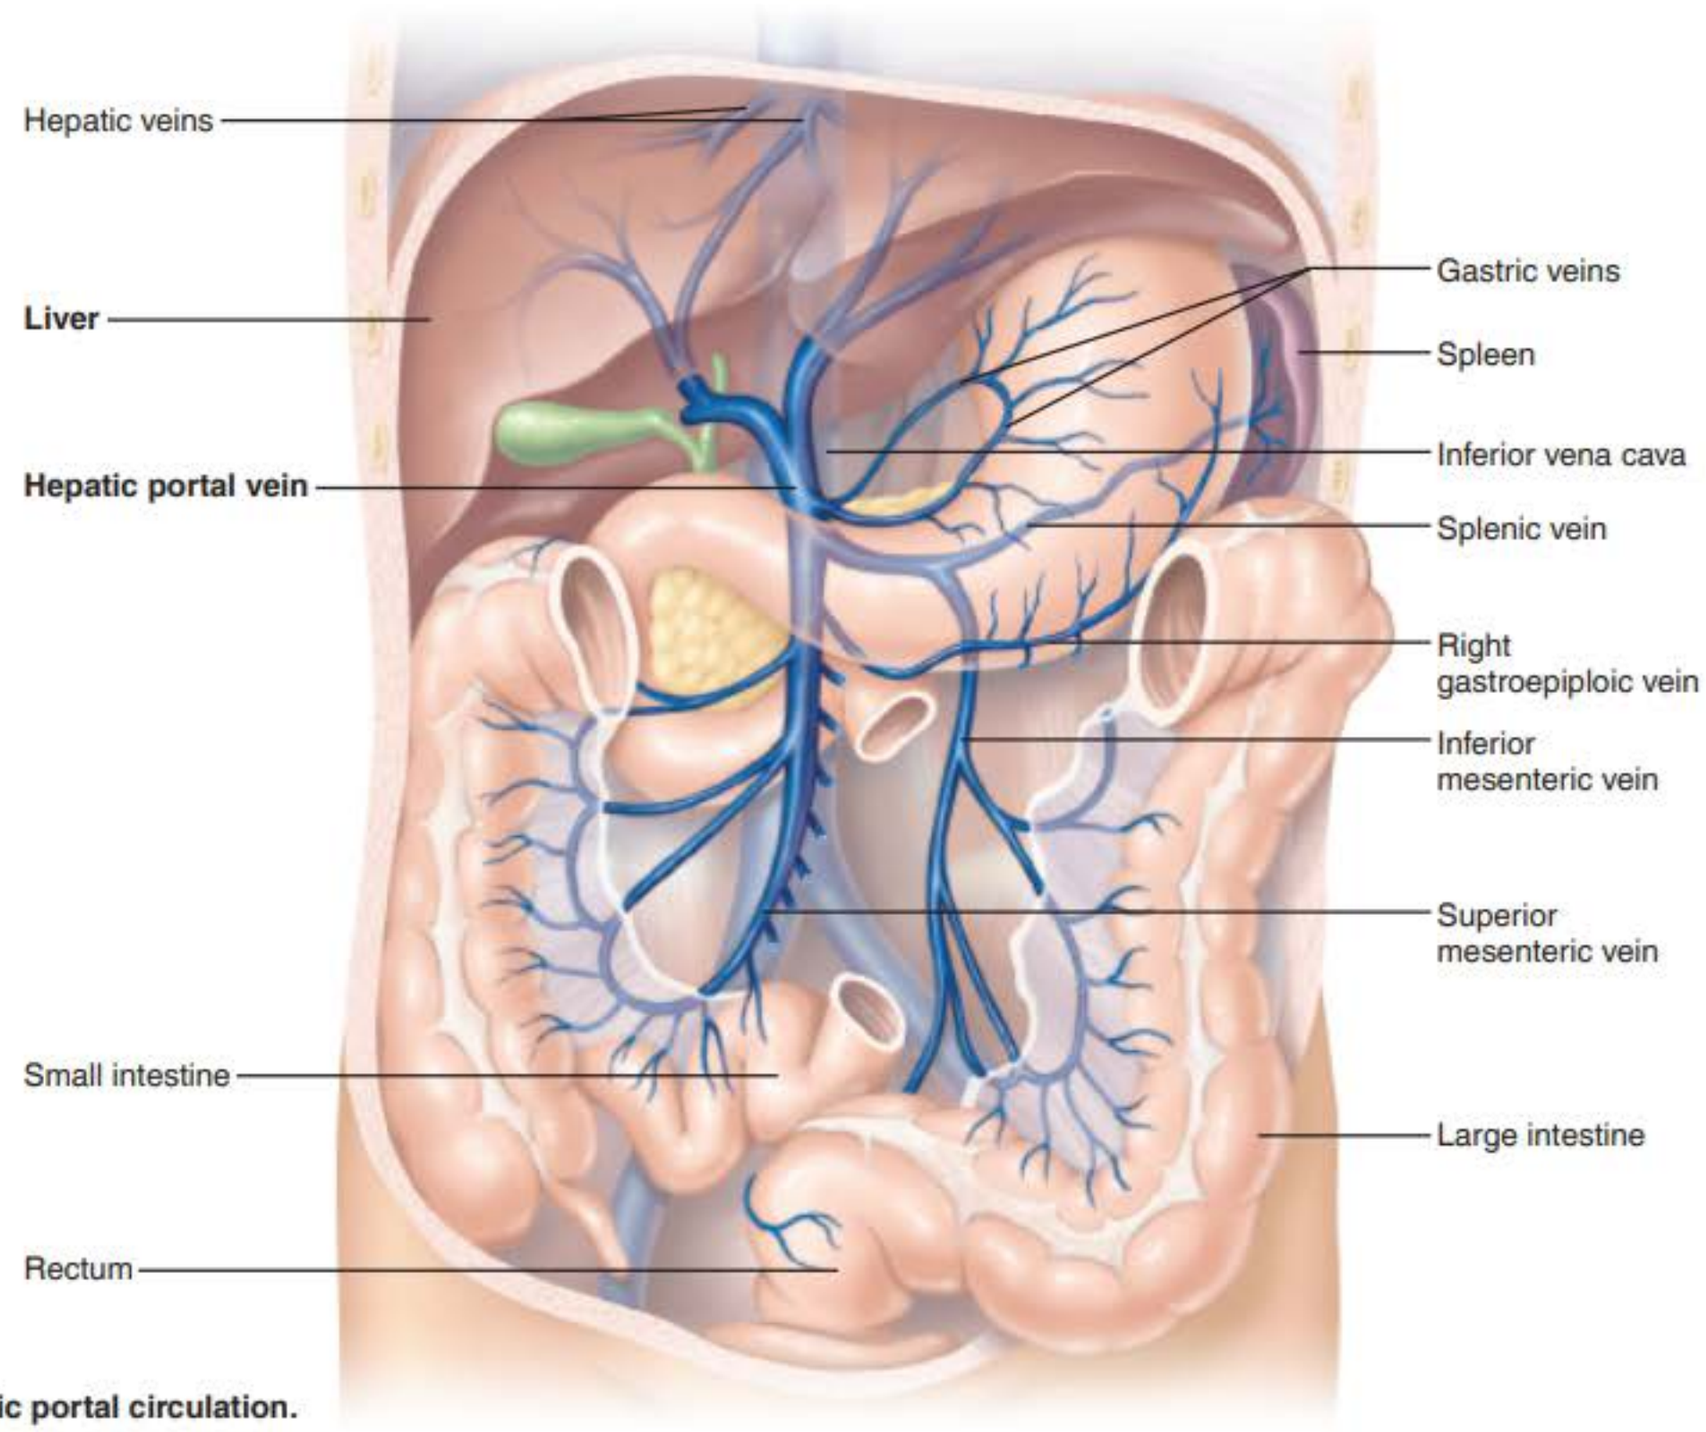
Cystic veins. The cystic veins drain the gallbladder and join the portal veins in the liver.

Inferior phrenic veins. The inferior phrenic veins drain the inferior surface of the diaphragm.

Table 19.12 *(continued)*



(b) Tributaries of the inferior vena cava. Venous drainage of abdominal organs not drained by the hepatic portal vein.



(c) The hepatic portal circulation.

Figure 19.31 *(continued)*

Table 19.13 Veins of the Pelvis and Lower Limbs

As in the upper limbs, most deep veins of the lower limbs have the same names as the arteries they accompany and many are double. Poorly supported by surrounding tissues, the two superficial saphenous veins (great and small) are common sites of varicosities. The great saphenous (*saphenous* = obvious) vein is frequently excised and used as a coronary bypass vessel.

Description and Areas Drained

Deep veins. After being formed by the union of the **medial** and **lateral plantar veins**, the **posterior tibial vein** ascends deep in the calf muscle and receives the **fibular (peroneal) vein** (**Figure 19.32**). The **anterior tibial vein**, which is the superior continuation of the **dorsalis pedis vein** of the foot, unites at the knee with the posterior tibial vein to form the **popliteal vein**, which crosses the back of the knee. As the popliteal vein emerges from the knee, it becomes the **femoral vein**, which drains the deep structures of the thigh. The femoral vein becomes the **external iliac vein** as it enters the pelvis. In the pelvis, the external iliac vein unites with the **internal iliac vein** to form the **common iliac vein**. The distribution of the internal iliac veins parallels that of the internal iliac arteries.

Superficial veins. The **great** and **small saphenous veins** (sah-fe′nus) issue from the **dorsal venous arch** of the foot (Figure 19.32b and c). These veins anastomose frequently with each other and with the deep veins along their course. The great saphenous vein is the longest vein in the body. It travels superiorly along the medial aspect of the leg to the thigh, where it empties into the femoral vein just distal to the inguinal ligament. The small saphenous vein runs along the lateral aspect of the foot and then through the deep fascia of the calf muscles, which it drains. At the knee, it empties into the popliteal vein.

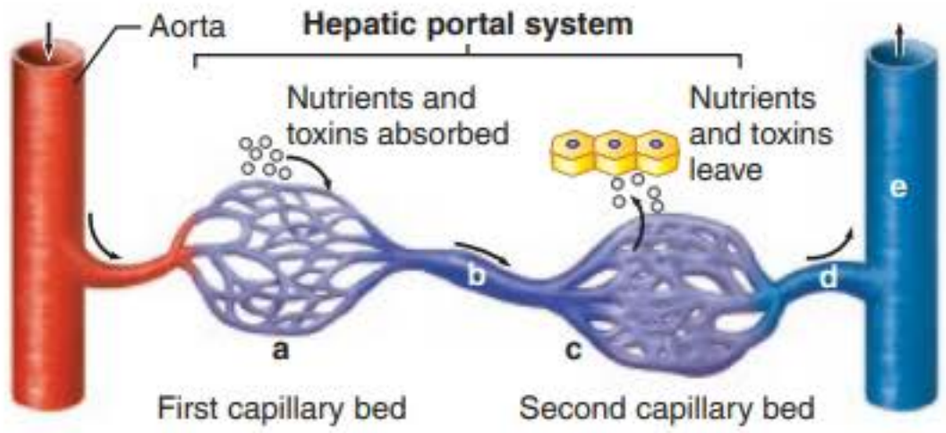
28. Below is a schematic drawing of the hepatic portal system showing two capillary beds separated by a vein. State the locations of capillary beds a and c. What type of capillaries are found in bed c? Name the major veins labeled b, d, and e.



29. Name the leg veins that often become varicosed.

30. MAKE CONNECTIONS You learned about another portal system in Chapter 16. Name that portal system.

For answers, see Answers Appendix.

Developmental Aspects of Blood Vessels

The endothelial lining of blood vessels is formed by mesodermal cells, which collect in little masses called **blood islands** throughout the microscopic embryo. These blood islands form fragile sprouting extensions that reach toward one another and toward the forming heart to lay down the rudimentary vascular tubes. Meanwhile, adjacent mesenchymal cells, stimulated by platelet-derived growth factor, surround the endothelial tubes, forming the stabilizing muscular and fibrous coats of the vessel walls.

How do blood vessels "know" where to grow? Many blood vessels simply follow the same guidance cues that nerves follow, which is why forming vessels often snuggle closely to nerves. Whether a vessel becomes an artery or a vein depends upon the local concentration of a differentiation factor called *vascular endothelial growth factor*. As noted in Chapter 18, the heart pumps blood through the rudimentary vascular system by the fourth week of development.

In addition to the fetal shunts that bypass the nonfunctional lungs (the *foramen ovale* and *ductus arteriosus*), other vascular modifications are found in the fetus. A special vessel, the *ductus venosus*, largely bypasses the liver. Also important are the *umbilical vein* and *arteries*, large vessels that circulate blood between the fetal circulation and the placenta where gas and nutrient exchanges occur with the mother's blood (see Chapter 28). Once the fetal circulatory pattern is laid down, few vascular changes occur until birth, when the umbilical vessels and shunts are occluded (blocked).

Unlike congenital heart diseases, congenital vascular problems are rare, and blood vessels are remarkably trouble-free during youth. Vessels form as needed to support body growth and wound healing, and to rebuild vessels lost each month during a woman's menstrual cycle. As we age, signs of vascular disease begin to appear. In some, the venous valves weaken, and purple, snakelike varicose veins appear. In others, more insidious signs of inefficient circulation appear: tingling fingers and toes and cramping muscles.

Although the degenerative process of atherosclerosis begins in youth, its consequences are rarely apparent until middle to old age, when it may precipitate a myocardial infarction (heart attack) or stroke. Until puberty, the blood vessels of boys and girls look alike, but from puberty to about age 45, women have strikingly less atherosclerosis than men because of the protective effects of estrogens. Estrogens reduce resistance to blood flow and increase the production of HDL ("good" lipoprotein), which reduces the risk of atherosclerosis.

Between the ages of 45 and 65, when estrogen production wanes in women, this "gap" between the sexes closes, and males and females above age 65 are equally at risk for cardiovascular disease. You might expect that giving postmenopausal women supplementary estrogens would maintain this protective effect. Surprisingly, clinical trials have shown that this is not the case.

Blood pressure changes with age. In a newborn baby, arterial pressure is about 90/55. Blood pressure rises steadily during childhood to finally reach the adult value (120/80). After age 40, the incidence of hypertension increases dramatically, as do associated illnesses such as heart attacks, strokes, vascular disease, and renal failure.

At least some vascular disease is a product of our modern technological culture. "Blessed" with high-protein and lipid-rich diets, empty-calorie snacks, energy-saving devices, and high-stress jobs, many of us are struck down prematurely. Lifestyle modifications—a healthy diet, regular aerobic exercise, and eliminating cigarette smoking—can help prevent cardiovascular disease.

19

RELATED CLINICAL TERMS

Aneurysm (an′u-rizm; *aneurysm* = a widening) A balloonlike outpocketing of an artery wall that places the artery at risk for rupture; most often reflects gradual weakening of the artery by chronic hypertension or atherosclerosis. The most common sites of aneurysms are the abdominal aorta and arteries feeding the brain and kidneys.

Angiogram (an′je-o-gram″; *angio* = a vessel; *gram* = writing) Diagnostic technique involving the infusion of a radiopaque substance into the circulation for X-ray examination of specific blood vessels (◀ p. 16). The major technique for diagnosing coronary artery occlusion and risk of a heart attack.

Deep venous thrombosis Clot formation in a deep vein. An ever-present danger is that the clot may detach and form a life-threatening pulmonary embolus.

(Text continues on p. 762.)

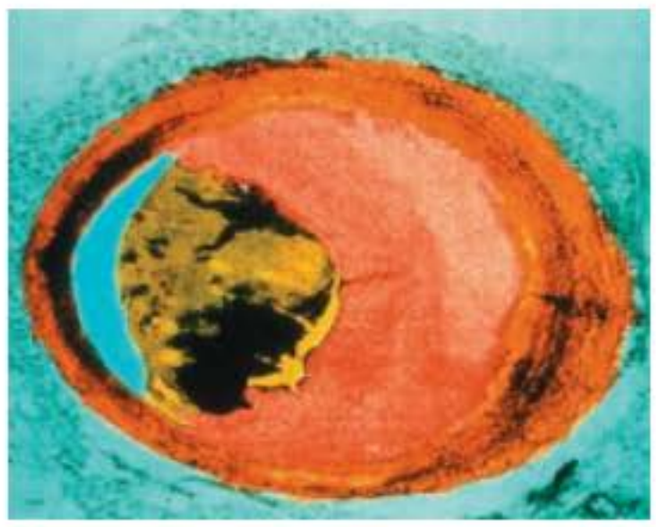
Atherosclerosis? Get Out the Cardiovascular Drāno®

When pipes get clogged, it is usually because we've dumped something down the drain that shouldn't be there, or something is growing inside (tree roots, for example), trapping the normal sludge coming through (see top photo). In **atherosclerosis**, small patchy thickenings called *atheromas* form that make the walls of our arteries thicker and stiffer, resulting in hypertension. Atheromas can intrude into the vessel lumen, making it easy for arterial spasms or a blood clot to close the vessel completely.

Onset and Stages

Atherosclerosis indirectly causes half of the deaths in the Western world. How does this scourge of blood vessels come about? The development of a full-blown atheroma is believed to occur in several stages.

1. **The endothelium is injured.** The initial event is damage to the endothelium caused by turbulent blood flow, bloodborne chemicals (such as cholesterol), hypertension, components of cigarette smoke, or viral or bacterial infections. Damaged endothelial cells become dysfunctional, and this sets the stage for atherosclerosis.
2. **Lipids accumulate and oxidize in the tunica intima.** Injured endothelial cells set up a local inflammatory response, attracting white blood cells. Endothelial cells then begin to transport and modify low-density lipoproteins (LDLs) that deliver cholesterol to tissue cells from the blood. The accumulated LDL oxidizes in the inflammatory environment. This not only damages neighboring cells, but also attracts more macrophages. Some of these macrophages become so engorged with LDLs that they are transformed into lipid-laden *foam cells*.
3. **Smooth muscle cells proliferate and a fibrous cap forms.** Smooth muscle cells from the tunica media deposit collagen and elastic fibers. The thickened intima, called a **fibrous** or **atherosclerotic plaque**, has a core of dead and dying foam cells. At first the vessel walls accommodate the growing plaque by expanding outward, but eventually these fatty mounds begin to protrude into the vessel lumen, producing full-blown atherosclerosis (see bottom photo).
4. **The plaque becomes unstable.** As the plaque enlarges, the cells at its center die, calcium is deposited, and collagen fiber production declines. Now called a **complicated plaque**, it is unstable and prone to rupture.



***Top* A pipe clogged by accumulated deposits. *Bottom* Atherosclerotic plaques nearly close a human artery.**

Consequences

Plaques stiffen artery walls, causing *hypertension*. The increased pressure stresses the plaques, making them even more unstable. Plaques also constrict the vessel and cause the arterial walls to fray and ulcerate, conditions that encourage thrombus (clot) formation.

Two other factors also promote thrombus formation: (1) Injured endothelial cells make less anti-thrombotic chemicals. (2) *Lipoprotein (a)*, an altered form of LDL found in some individuals, inhibits fibrinolysis.

Plaque formation increases the risk of heart attacks and strokes, and is responsible for the pain (angina) that occurs when heart muscle is ischemic. Atherosclerosis, particularly of the aorta, can also cause *aneurysms* (ballooning of the arterial wall) that may burst.

Risk Factors

Why are some of us so troubled by atherosclerosis while others are seemingly immune to its ravages? A large number of interacting risk factors, such as increasing age, being male, family history, high blood cholesterol, hypertension, cigarette smoking, lack of exercise, diabetes, obesity, stress, and intake of trans fats are involved.

A growing body of evidence links systemic inflammation with the formation and subsequent rupture of atherosclerotic plaques. *C-reactive protein* is a marker of systemic inflammation that is measured to predict the likelihood of future heart attacks and strokes.

Prevention and Treatment

Some risk factors are under our control. We can avoid smoking, lose weight, exercise regularly to increase blood levels of high-density lipoprotein (HDL, the "good" lipoprotein that removes cholesterol from vessel walls and carries it to the liver), and eat a healthy diet low in saturated and trans fats.

But for many of us, these measures are not enough. Cholesterol-lowering, anti-inflammatory statins (and even the humble aspirin) can help decrease the risk of heart attacks and strokes.

Plaques that partially block arteries are treated in much the same way we would treat a blocked sewer pipe—dig it up and replace it or call a plumber to drill through the obstruction. In *coronary bypass surgery*, veins or small arteries removed from other areas of the body are implanted in the heart to restore its circulation. In *balloon angioplasty*, a balloon is passed through the vessels to the obstruction and then inflated to compress the fatty mass against the vessel wall.

Angioplasty temporarily clears the path, but *restenoses* (new blockages) often occur. *Stents*, short metal-mesh tubes, are sometimes used to help hold the vessel open.

When an atheroma ruptures and induces clot formation, *thrombolytic (clot-dissolving) agents* can help. A genetically engineered form of the naturally occurring *tissue plasminogen activator* (*tPA*) is injected directly into the blocked vessel. tPA restores blood flow quickly and puts an early end to many heart attacks and strokes in progress.

Of course, it's best to prevent atherosclerosis from progressing in the first place by changing our lifestyles. But how many of us will give up our burgers, butter, and sedentary lifestyles for the sake of preventing atherosclerosis?

Homeostatic Interrelationships between the Cardiovascular System and Other Body Systems

Integumentary System Chapter 5

- The cardiovascular system delivers oxygen and nutrients; carries away wastes
- The skin vasculature is an important blood reservoir and provides a site for heat loss from the body

Skeletal System Chapters 6–8

- The cardiovascular system delivers oxygen and nutrients; carries away wastes
- Bones are the sites of hematopoiesis; protect cardiovascular organs by enclosure; and provide a calcium depot

Muscular System Chapters 9–10

- The cardiovascular system delivers oxygen and nutrients; carries away wastes
- The muscular "pump" aids venous return; aerobic exercise enhances cardiovascular efficiency and helps prevent atherosclerosis

Nervous System Chapters 11–15

- The cardiovascular system delivers oxygen and nutrients; carries away wastes
- The ANS regulates cardiac rate and force; sympathetic division maintains blood pressure and controls blood flow to skin for thermoregulation

Endocrine System Chapter 16

- The cardiovascular system delivers oxygen and nutrients; carries away wastes; blood serves as a transport vehicle for hormones
- Various hormones influence blood pressure (epinephrine, ANP, angiotensin II, thyroxine, ADH); estrogens maintain vascular health in premenopausal women

Lymphatic System/Immunity Chapters 20–21

- The cardiovascular system delivers oxygen and nutrients to lymphatic organs, which house immune cells; provides transport medium for lymphocytes and antibodies; carries away wastes
- The lymphatic system picks up leaked fluid and plasma proteins and returns them to the cardiovascular system; immune cells protect cardiovascular organs from specific pathogens

Respiratory System Chapter 22

- The cardiovascular system delivers oxygen and nutrients; carries away wastes
- The respiratory system carries out gas exchange: loads oxygen and unloads carbon dioxide from the blood; respiratory "pump" aids venous return

Digestive System Chapter 23

- The cardiovascular system delivers oxygen and nutrients; carries away wastes
- The digestive system provides nutrients to the blood including iron and B vitamins essential for RBC (and hemoglobin) formation

Urinary System Chapters 25–26

- The cardiovascular system delivers oxygen and nutrients; carries away wastes; blood pressure drives filtration in the kidneys
- The urinary system helps regulate blood volume and pressure by altering urine volume and releasing renin

Reproductive System Chapter 27

- The cardiovascular system delivers oxygen and nutrients; carries away wastes
- Estrogens maintain vascular and bone health in women

Diuretic (*diure* = urinate) A chemical that promotes urine formation, thus reducing blood volume. Diuretic drugs are frequently prescribed to manage hypertension.

Phlebitis (flĕ-bi′tis; *phleb* = vein; *itis* = inflammation) Inflammation of a vein accompanied by painful throbbing and redness of the skin over the inflamed vessel. It is most often caused by bacterial infection or local physical trauma.

Phlebotomy (flĕ-bot′o-me; *tomy* = cut) A venous incision or puncture made for the purpose of withdrawing blood or bloodletting.

Sclerotherapy Procedure for removing varicose or spider veins. Tiny needles are used to inject scarring agents into the abnormal vein. The vein scars, closes down, and is absorbed by the body.

Superficial thrombophlebitis Inflammation and clot formation in superficial veins, usually in the leg.

CHAPTER SUMMARY

PART 1
BLOOD VESSEL STRUCTURE AND FUNCTION

1. Blood is transported throughout the body via a continuous system of blood vessels. Arteries transport blood away from the heart; veins carry blood back to the heart. Capillaries carry blood to tissue cells and are exchange sites.

19.1 Most blood vessel walls have three layers (p. 709)

1. All blood vessels except capillaries have three layers: tunica intima, tunica media, and tunica externa. Capillary walls are composed of the tunica intima only.

19.2 Arteries are pressure reservoirs, distributing vessels, or resistance vessels (p. 710)

1. Elastic (conducting) arteries are the large arteries close to the heart that expand during systole, acting as pressure reservoirs, and then recoil during diastole to keep blood moving. Muscular (distributing) arteries carry blood to specific organs; they are less stretchy and more active in vasoconstriction. Arterioles regulate blood flow into capillary beds.
2. Atherosclerosis is a degenerative vascular disease that decreases the elasticity of arteries.

19.3 Capillaries are exchange vessels (pp. 710–712)

1. Capillaries are microscopic vessels with very thin walls. Most exhibit intercellular clefts, which aid in the exchange between blood and interstitial fluid.
2. The most permeable capillaries are sinusoid capillaries (wide, tortuous channels). Fenestrated capillaries with pores are next most permeable. Least permeable are continuous capillaries, which lack pores.
3. Most capillary beds consist of a terminal arteriole leading into capillaries drained by a postcapillary venule. The diameter of the terminal arteriole and upstream arterioles determines the amount of blood flowing through the capillaries. In select capillary beds (e.g., mesenteric capillary beds), vascular shunts (metarteriole–thoroughfare channels) connect the terminal arteriole and postcapillary venule at opposite ends of a capillary bed. In this case, the amount of blood flowing into the true capillaries is regulated by precapillary sphincters.

19.4 Veins are blood reservoirs that return blood toward the heart (pp. 712–714)

1. Veins have comparatively larger lumens than arteries, and a system of valves prevents backflow of blood.
2. Normally most veins are not filled to capacity; for this reason, they can serve as blood reservoirs.

19.5 Anastomoses are special interconnections between blood vessels (p. 714)

1. The joining together of blood vessels to provide alternate channels in the same organ is called an anastomosis. Vascular anastomoses form between arteries, between veins, and between arterioles and venules.

PART 2
PHYSIOLOGY OF CIRCULATION

19.6 Blood flows from high to low pressure against resistance (pp. 714–715)

1. Blood flow is the amount of blood flowing through a vessel, an organ, or the entire circulation in a given period of time. Blood pressure (BP) is the force per unit area exerted on a vessel wall by the contained blood. Resistance is opposition to blood flow; blood viscosity and blood vessel length and diameter contribute to resistance.
2. Blood flow is directly proportional to blood pressure and inversely proportional to resistance.

Complete an interactive tutorial: MasteringA&P® > Study Area > Interactive Physiology > Cardiovascular System: Factors Affecting Blood Pressure.

19.7 Blood pressure decreases as blood flows from arteries through capillaries and into veins (pp. 716–718)

1. Systemic blood pressure is highest in the aorta and lowest in the venae cavae. The steepest drop in BP occurs in the arterioles, where resistance is greatest.
2. Arterial BP depends on compliance of the elastic arteries and on how much blood is forced into them. Arterial blood pressure is pulsatile, and peaks during systole; this is measured as systolic pressure. During diastole, as blood is forced distally in the circulation by the rebound of elastic arteries, arterial BP drops to its lowest value, called the diastolic pressure.
3. Pulse pressure is systolic pressure minus diastolic pressure. The mean arterial pressure (MAP) = diastolic pressure plus one-third of pulse pressure and is the pressure that keeps blood moving throughout the cardiac cycle.
4. Pulse and blood pressure measurements are used to assess cardiovascular efficiency.
5. The pulse is the alternating expansion and recoil of arterial walls with each heartbeat. Pulse points are also pressure points.
6. Blood pressure is routinely measured by the auscultatory method. Normal BP in adults is 120/80 mm Hg (systolic/diastolic).
7. Low capillary pressure (35 to 17 mm Hg) protects the delicate capillaries from rupture while still allowing adequate exchange across the capillary walls.

8. Venous pressure is nonpulsatile and low (declining to zero) because of the cumulative effects of resistance. Venous valves, large lumens, functional adaptations (muscular and respiratory pumps), and sympathetic nervous system activity promote venous return.

19.8 Blood pressure is regulated by short- and long-term controls (pp. 718–725)

1. Blood pressure varies directly with cardiac output, total peripheral resistance (TPR), and blood volume. Vessel diameter is the major factor determining resistance, and small changes in the diameter of vessels (chiefly arterioles) significantly affect blood pressure.
2. BP is regulated by autonomic neural reflexes involving baroreceptors or chemoreceptors, the cardiovascular center (a medullary center that includes the cardiac and vasomotor centers), and autonomic fibers to the heart and vascular smooth muscle.
3. Activation of the receptors by falling BP (and to a lesser extent by a rise in blood CO_2, or falling blood pH or O_2 levels) stimulates the vasomotor center to increase vasoconstriction and the cardioacceleratory center to increase heart rate and contractility. Rising BP inhibits the vasomotor center (permitting vasodilation) and activates the cardioinhibitory center.
4. Higher brain centers (cerebrum and hypothalamus) may modify neural controls of BP via medullary centers.
5. Hormones that increase BP by promoting vasoconstriction include epinephrine and NE (these also increase heart rate and contractility), ADH, and angiotensin II (generated in response to renin release by kidney cells). Atrial natriuretic peptide is a hormone that promotes vasodilation and also causes a decline in blood volume.
6. The kidneys regulate blood pressure by regulating blood volume. Rising BP directly enhances filtrate formation and fluid losses in urine; falling BP causes the kidneys to retain more water, increasing blood volume.
7. Indirect renal regulation of blood volume involves the renin-angiotensin-aldosterone mechanism, a hormonal mechanism. When BP falls, the kidneys release renin, which triggers the formation of angiotensin II. Angiotensin II causes (1) release of aldosterone, stimulating salt and water retention, (2) vasoconstriction, (3) release of ADH, and (4) thirst.
8. Chronic hypertension (high blood pressure) is persistent BP readings of 140/90 or higher. It indicates increased total peripheral resistance, which strains the heart and promotes vascular complications of other organs, particularly the eyes and kidneys. It is a major cause of myocardial infarction, stroke, and renal disease. Risk factors are high-fat, high-salt diet, obesity, diabetes mellitus, advanced age, smoking, stress, and being a member of the black race or a family with a history of hypertension.
9. Hypotension, or low blood pressure (below 90/60 mm Hg), is rarely a problem except in circulatory shock.
10. Circulatory shock occurs when blood perfusion of body tissues is inadequate. Most cases of shock reflect low blood volume (hypovolemic shock), abnormal vasodilation (vascular shock), or pump failure (cardiogenic shock).

19.9 Intrinsic and extrinsic controls determine blood flow through tissues (pp. 725–730)

1. Intrinsic controls (autoregulation) involve local adjustment of blood flow to individual organs based on their immediate requirements. Extrinsic controls (nerves and hormones) maintain MAP and redistribute blood during exercise and thermoregulation.
2. Autoregulation involves myogenic controls that maintain flow despite changes in blood pressure, and local chemical factors. Vasodilators include increased CO_2, H^+, and nitric oxide. Decreased O_2 concentrations also cause vasodilation. Other factors, including endothelins, decrease blood flow.
3. In most instances, autoregulation is controlled by the accumulation of local metabolites and the lack of oxygen. However, autoregulation in the brain is controlled primarily by a drop in pH and by myogenic mechanisms; and pulmonary circuit vessels dilate in response to high levels of oxygen.

19.10 Slow blood flow through capillaries promotes diffusion of nutrients and gases, and bulk flow of fluids (pp. 730–734)

1. Blood flows fastest where the cross-sectional area of the vascular bed is least (aorta), and slowest where the total cross-sectional area is greatest (capillaries). The slow flow in capillaries allows time for nutrient-waste exchanges.
2. Nutrients, gases, and other solutes smaller than plasma proteins cross the capillary wall by diffusion; larger molecules are actively transported via pinocytotic vesicles. Water-soluble substances move through the clefts or fenestrations; fat-soluble substances pass through the lipid portion of the endothelial cell membrane.
3. Bulk flow of fluids at capillary beds determines the distribution of fluids between the bloodstream and the interstitial space. It reflects the relative effects of hydrostatic and osmotic pressures acting at the capillary (outward minus inward pressures). In general, fluid flows out of the capillary bed at the arteriolar end and reenters the capillary blood at the venule end.
4. Lymphatic vessels collect the small net loss of fluid and protein into the interstitial space and return it to the cardiovascular system.
5. Edema is an abnormal accumulation of fluid in the interstitial space as a result of imbalances in pressures that drive bulk flow or a block of lymphatic drainage.

PART 3
CIRCULATORY PATHWAYS: BLOOD VESSELS OF THE BODY

1. The pulmonary circulation transports O_2-poor, CO_2-laden blood to the lungs for oxygenation and carbon dioxide unloading. Blood returning to the right atrium of the heart is pumped by the right ventricle to the lungs via the pulmonary trunk. Blood issuing from the lungs is returned to the left atrium by the pulmonary veins. (See Table 19.3 and Figure 19.21.)
2. The systemic circulation transports oxygenated blood from the left ventricle to all body tissues via the aorta and its branches. Venous blood returning from the systemic circuit is delivered to the right atrium via the venae cavae.
3. All arteries are deep, while veins are both deep and superficial. Superficial veins tend to have numerous interconnections. Dural venous sinuses and the hepatic portal circulation are unique venous drainage patterns.

19.8 The vessels of the systemic circulation transport blood to all body tissues (pp. 735–759)

1. Tables 19.3 to 19.13 and Figures 19.22 to 19.32 illustrate and describe vessels of the systemic circulation.

Developmental Aspects of Blood Vessels (p. 759)

1. The fetal vasculature develops from embryonic blood islands and mesenchyme and functions in blood delivery by the fourth week.
2. Fetal circulation differs from circulation after birth. The pulmonary and hepatic shunts and special umbilical vessels are normally occluded shortly after birth.
3. Blood pressure is low in infants and rises to adult values. Age-related vascular problems include varicose veins, hypertension, and atherosclerosis. Hypertension and associated atherosclerosis are the most important causes of cardiovascular disease in the aged.

REVIEW QUESTIONS

To access additional practice questions using your smartphone, tablet, or computer: MasteringA&P® > Study Area > Practice Tests & Quizzes

Level 1 Remember/Understand

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Which statement does not accurately describe veins? **(a)** have less elastic tissue and smooth muscle than arteries, **(b)** contain more fibrous tissue than arteries, **(c)** most veins in the extremities have valves, **(d)** always carry deoxygenated blood.
2. Total peripheral resistance **(a)** is inversely proportional to the length of the vascular bed, **(b)** increases in anemia, **(c)** decreases in polycythemia, **(d)** is inversely related to the diameter of the arterioles.
3. Which of the following can lead to decreased venous return of blood to the heart? **(a)** an increase in blood volume, **(b)** an increase in venous pressure, **(c)** damage to the venous valves, **(d)** increased muscular activity.
4. Arterial blood pressure increases in response to **(a)** increasing stroke volume, **(b)** increasing heart rate, **(c)** atherosclerosis, **(d)** rising blood volume, **(e)** all of these.
5. Which of the following would *not* result in the dilation of the terminal arterioles and upstream arterioles in systemic capillary beds? **(a)** a decrease in local tissue O_2 content, **(b)** an increase in local tissue CO_2, **(c)** a local increase in histamine, **(d)** a local increase in pH.
6. The structure of a capillary wall differs from that of a vein or an artery because **(a)** it has two tunics instead of three, **(b)** there is less smooth muscle, **(c)** it has a single tunic—only the tunica intima, **(d)** none of these.
7. The baroreceptors in the carotid sinus and aortic arch are sensitive to **(a)** a decrease in CO_2, **(b)** changes in arterial pressure, **(c)** a decrease in O_2, **(d)** all of these.
8. The myocardium receives its blood supply directly from the **(a)** aorta, **(b)** coronary arteries, **(c)** coronary sinus, **(d)** pulmonary arteries.
9. Blood flow in the capillaries is steady despite the rhythmic pumping of the heart because of the **(a)** elasticity of the large arteries, **(b)** small diameter of capillaries, **(c)** thin walls of the veins, **(d)** venous valves.
10. Using the letters from column B, match the artery descriptions in column A. (Note that some require more than a single choice.)

Column A	Column B
____ **(1)** unpaired branch of abdominal aorta	**(a)** right common carotid
____ **(2)** second branch of aortic arch	**(b)** superior mesenteric
____ **(3)** branch of internal carotid	**(c)** left common carotid
____ **(4)** branch of external carotid	**(d)** external iliac
____ **(5)** origin of femoral arteries	**(e)** inferior mesenteric
	(f) superficial temporal
	(g) celiac trunk
	(h) facial
	(i) ophthalmic
	(j) internal iliac

11. Which of the following do not drain directly into the inferior vena cava? **(a)** inferior phrenic veins, **(b)** hepatic veins, **(c)** inferior mesenteric vein, **(d)** renal veins.

Level 2 Apply/Analyze

12. Tracing the blood from the heart to the right hand, we find that blood leaves the heart and passes through the aorta, the right subclavian artery, the axillary and brachial arteries, and through either the radial or ulnar artery to arrive at the hand. Which artery is missing from this sequence? **(a)** coronary, **(b)** brachiocephalic, **(c)** cephalic, **(d)** right common carotid.
13. How is the anatomy of capillaries and capillary beds well suited to their function?
14. **(a)** Define blood pressure. Differentiate between systolic and diastolic blood pressure. **(b)** What is the normal blood pressure value for an adult?
15. Describe the neural mechanisms responsible for controlling blood pressure.
16. How are nutrients, wastes, and respiratory gases transported to and from the blood and tissue spaces?
17. **(a)** What blood vessels contribute to the formation of the hepatic portal circulation? **(b)** Why is a portal circulation a "strange" circulation?
18. Physiologists often consider capillaries and postcapillary venules together. **(a)** What functions do these vessels share? **(b)** Structurally, how do they differ?

Level 3 Evaluate/Synthesize

19. Distinguish between elastic arteries, muscular arteries, and arterioles relative to location, histology, and functional adaptations.
20. Write an equation showing the relationship between total peripheral resistance, blood flow, and blood pressure.
21. Explain the reasons for the observed changes in blood flow velocity in the different regions of the circulation.
22. How does the control of blood flow to the skin for the purpose of regulating body temperature differ from the control of nutrient blood flow to skin cells?
23. Describe neural and chemical (both systemic and local) effects exerted on the blood vessels when you are fleeing from a mugger. (Be careful, this is more involved than it appears at first glance.)
24. A 60-year-old man is unable to walk more than 100 yards without experiencing severe pain in his left leg; the pain is relieved by resting for 5–10 minutes. He is told that the arteries of his leg are becoming occluded with fatty material and is advised to have the sympathetic nerves serving that body region severed. Explain how such surgery might help to relieve this man's problem.
25. Your friend Jillian, who knows little about science, is reading a magazine article about a patient who had an "aneurysm at the base of his brain that suddenly grew much larger." The surgeons' first goal was to "keep it from rupturing," and the second goal was to

"relieve the pressure on the brain stem and cranial nerves." The surgeons were able to "replace the aneurysm with a section of plastic tubing," so the patient recovered. Jillian asks you what all this means. Explain. (Hint: Check this chapter's Related Clinical Terms, p. 759.)

26. The Agawam High School band is playing some lively marches while the coaches are giving pep talks to their respective football squads. Although it is September, it is unseasonably hot (88°F/31°C) and the band uniforms are wool. Suddenly Ryan, the tuba player, becomes light-headed and faints. Explain his fainting in terms of vascular events.

27. When we are cold or the external temperature is low, most venous blood returning from the distal part of the arm travels in the deep veins where it picks up heat (by countercurrent exchange) from the nearby brachial artery en route. However, when we are hot, and especially during exercise, venous return from the distal arm travels in the superficial veins and those veins tend to bulge superficially in a person who is working out. Explain why venous return takes a different route in the second situation.

28. Edema is a common clinical problem. On your first day of a clinical rotation, you encounter four patients who have edema for different reasons. Your challenge is to explain the edema in terms of either an increase or a decrease in one of the four pressures that causes bulk flow (see Focus Figure 19.1 on pp. 732–733).

(1) First you encounter Mrs. Taylor in the medical unit awaiting a liver transplant. What is the connection between liver failure and her edema?

(2) Next in the obstetric ward, Mrs. So is experiencing premature labor and has edema in her legs. Which bulk flow pressures might be altered here?

(3) In emergency, Mr. Herrera is in anaphylactic shock. His capillaries have become leaky, allowing plasma proteins that are normally kept inside the blood vessels to escape into the interstitial fluid. Which of the bulk flow pressures is altered in this case and in what direction is the change?

(4) Finally, in oncology Mrs. O'Leary is recovering from breast cancer surgery. Her right breast and all of her axillary lymph nodes were removed. Unfortunately, this severed most of the lymphatic vessels draining her right arm. You notice that this arm is quite edematous. Why? Mrs. O'Leary is given a compression sleeve to wear on this arm to help relieve the edema. Which of the bulk flow pressures will be altered by the compression sleeve?

CLINICAL CASE STUDY

62-Year-Old Male Astronaut with Hypotension

You're working in the ER when a crowd of security guards and photographers arrive! They're all here with Captain Fallowell, an astronaut who has spent the last eight months aboard the International Space Station. He passed out in the middle of his first speaking engagement.

Captain Fallowell is a fit-looking 62-year-old male, alert and oriented. His heart rate is 85 beats/min, but he admits it was racing during his speech. His pulse is weak and his BP is 116/66 mm Hg while lying down, but his heart rate is 112 beats/min and BP is 94/52 mm Hg when standing. Reflexes are normal and there is no sign of head trauma. He admits to occasional dizziness and blackouts upon standing.

1. Calculate Captain Fallowell's pulse pressure and MAP when he is lying down and when he is standing.

2. ✚ NCLEX-STYLE When the patient stood up, his heart rate increased. This was most likely caused by which of the following?
- **a.** Parasympathetic activation due to the change in posture
- **b.** The baroreceptor reflex activated by blood pooling in his lower body due to gravity
- **c.** A decrease in sympathetic tone due to the stress of movement
- **d.** An increase in the amount of blood the heart has to pump, because the movements of his leg muscles forced venous blood up into the right atrium

3. As Captain Fallowell stands up, he complains of dizziness and you notice that he turns pale. What causes this, and why does it happen?

4. Two of the nurses are discussing the case. One says "He must be fit. They make them exercise two hours a day up there!" The second nurse says, "Yes, but I heard the blood and tissue fluids all shift up into their head and torso and they get skinny 'chicken legs.'" What effect would increased circulating blood volume in the head and torso have on the sympathetic and parasympathetic nervous systems and on the heart rate?

5. ✚ NCLEX-STYLE Captain Fallowell's drop in blood pressure when standing up is most likely due to:
- **a.** Decreased total peripheral resistance due to lowered blood viscosity
- **b.** Increased total peripheral resistance due to vasodilation
- **c.** Decreased cardiac output due to low heart rate
- **d.** Decreased cardiac output due to low stroke volume

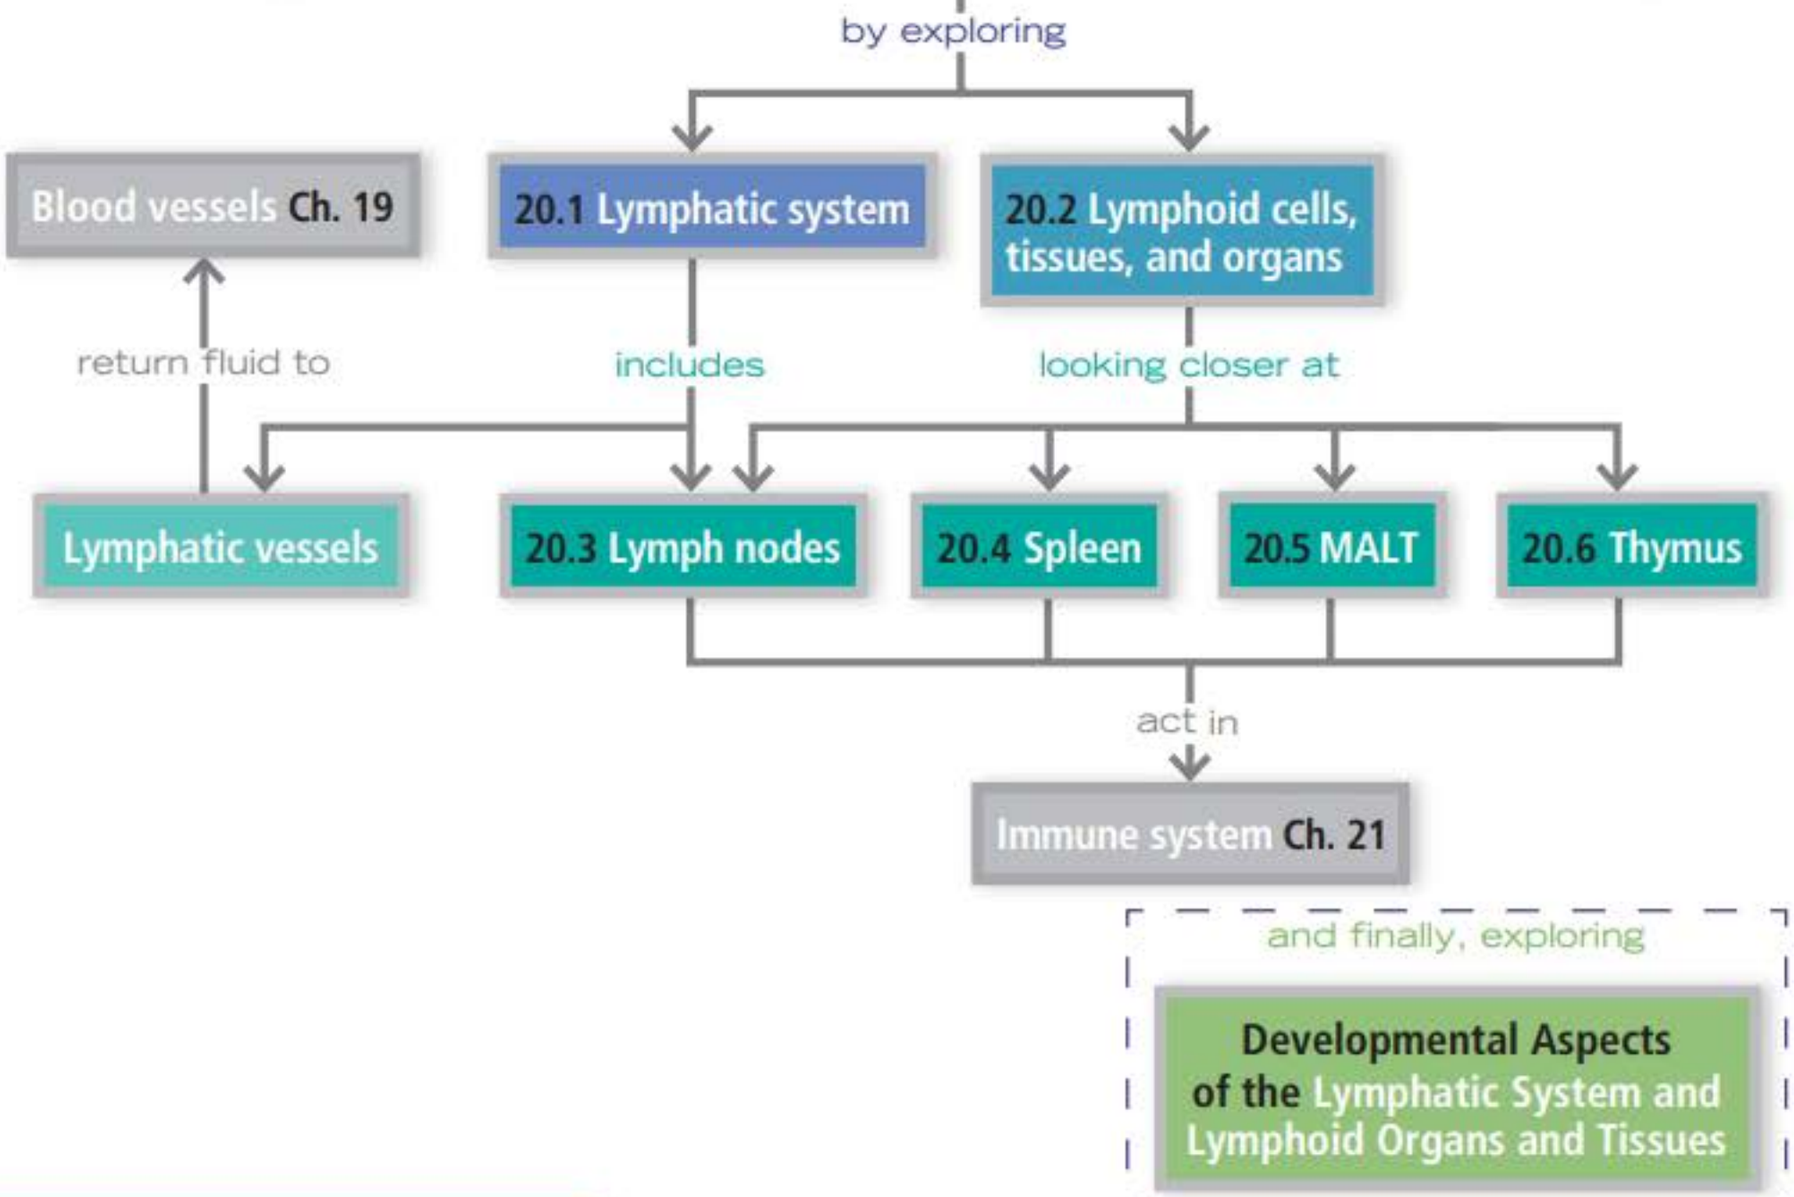
6. When Captain Fallowell was in the space station, he had more blood circulating through his torso and to his internal organs. As a result, what happened to each of the following measures for him?
- **a.** Renin levels
- **b.** Aldosterone levels
- **c.** ADH levels
- **d.** Thirst
- **e.** Atrial natriuretic peptide
- **f.** Urine volume
- **g.** Blood volume

20 The Lymphatic System and Lymphoid Organs and Tissues

In this chapter, you will learn that

The lymphatic system returns leaked fluid to the blood; the lymphoid organs and tissues provide the anatomical basis for the body's defenses

by exploring



CAREER CONNECTION

Watch a video to learn how the chapter content is used in a real health care setting. Go to Mastering A&P® > Study Area > Animations and Videos or use quick access URL https://goo.gl/88srfV

They can't all be superstars! When we mentally tick off the names of the body's organ systems, the lymphatic (lim-fat′ik) system and the lymphoid organs and tissues are probably not the first to come to mind. Yet if they failed their quiet background work, our cardiovascular system would stop working and our immune system would be hopelessly impaired.

In this chapter, we will explore two functionally different but structurally overlapping systems, the *lymphatic system* and the *lymphoid organs and tissues*. The **lymphatic system** returns fluids that have leaked from the vascular system back to the blood. It consists of three parts:

- A meandering network of *lymphatic vessels*
- *Lymph*, the fluid contained in those vessels
- *Lymph nodes* that cleanse the lymph as it passes through them

The **lymphoid organs and tissues** provide the structural basis of the immune system. These organs and tissues play essential roles in the body's defense mechanisms and its resistance to disease. These structures include the spleen, thymus, tonsils, and other lymphoid tissues scattered throughout the body. The lymph nodes are also part of this system, and like a keystone, they have important roles to play in both the lymphoid organs and tissues and the lymphatic system.

Let's begin by looking at the lymphatic system.

20.1 The lymphatic system includes lymphatic vessels, lymph, and lymph nodes

Learning Outcomes

- **List the functions of the lymphatic vessels.**
- **Describe the structure and distribution of lymphatic vessels.**
- **Describe the source of lymph and mechanism(s) of lymph transport.**

As blood circulates through the body, nutrients, wastes, and gases are exchanged between the blood and the interstitial fluid. As we explained in *Focus on Bulk Flow across Capillary Walls* (◀ Focus Figure 19.1, pp. 732–733), the hydrostatic and colloid osmotic pressures operating at capillary beds force fluid out of the blood at the arterial ends of the beds ("upstream") and cause most of it to be reabsorbed at the venous ends ("downstream"). The fluid that remains behind in the tissue spaces, as much as 3 L daily, becomes part of the interstitial fluid.

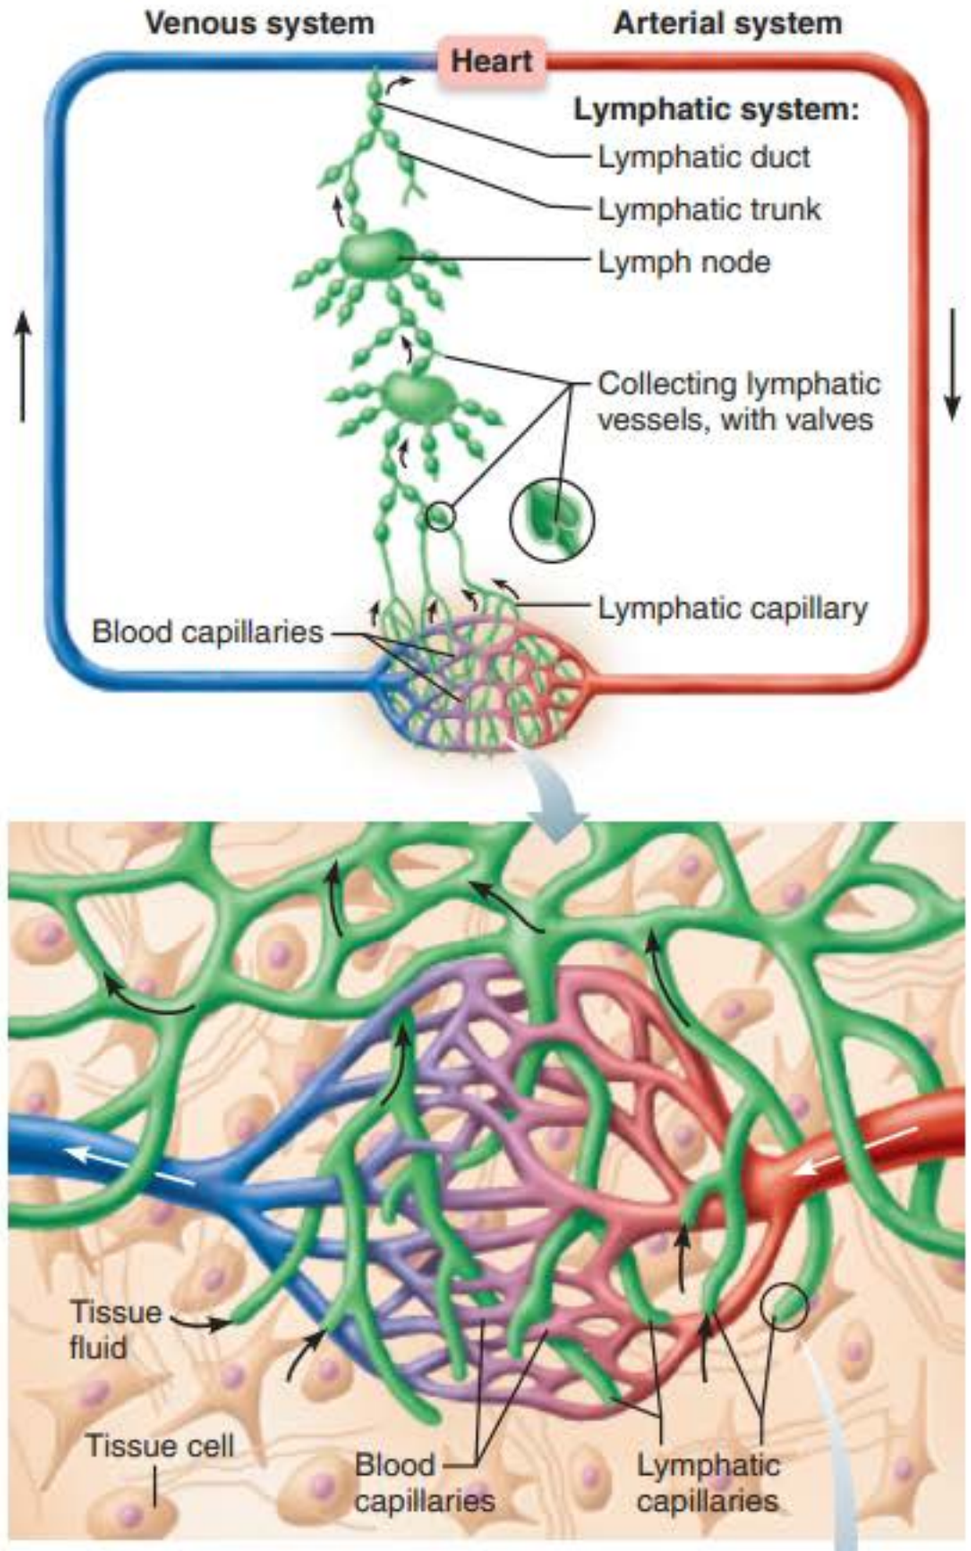
This leaked fluid, plus any plasma proteins that escape from the bloodstream, must somehow be returned to the blood to ensure that the cardiovascular system has sufficient blood volume. This problem of circulatory dynamics is resolved by the **lymphatic vessels**, or **lymphatics**, elaborate networks of drainage vessels that collect the excess protein-containing interstitial fluid and return it to the bloodstream. Once interstitial fluid enters the lymphatic vessels, it is called **lymph** (*lymph* = clear water).

Distribution and Structure of Lymphatic Vessels

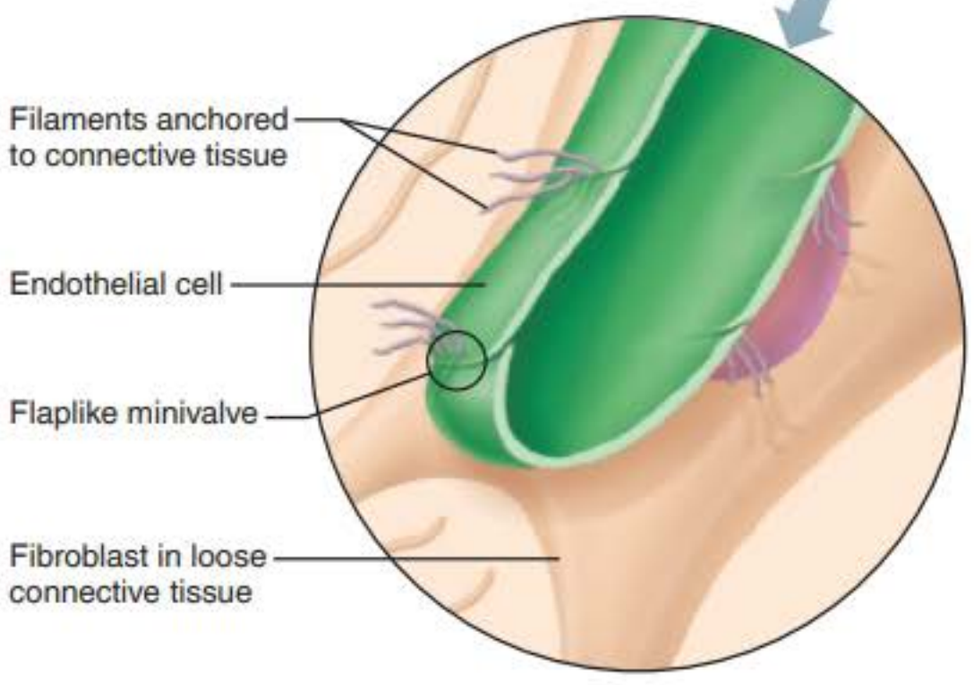
The lymphatic vessels form a one-way system in which lymph flows only toward the heart.

Lymphatic Capillaries

The transport of lymph begins in microscopic blind-ended **lymphatic capillaries** (**Figure 20.1a**). These capillaries weave between the tissue cells and blood capillaries in the loose connective tissues of the body. Lymphatic capillaries are widespread, but they are absent from bones (including bone marrow) and



(a) Structural relationship between a capillary bed of the blood vascular system and lymphatic capillaries.



(b) Lymphatic capillaries are blind-ended tubes in which adjacent endothelial cells overlap each other, forming flaplike minivalves.

Figure 20.1 Distribution and special features of lymphatic capillaries. Arrows in (a) indicate direction of fluid movement.

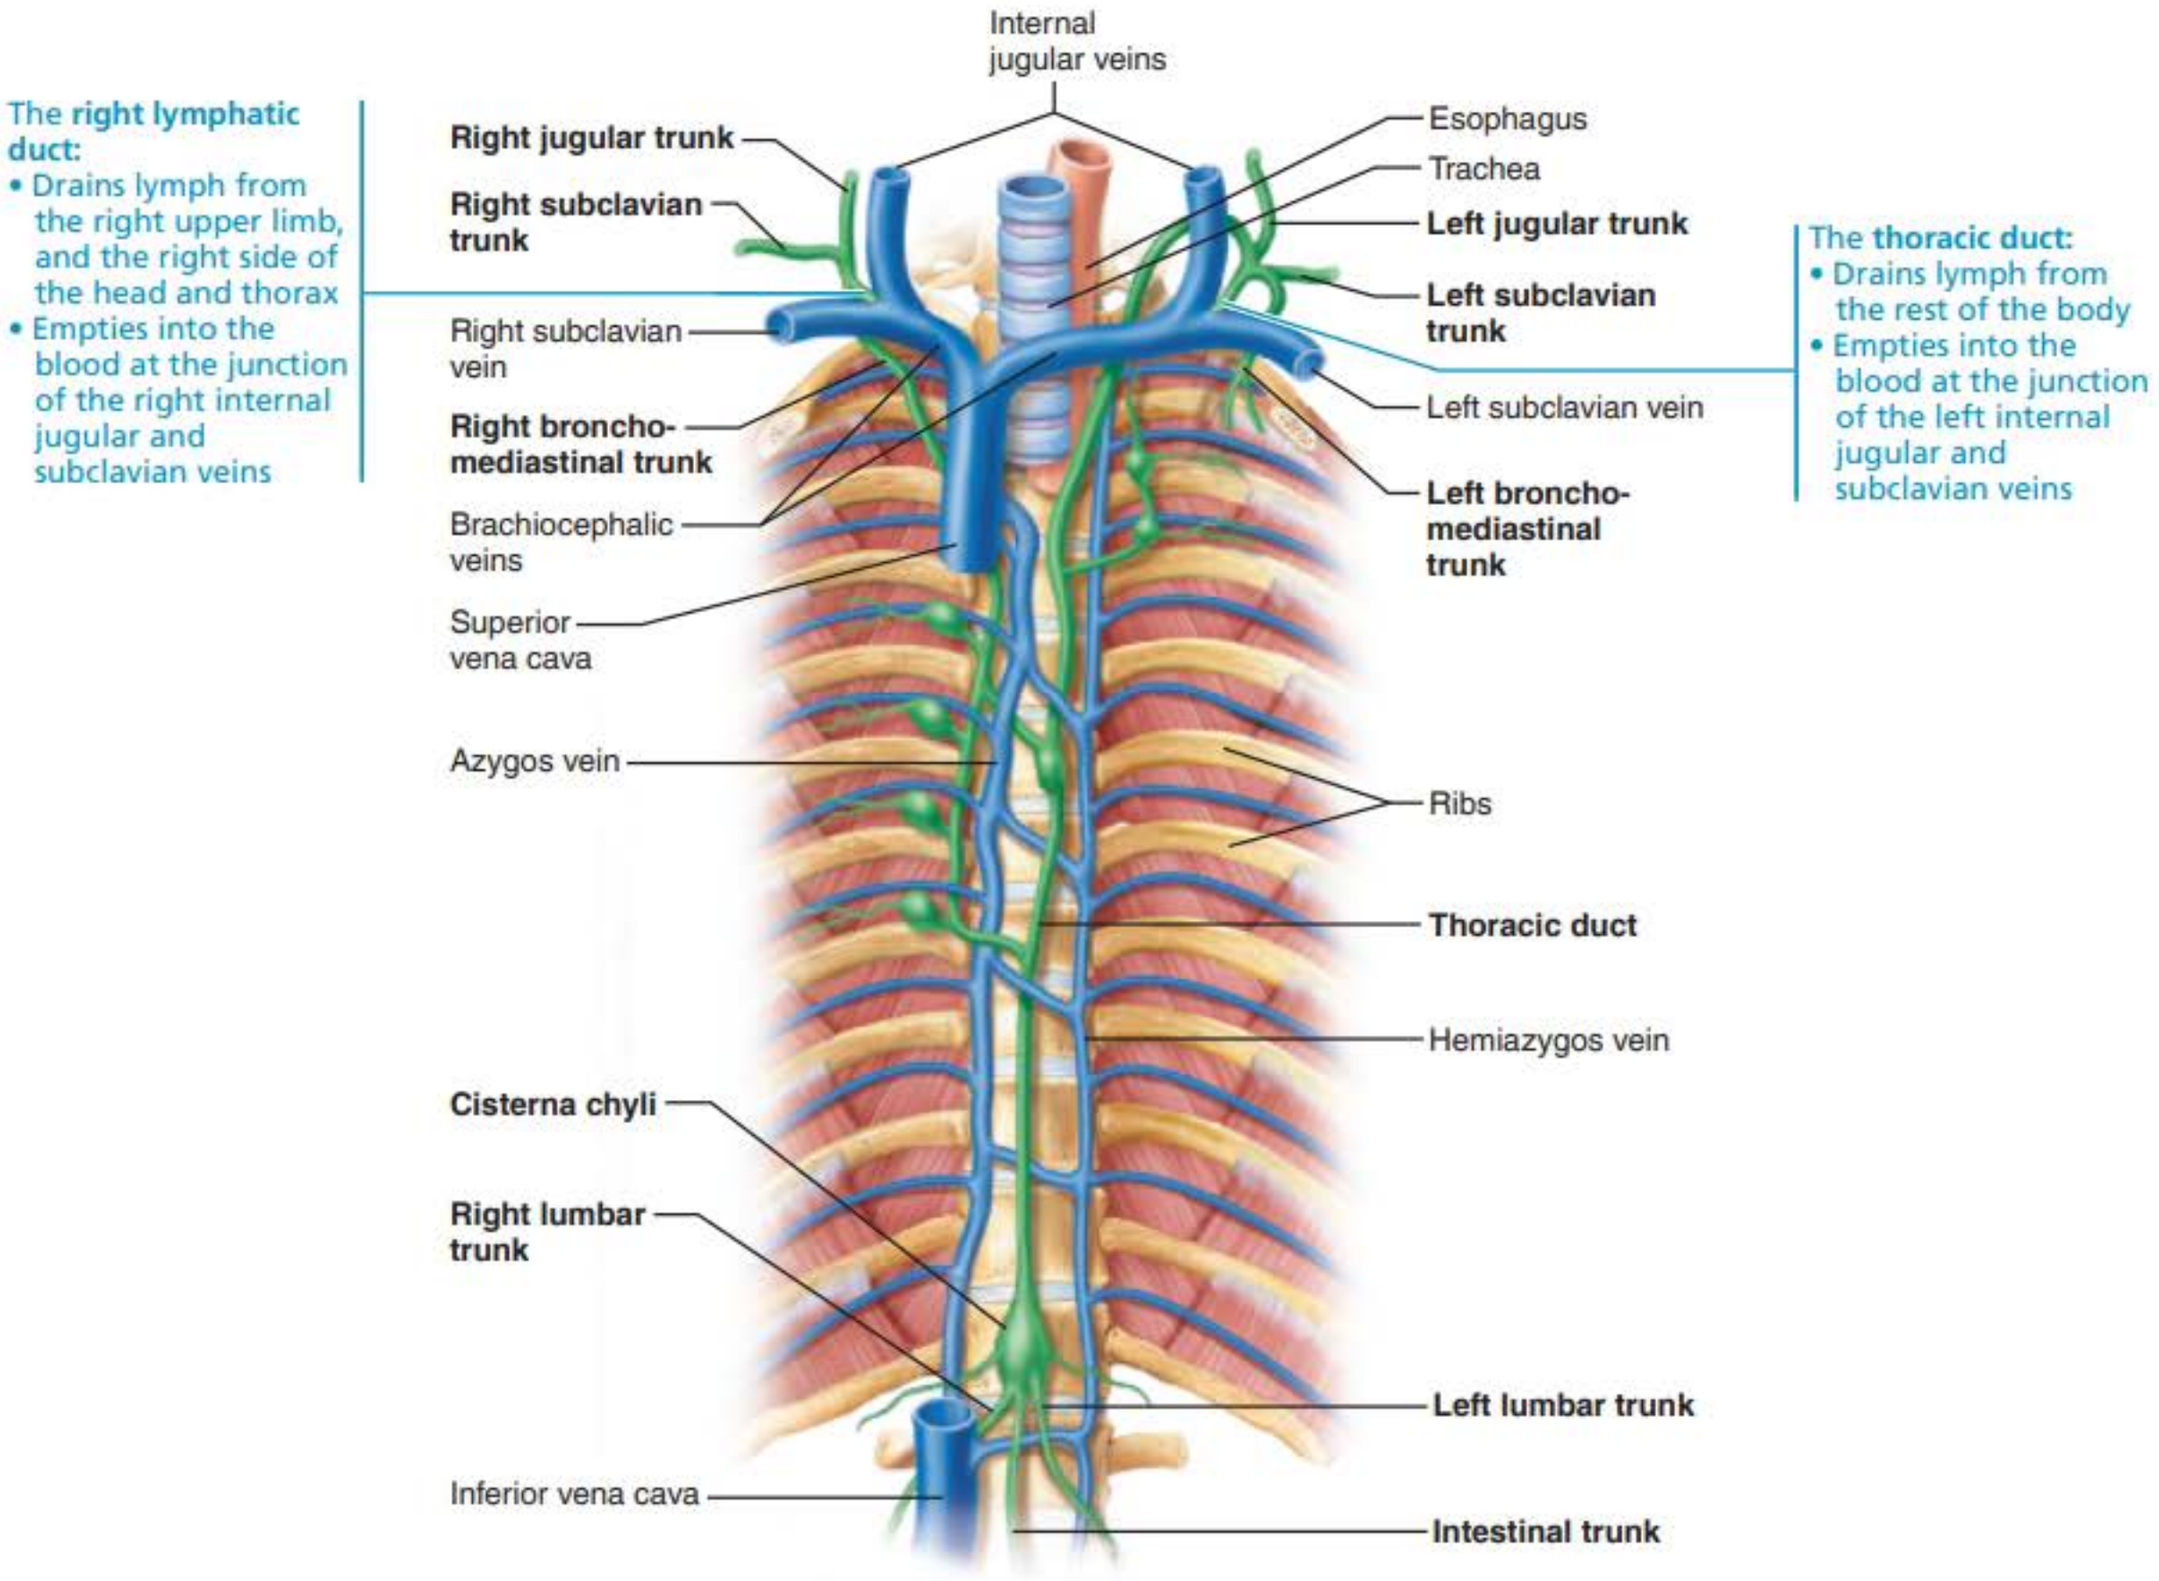


Figure 20.2 Major lymphatic trunks and ducts. Anterior view of thoracic and abdominal wall. See Figure 20.3 for regions drained by each duct.

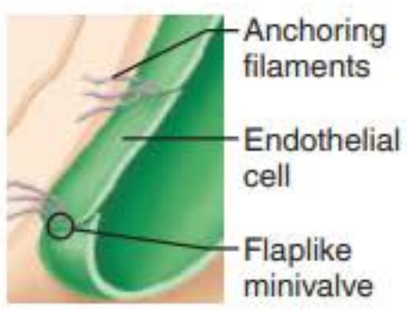
teeth. Lymphatic capillaries were long thought to be absent from the central nervous system, but recent evidence shows that they are present but restricted to limited locations in the meninges. These vessels help drain the extracellular fluids in the brain (interstitial and cerebrospinal fluids).

Although similar to blood capillaries, lymphatic capillaries are so remarkably permeable that they were once thought to be open at one end like a straw. We now know that they owe their permeability to two unique structural modifications:

- The endothelial cells forming the walls of lymphatic capillaries are not tightly joined. Instead, the edges of adjacent cells overlap each other loosely, forming easily opened, flaplike *minivalves* (shown at right).



- Collagen filaments anchor the endothelial cells to surrounding structures so that any increase in interstitial fluid volume opens the minivalves, rather than causing the lymphatic capillaries to collapse.

So, what we have is a system analogous to one-way swinging doors in the lymphatic capillary wall. When fluid pressure in the interstitial space is greater than the pressure in the lymphatic capillary, the minivalve flaps gape open, allowing fluid to enter the lymphatic capillary. However, when the pressure is greater *inside* the lymphatic capillary, it forces the endothelial minivalve flaps shut, preventing lymph from leaking back out as the pressure moves it along the vessel.

Proteins in the interstitial space are unable to enter blood capillaries, but they enter lymphatic capillaries easily. In addition, when tissues become inflamed, lymphatic capillaries develop openings that permit uptake of even larger particles such as cell debris, pathogens (disease-causing microorganisms such as bacteria and viruses), and cancer cells. These particles travel with the lymph to the lymph nodes, where they are removed by cells of the immune system. The process of pathogens meeting up with immune cells in lymph nodes is critical

for activating an immune response. In some cases, unfortunately, pathogens or cancer cells manage to pass through the lymph nodes and can then travel throughout the body.

A special set of lymphatic capillaries called **lacteals** (lak′te-alz) transports absorbed fat from the small intestine to the bloodstream (see Figure 23.31b, p. 902). Lacteals are so called because of the milky white lymph that drains through them (*lact* = milk). This fatty lymph, called **chyle** ("juice"), drains from the fingerlike villi of the intestinal mucosa.

Larger Lymphatic Vessels

From the lymphatic capillaries, lymph flows through successively larger and thicker-walled channels:

Lymphatic capillaries → Collecting lymphatic vessels → Lymphatic trunks → Lymphatic ducts

The **collecting lymphatic vessels** have the same three tunics as veins, but the collecting vessels have thinner walls and more internal valves, and they anastomose more. In general, lymphatics in the skin travel along with superficial *veins*, while the deep lymphatic vessels of the trunk and digestive viscera travel with the deep *arteries*. The exact anatomical distribution of lymphatic vessels varies greatly between individuals, even more than it does for veins.

The largest collecting vessels unite to form **lymphatic trunks**, which drain fairly large areas of the body. The major trunks, named mostly for the regions from which they drain lymph, are the paired **lumbar**, **bronchomediastinal**, **subclavian**, and **jugular trunks**, and the single **intestinal trunk** (**Figure 20.2**).

Lymph is eventually delivered to one of two large *ducts* in the thoracic region. The **right lymphatic duct** drains lymph from the right upper limb and the right side of the head and thorax (**Figure 20.3**). The much larger **thoracic duct** receives lymph from the rest of the body. It collects lymph from the two large lumbar trunks that drain the lower limbs and from the intestinal trunk that drains the digestive organs. In about half of individuals, the thoracic duct begins as an enlarged sac, the **cisterna chyli** (sis-ter′nah ki′li), located in the region between the last thoracic and second lumbar vertebrae. As the thoracic duct runs superiorly, it receives lymphatic drainage from the left side of the thorax, left upper limb, and the left side of the head. Each terminal duct empties its lymph into the venous circulation at the junction of the internal jugular vein and subclavian vein on its own side of the body (Figure 20.2).

HOMEOSTATIC IMBALANCE 20.1 CLINICAL

Like the larger blood vessels, the larger lymphatics receive their nutrient blood supply from a branching vasa vasorum. When lymphatic vessels are severely inflamed, the related vessels of the vasa vasorum become congested with blood. As a result, the pathway of the associated superficial lymphatics becomes visible through the skin as red streaks that are tender to the touch. This unpleasant condition is called *lymphangitis* (lim″fan-ji′tis; *angi* = vessel).

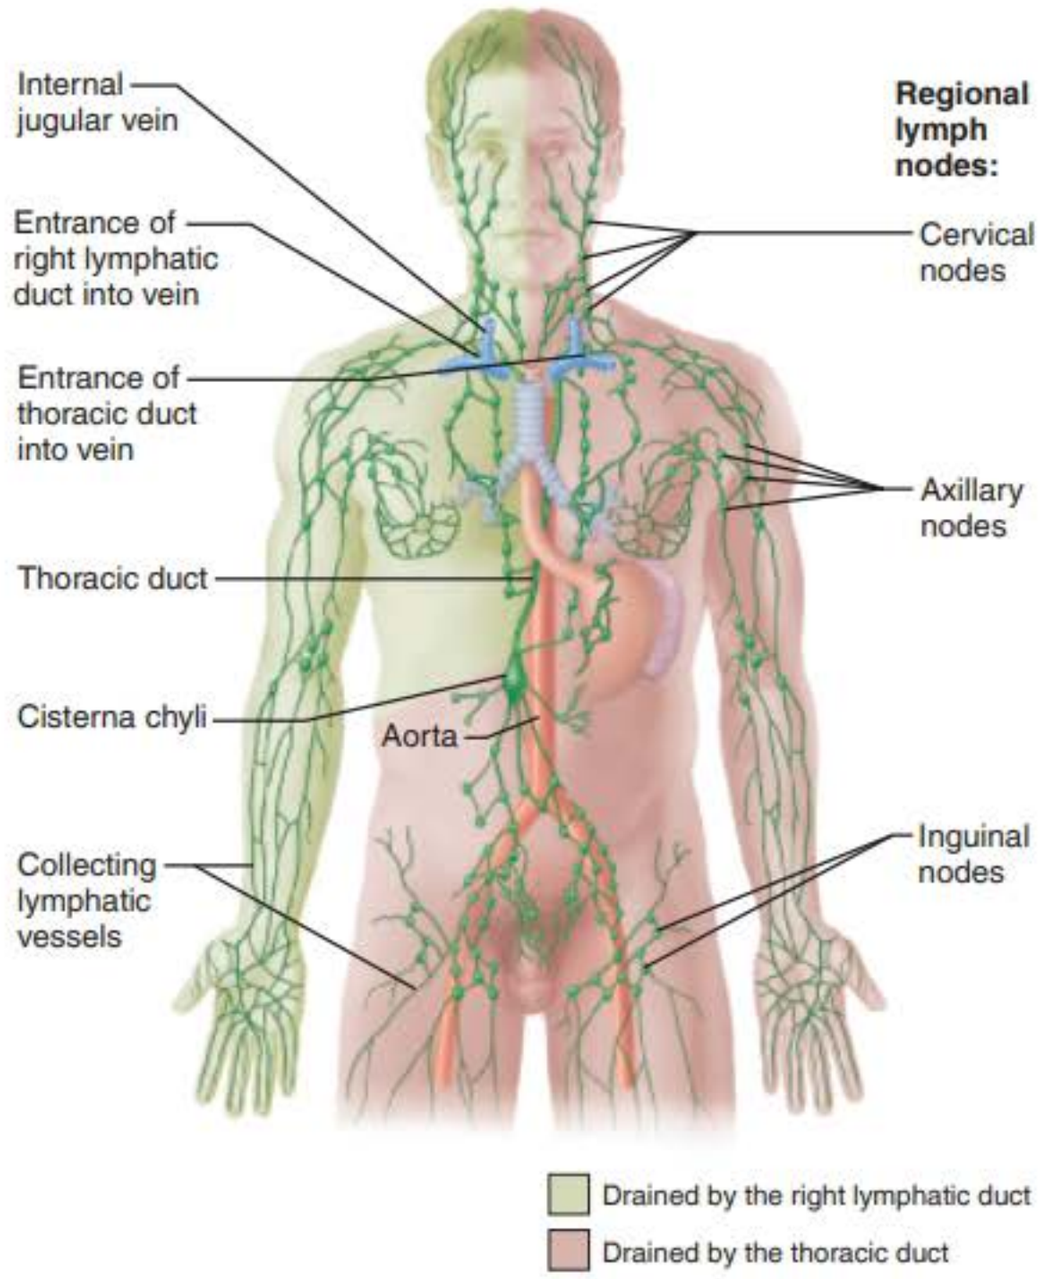


Figure 20.3 The lymphatic system. General distribution of collecting lymphatic vessels and regional lymph nodes.

Lymph Transport

The lymphatic system lacks an organ that acts as a pump. Under normal conditions, lymphatic vessels are low-pressure conduits, and the same mechanisms that promote venous return in blood vessels act here as well—the milking action of active skeletal muscles, pressure changes in the thorax during breathing, and valves to prevent backflow. Lymphatic vessels are usually bundled together in connective tissue sheaths along with blood vessels, and pulsations of nearby arteries also promote lymph flow. In addition to these mechanisms, smooth muscle in the walls of all but the smallest lymphatic vessels contracts rhythmically, helping to pump the lymph along.

Even so, lymph transport is sporadic and slow. Movement of adjacent tissues is extremely important in propelling lymph through the lymphatics. When physical activity or passive movements increase, lymph flows much more rapidly (balancing the greater rate of fluid loss from the blood in such situations). For this reason, it is a good idea to immobilize a badly infected body part to hinder flow of inflammatory material from that region.

HOMEOSTATIC IMBALANCE 20.2 CLINICAL

Anything that prevents the normal return of lymph to the blood—such as when tumors block the lymphatics or

lymphatics are removed during cancer surgery—results in short-term but severe localized edema (*lymphedema*) (◀ p. 734). In some cases, the lymphedema improves if some lymphatic pathways remain and can enlarge.

To summarize, the lymphatic vessels:

- Return excess tissue fluid to the blood
- Return leaked proteins to the blood
- Carry pathogens to lymph nodes
- Carry absorbed fat from the intestine to the blood (through lacteals)

Check Your Understanding

1. What is lymph? Where does it come from?
2. Name two lymphatic ducts and indicate the body regions usually drained by each.
3. What is the driving force for lymph movement?
4. MAKE CONNECTIONS A tumor in the left groin is blocking lymphatic drainage from Mr. Thomas's left leg, causing obvious edema. Which two of the functions of lymphatic vessels listed above no longer work in that leg? Think about the pressures driving bulk flow (Chapter 19) and state which two pressures are affected by the loss of these two lymphatic vessel functions and how the pressures are affected.

For answers, see Answers Appendix.

20.2 Lymphoid cells and tissues are found in lymphoid organs and in connective tissue of other organs

Learning Outcome

▶ **Describe the basic structure and cellular population of lymphoid tissue. Differentiate between diffuse and follicular lymphoid tissues.**

To understand the role of the lymphoid organs in the body, we need to investigate their components—lymphoid cells and lymphoid tissues—before considering the organs themselves.

Lymphoid Cells

The lymphoid cells consist of immune system cells found in lymphoid tissues together with the supporting cells that form the "scaffolding" of those tissues.

Lymphocytes are the main warriors of the immune system. There are two main varieties of lymphocytes—**T cells (T lymphocytes)** and **B cells (B lymphocytes)**—that protect the body against antigens. (*Antigens* are anything that provokes an immune response, such as bacteria and their toxins, viruses, mismatched RBCs, or cancer cells.) Activated T cells manage the immune response, and some of them directly attack and destroy infected cells. Activated B cells protect the body by producing **plasma cells**, daughter cells that secrete antibodies into the blood (or other body fluids). Antibodies mark antigens for destruction. Chapter 21 explores the roles of the lymphocytes in immunity.

Macrophages play a crucial role in body protection and the immune response by phagocytizing foreign substances and by helping to activate T cells. So, too, do the spiny-looking **dendritic cells** that capture antigens and bring them back to the lymph nodes.

Last but not least are the **reticular cells**, fibroblast-like cells that produce the reticular fiber **stroma** (stro′mah), which is the network that supports the other cell types in lymphoid organs and tissues (**Figure 20.4**).

Lymphoid Tissue

Lymphoid tissue is an important component of the immune system, mainly because it:

- Houses lymphocytes and provides a site where they can be activated and proliferate (multiply)
- Furnishes an ideal surveillance vantage point for lymphocytes and macrophages

Lymphoid tissue, largely composed of loose connective tissue called **reticular connective tissue** (◀ p. 133), dominates all the lymphoid organs except the thymus. Macrophages live on the fibers of the reticular connective tissue network. Huge numbers of lymphocytes squeeze through the walls of postcapillary venules (◀ p. 712) coursing through this network. The lymphocytes temporarily occupy the spaces in the network before returning to the bloodstream via the lymphatics so they can patrol the body again (Figure 20.4). The cycling of lymphocytes between the circulatory vessels, lymphoid tissues, and loose connective tissues of the body ensures that lymphocytes reach infected or damaged sites quickly.

Lymphoid tissue comes in various "packages":

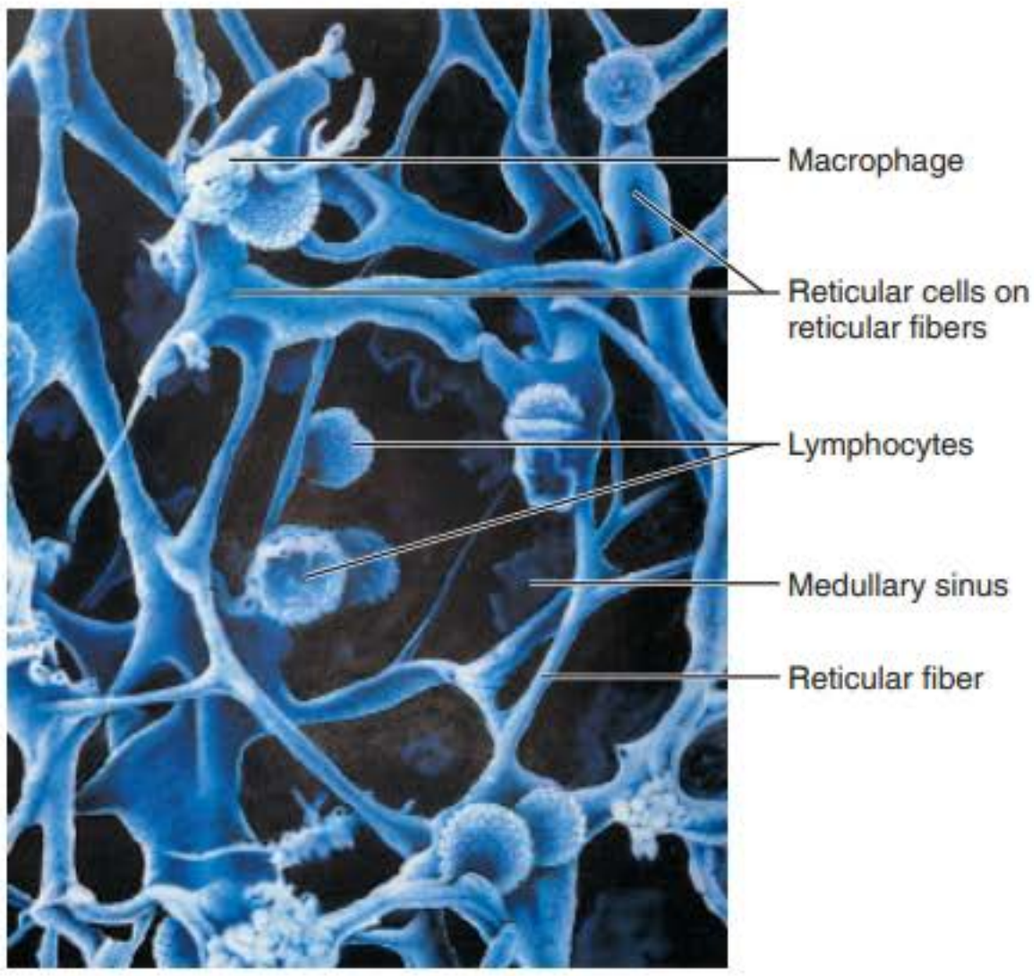

Figure 20.4 Reticular connective tissue in a human lymph node. Scanning electron micrograph (690×).

- **Diffuse lymphoid tissue**—a loose arrangement of lymphoid cells and some reticular fibers—is found in virtually every body organ. Larger collections appear in the lamina propria (loose connective tissue, ◀ p. 141) of mucous membranes such as those lining the digestive tract.
- **Lymphoid follicles (lymphoid nodules)** are solid, spherical bodies consisting of tightly packed lymphoid cells and reticular fibers. Follicles often have lighter-staining **germinal centers** where proliferating (rapidly dividing) B cells predominate (see Figure 20.6). These centers enlarge dramatically when the B cells are dividing rapidly and producing plasma cells. In many cases, the follicles form part of larger lymphoid organs, such as lymph nodes. However, isolated aggregations of lymphoid follicles occur in the intestinal wall as Peyer's patches (aggregated lymphoid nodules) and in the appendix (see p. 775).

Lymphoid Organs

The **lymphoid organs** (**Figure 20.5**) are grouped into two functional categories.

- The **primary lymphoid organs** are where B and T cells mature—the *red bone marrow* and the *thymus*. While both B and T cells originate in the red bone marrow, B cells mature in the red bone marrow and T cells mature in the thymus. We described red marrow and its role in blood cell formation earlier (◀ p. 647) and we will describe the thymus shortly.
- The **secondary lymphoid organs** are where mature lymphocytes first encounter their antigens and are activated. They include the lymph nodes, the spleen, and the collections of mucosa-associated lymphoid tissue (MALT) that form the tonsils, Peyer's patches (aggregated lymphoid nodules) in the small intestine, and the appendix. Lymphocytes also encounter antigens and are activated in the diffuse lymphoid tissues.

Although all lymphoid organs help protect the body, only the lymph nodes cleanse the lymph. The other secondary lymphoid organs typically have efferent lymphatics draining them, but lack afferent lymphatics.

Check Your Understanding

5. What are the primary lymphoid organs and what makes them special?
6. MAKE CONNECTIONS Both B and T cells originate in red bone marrow. Where do you find red marrow in adults? (Hint: See Chapter 6.)

For answers, see Answers Appendix.

20.3 Lymph nodes cleanse lymph and house lymphocytes

Learning Outcome

▶ **Describe the general location, histological structure, and functions of lymph nodes.**

The most important of the secondary lymphoid organs in the body are the **lymph nodes**, which cluster along the lymphatic

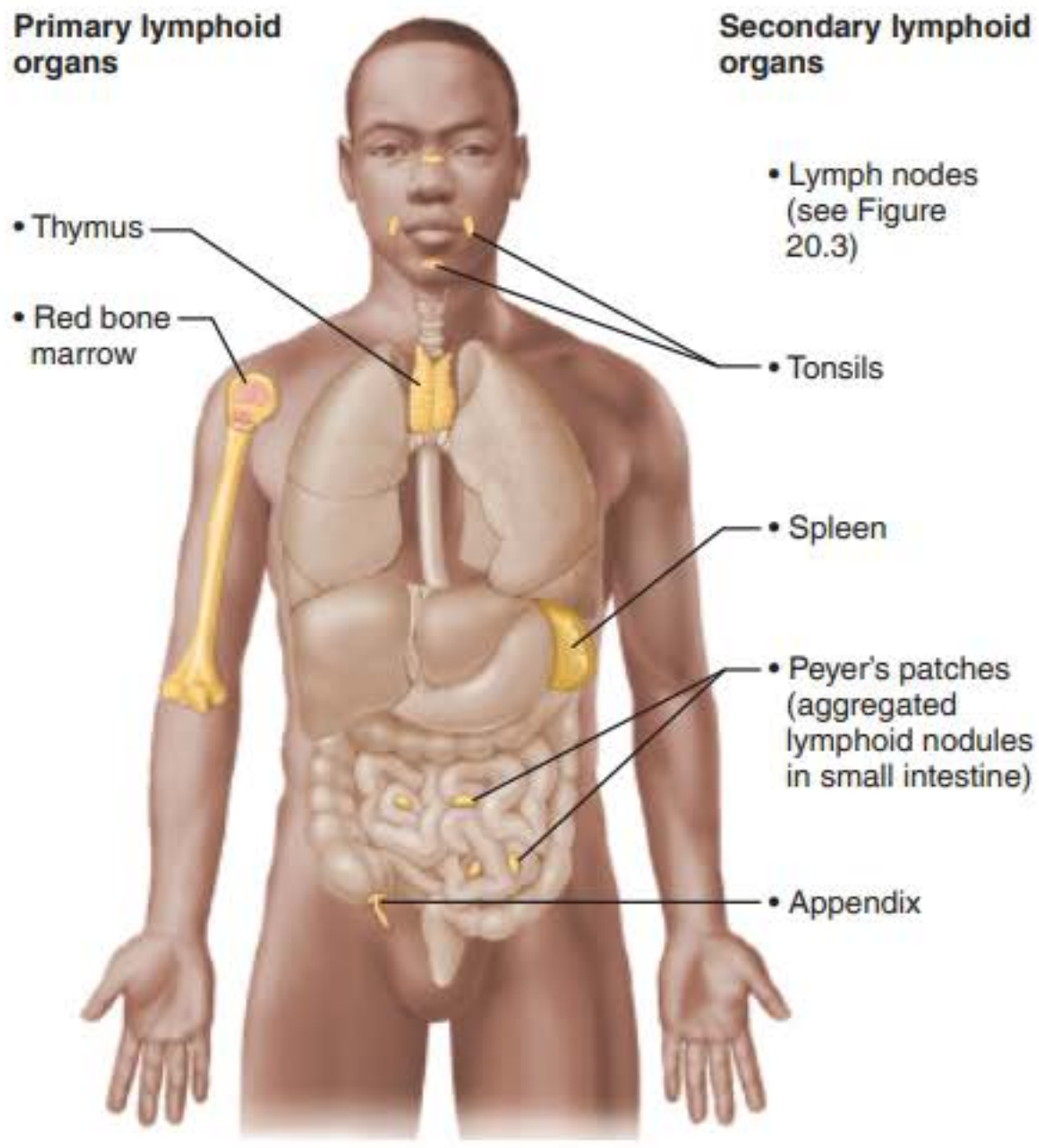

Figure 20.5 Lymphoid organs.

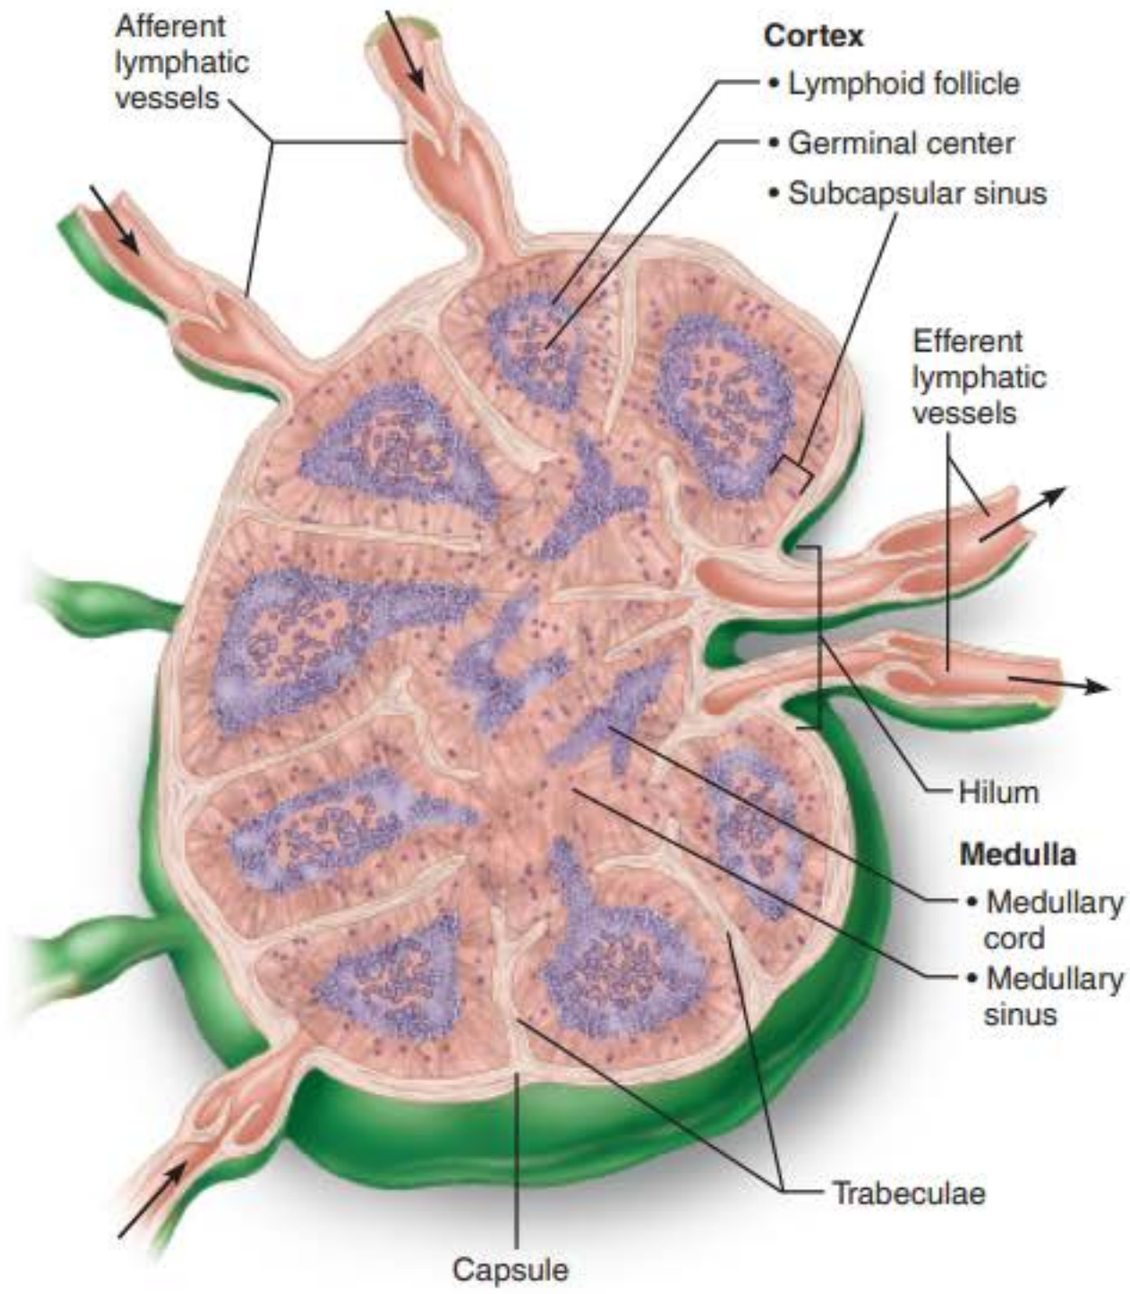
vessels of the body. There are hundreds of these small organs, but because they are usually embedded in connective tissue, they are not ordinarily visible. Large clusters of lymph nodes occur near the body surface in the inguinal, axillary, and cervical regions, places where the collecting lymphatic vessels converge to form trunks (see Figure 20.3).

Lymph nodes have two basic protective functions:

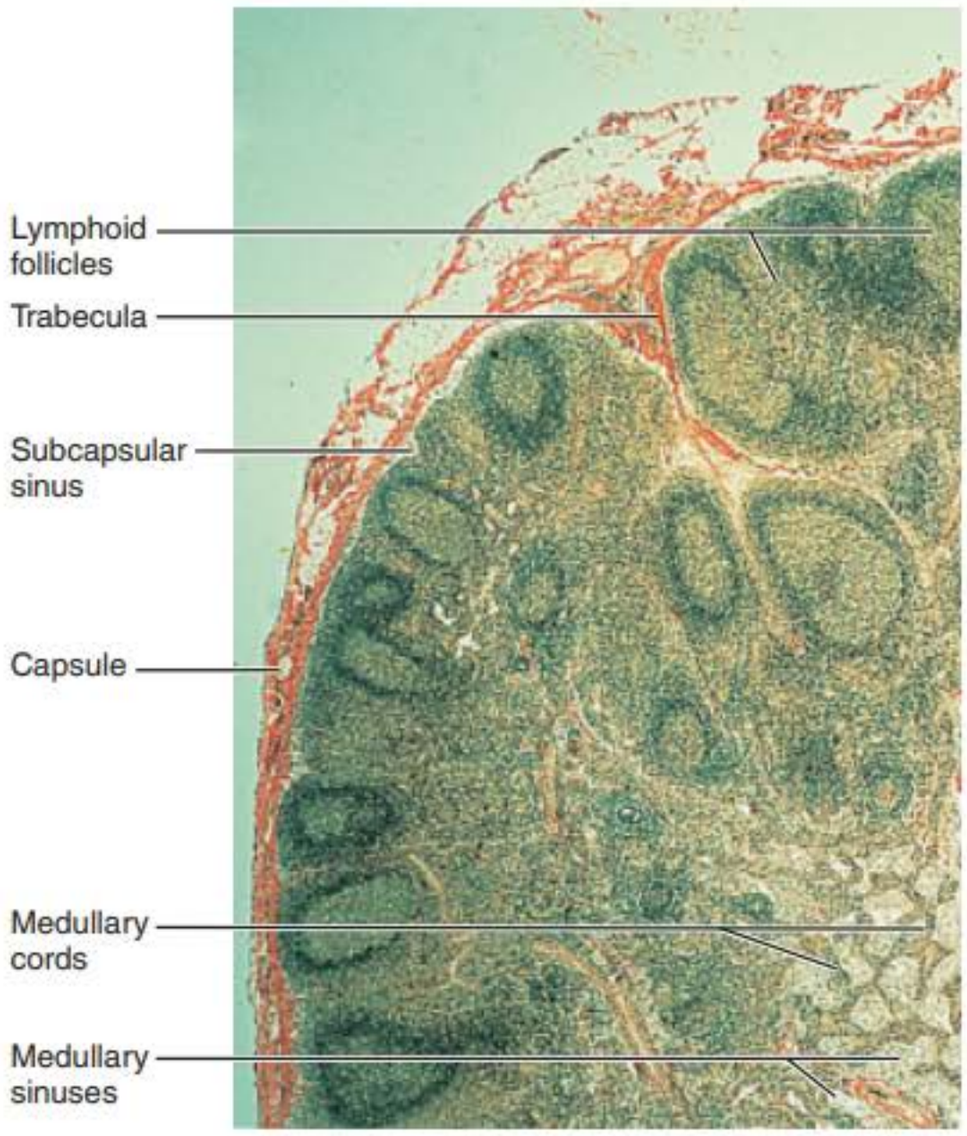
- **Cleansing the lymph.** As lymph is transported back to the bloodstream, the lymph nodes act as lymph "filters." Macrophages in the nodes remove and destroy microorganisms and other debris that enter the lymph from the loose connective tissues, preventing them from being delivered to the blood and spreading to other parts of the body.
- **Immune system activation.** Lymph nodes and other lymphoid organs are strategically located sites where lymphocytes encounter antigens and are activated to mount an attack against them. Many antigens are brought to lymph nodes from their point of entry into the body by dendritic cells. Dendritic cells use these antigens to activate T cells in the lymph nodes.

Structure of a Lymph Node

The structure of a lymph node supports its defensive functions. Lymph nodes vary in shape and size, but most are bean shaped and less than 2.5 cm (1 inch) in length. Each node is surrounded by a dense fibrous **capsule** from which connective tissue strands called **trabeculae** extend inward to divide the node into



(a) Longitudinal view of the internal structure of a lymph node and associated lymphatics



(b) Photomicrograph of part of a lymph node (72×)

Figure 20.6 Lymph node. In (a), notice that several afferent lymphatics converge on its convex side, whereas fewer efferent lymphatics exit at its hilum.

a number of compartments (**Figure 20.6**). The node's internal framework, or stroma, of reticular fibers physically supports its ever-changing population of lymphocytes.

A lymph node has two histologically distinct regions:

- **Cortex.** The superficial part of the **cortex** contains densely packed follicles, many with germinal centers heavy with dividing B cells. The deeper part of the cortex primarily houses T cells in transit. T cells circulate continuously between the blood, lymph nodes, and lymph, performing their surveillance role. Dendritic cells are abundant in the cortex and intimately associated with both B and T cells.
- **Medulla.** The **medulla** consists of **medullary cords**, thin inward extensions from the cortical lymphoid tissue. Both B and T lymphocytes are found here.

Throughout the node are **lymph sinuses** (e.g., the subcapsular and medullary sinuses described below). These sinuses are large lymphatic capillaries spanned by crisscrossing reticular fibers. Numerous macrophages reside on these reticular fibers and phagocytize foreign matter in the lymph as it flows by in the sinuses. Additionally, some of the lymph-borne antigens in the percolating lymph leak into the surrounding lymphoid tissue, where they activate lymphocytes to mount an immune attack against them.

Circulation in the Lymph Nodes

Lymph enters the convex side of a lymph node through a number of **afferent lymphatic vessels**. It then moves through a large, baglike sinus, the **subcapsular sinus**, into a number of smaller sinuses that cut through the cortex and enter the medulla. The lymph meanders through these **medullary sinuses** and finally exits the node at its **hilum** (hi′lum), the indented region on the concave side, via **efferent lymphatic vessels**.

There are fewer efferent vessels draining the node than afferent vessels feeding it, so the flow of lymph through the node stagnates somewhat, allowing time for the lymphocytes and macrophages to carry out their protective functions. Lymph passes through several nodes before it is completely cleansed.

HOMEOSTATIC IMBALANCE 20.3 CLINICAL

Sometimes lymph nodes are overwhelmed by the agents they are trying to destroy. For example, when large numbers of bacteria

are trapped in the nodes, the nodes become inflamed, swollen, and tender to the touch, a condition often referred to (erroneously) as swollen "glands" but correctly called *lymphadenopathy*. Such infected lymph nodes (often pus-filled) are called *buboes* (bu′bōz). (The bubonic plague was named for these buboes.)

Lymph nodes can also become secondary cancer sites, particularly when metastasizing cancer cells enter lymphatic vessels and become trapped there. Cancer-infiltrated lymph nodes are swollen but usually not painful, a fact that helps distinguish cancerous nodes from those infected by microorganisms.

Check Your Understanding

7. What is a lymphoid follicle? What type of lymphocyte predominates in follicles, especially in their germinal centers?
8. What is the benefit of having fewer efferent than afferent lymphatics in lymph nodes?
9. DRAW Sketch a lymph node including its afferent and efferent lymphatic vessels. Label the hilum, cortex, and medulla. Draw and label some lymphoid follicles and their germinal centers.

For answers, see Answers Appendix.

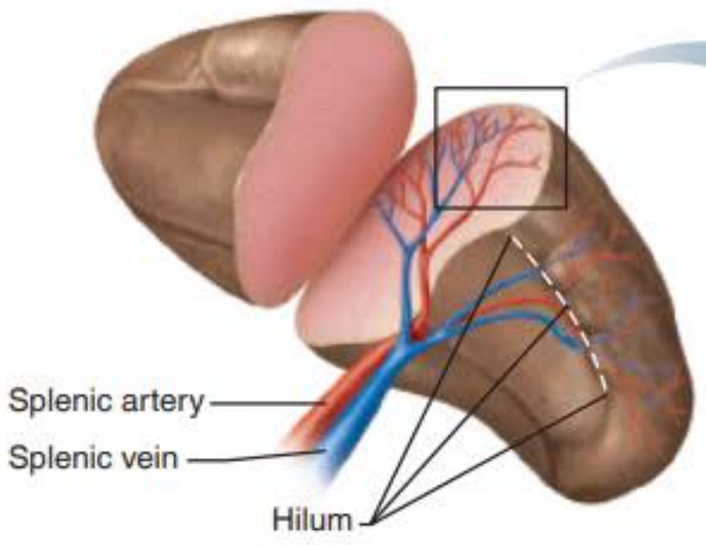
20.4 The spleen removes bloodborne pathogens and aged red blood cells

Learning Outcome

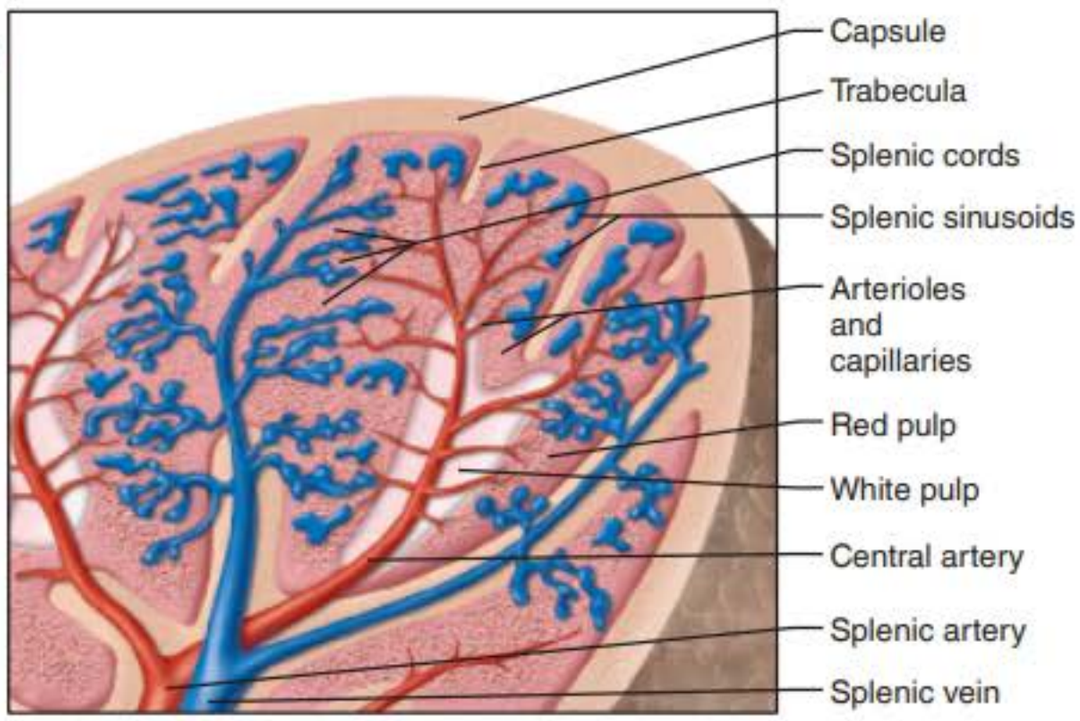
- **Compare and contrast the structure and function of the spleen and lymph nodes.**

The soft, blood-rich **spleen** is about the size of a fist and is the largest lymphoid organ. Located in the left side of the abdominal cavity just beneath the diaphragm, it curls around the anterior aspect of the stomach (Figure 20.5 and **Figure 20.7**). It is served by the large *splenic artery* and *vein*, which enter and exit the *hilum* on its slightly concave anterior surface.

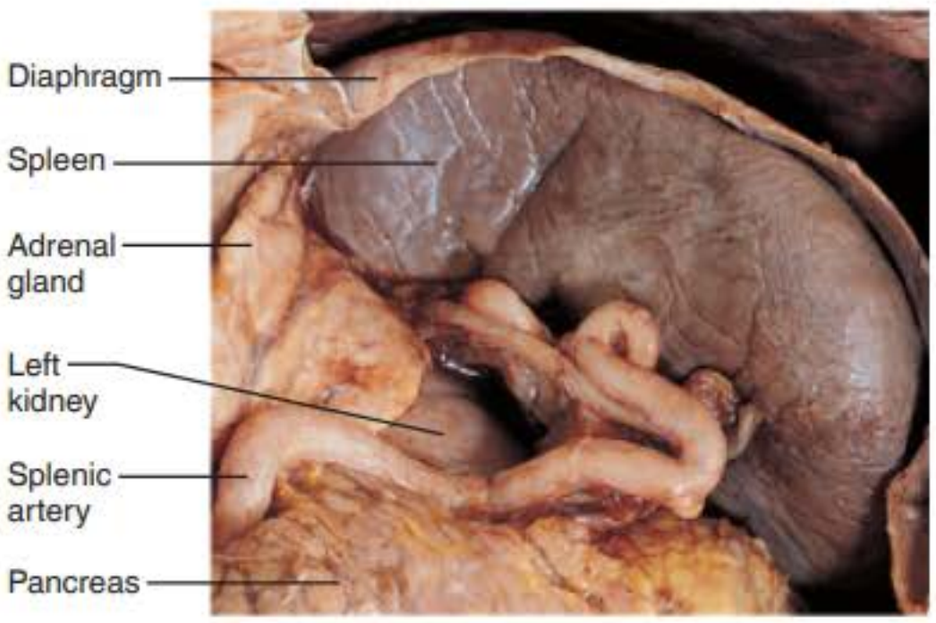
The spleen provides a site for lymphocyte proliferation and immune surveillance and response. But perhaps even more important are its blood-cleansing functions. Besides extracting aged and defective blood cells and platelets from the blood, its macrophages remove debris and foreign matter. The spleen also performs three additional, and related, functions. The spleen:



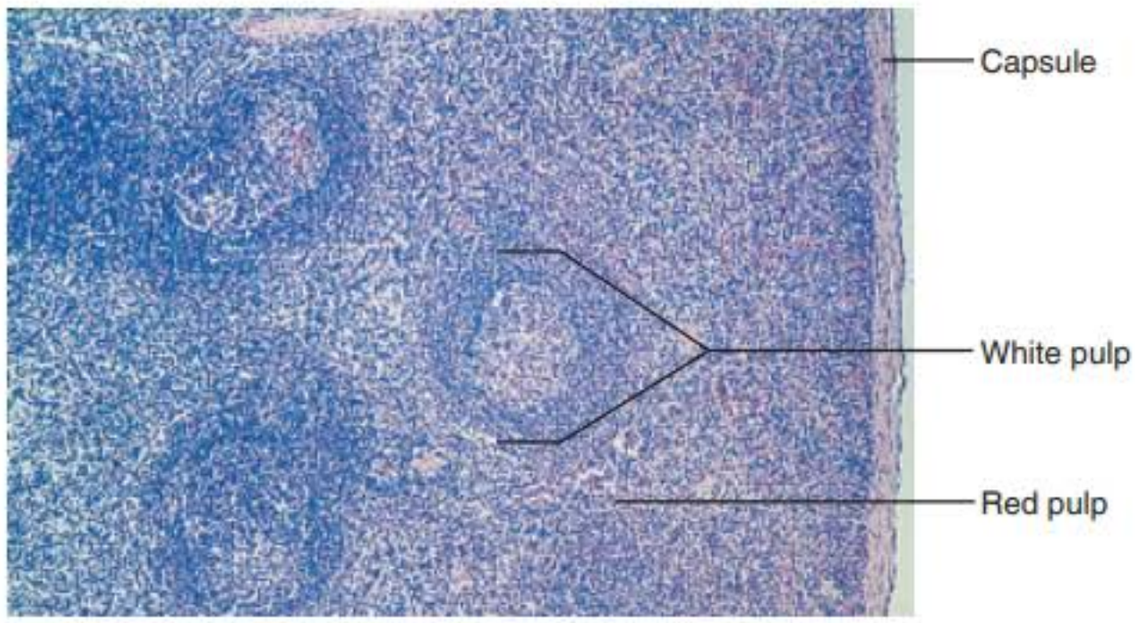
(a) Diagram of the spleen, anterior view.



(b) Diagram of spleen histology.



(c) Photograph of the spleen in its normal position in the abdominal cavity, anterior view.



(d) Photomicrograph of spleen tissue (30×). The white pulp, a lymphoid tissue with many lymphocytes, is surrounded by red pulp containing abundant erythrocytes.

Figure 20.7 The spleen.

Practice Histology questions: MasteringA&P® > Study Area > Lab Tools > PAL

- Recycles the breakdown products of red blood cells for later reuse. It releases the breakdown products to the blood for processing by the liver and stores some of the iron salvaged from hemoglobin.
- Stores blood platelets and monocytes for release into the blood when needed.
- May be a site of erythrocyte production in the fetus.

Like lymph nodes, the spleen is surrounded by a fibrous capsule and has trabeculae that extend inward. Histologically, the spleen consists of two components: white pulp and red pulp.

- **White pulp** is where immune functions take place, so it is composed mostly of lymphocytes suspended on reticular fibers. The white pulp clusters or forms "cuffs" around central arteries (small branches of the splenic artery). These clusters of white pulp look like islands in a sea of red pulp.
- **Red pulp** is where worn-out red blood cells and blood-borne pathogens are destroyed, so it contains huge numbers of erythrocytes and the macrophages that engulf them. It is essentially all splenic tissue that is not white pulp. It consists of **splenic cords**, regions of reticular connective tissue, that separate the blood-filled **splenic sinusoids** (venous sinuses).

The names of the pulp regions reflect their appearance in fresh spleen tissue rather than their staining properties. Indeed, as you can see in Figure 20.7d, the white pulp sometimes appears darker than the red pulp due to the darkly staining nuclei of the densely packed lymphocytes.

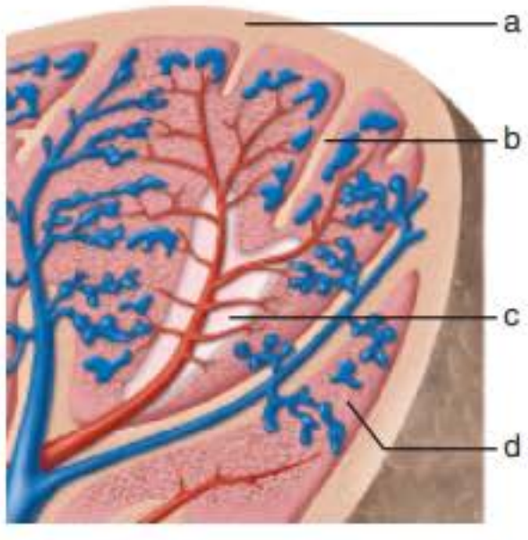
HOMEOSTATIC IMBALANCE 20.4 — CLINICAL

Because the spleen's capsule is relatively thin, a direct blow or severe infection may cause it to rupture, spilling blood into the peritoneal cavity. Once, *splenectomy* (surgical removal of the ruptured spleen) was the standard treatment and thought necessary to prevent life-threatening hemorrhage and shock. However, surgeons have discovered that, if left alone, the spleen can often repair itself. As a result, the frequency of emergency splenectomies has decreased dramatically. If the spleen must be removed, the liver and bone marrow take over most of its functions. In children younger than 12, the spleen will regenerate if a small part of it is left in the body.

Check Your Understanding

10. List several functions of the spleen.

11. Identify structures a and b in this diagram of the spleen. With respect to regions c and d: Which region is the site of red blood cell destruction? Which region is composed mostly of lymphocytes? Which region has splenic cords and splenic sinusoids?



12. MAKE CONNECTIONS From which blood vessel does the splenic artery arise? The splenic vein empties into which blood vessel? (Hint: See Chapter 19.)

For answers, see Answers Appendix.

20.5 MALT guards the body's entryways against pathogens

Learning Outcome

▶ **Define MALT and list its major components.**

Mucosa-associated lymphoid tissues (MALT) are a set of distributed lymphoid tissues strategically located in mucous membranes throughout the body (◀ Figure 4.14b, p. 141, introduced mucous membranes). MALT helps protect us from the never-ending onslaught of pathogens that seek to enter our bodies. Here

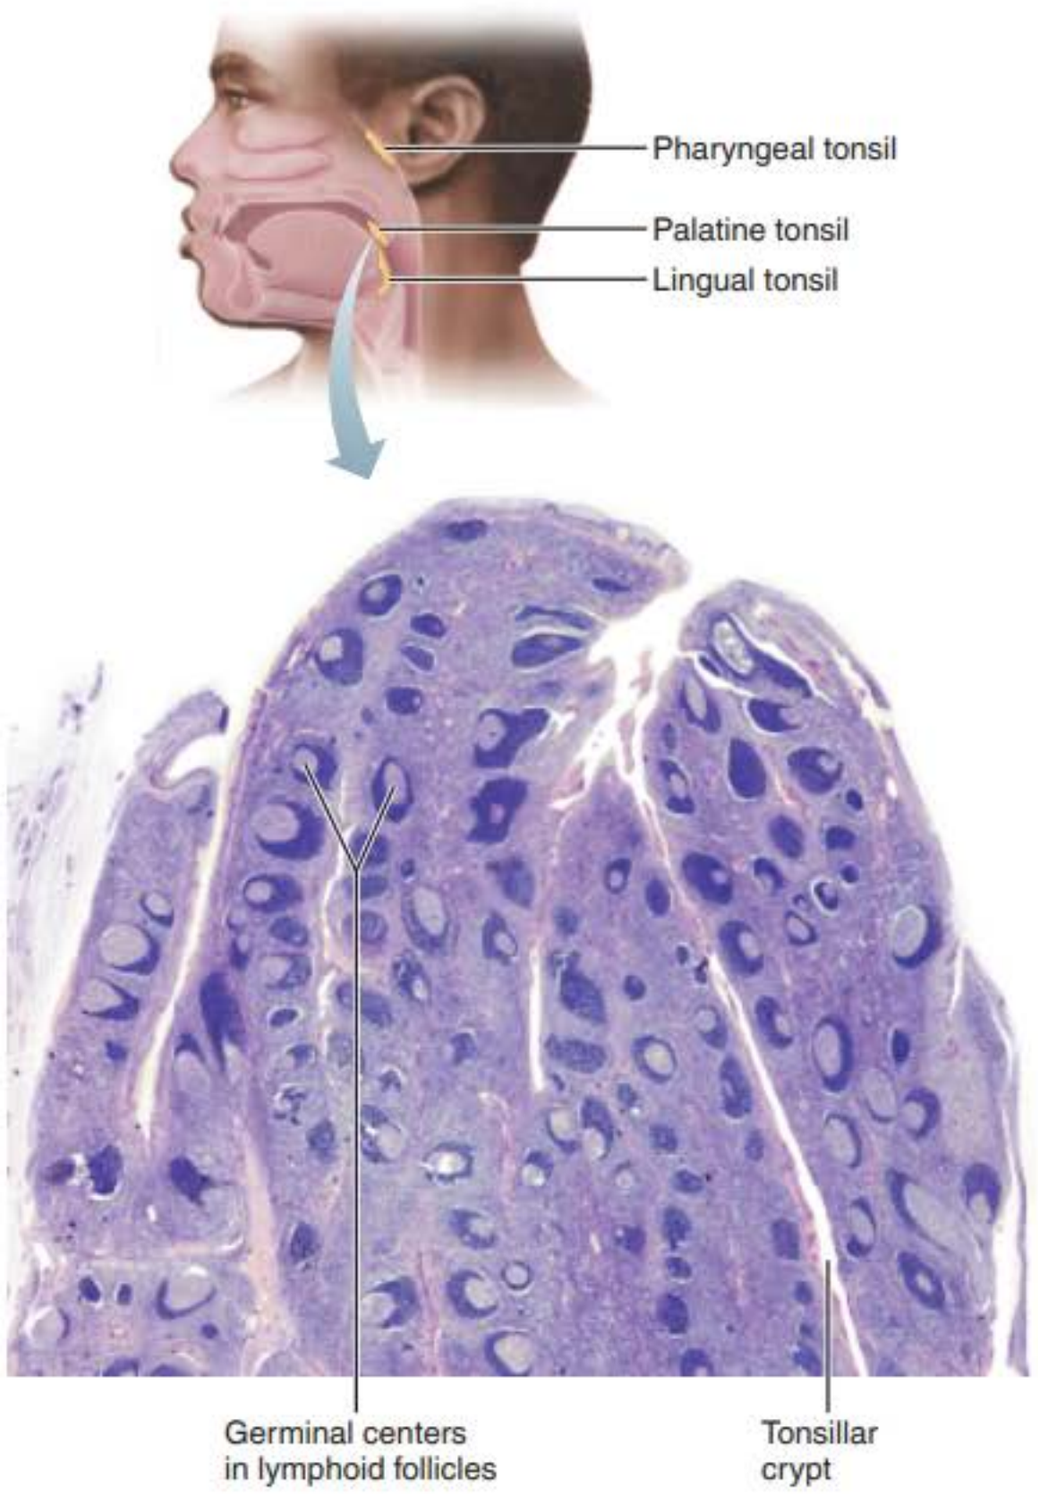


Figure 20.8 Histology of the palatine tonsil. The exterior surface of the tonsil is covered by stratified squamous epithelium, which invaginates deeply to form tonsillar crypts (10×).

Practice Histology questions: MasteringA&P® > Study Area > Lab Tools > PAL

we will consider the largest collections of MALT—the tonsils, Peyer's patches, and appendix. In addition to these large named collections, MALT also occurs in the mucosa of the respiratory and genitourinary organs as well as the rest of the digestive tract.

Tonsils

The **tonsils** form a ring of lymphoid tissue around the entrance to the pharynx (throat), where they appear as swellings of the mucosa (**Figure 20.8** and Figure 22.5 on p. 823). The tonsils are named according to location.

- The paired **palatine tonsils** are located on either side at the posterior end of the oral cavity. These are the largest tonsils and the ones most often infected.
- The **lingual tonsil** is the collective term for a lumpy collection of lymphoid follicles at the base of the tongue.
- The **pharyngeal tonsil** (referred to as the *adenoids* if enlarged) is in the posterior wall of the nasopharynx.
- The tiny **tubal tonsils** surround the openings of the auditory tubes into the pharynx.

The tonsils gather and remove many of the pathogens entering the pharynx in food or in inhaled air.

The lymphoid tissue of the tonsils contains follicles with obvious germinal centers surrounded by diffusely scattered lymphocytes. The tonsils are not fully encapsulated, and the epithelium overlying them invaginates deep into their interior, forming blind-ended **tonsillar crypts** (Figure 20.8). The crypts trap bacteria and particulate matter, and the bacteria work their way through the mucosal epithelium into the lymphoid tissue, where most are destroyed. It seems a bit dangerous to "invite" infection this way, but this strategy produces a wide variety of immune cells that have a "memory" for the trapped pathogens. In other words, the body takes a calculated risk early on (during childhood) for the benefits of heightened immunity and better health later.

Peyer's Patches

Peyer's patches (pi′erz), or **aggregated lymphoid nodules**, are large clusters of lymphoid follicles, structurally similar to the tonsils. They are located in the wall of the distal portion of the small intestine (Figure 20.5 and **Figure 20.9**).

Appendix

The **appendix** is a tubular offshoot of the first part of the large intestine and contains a high concentration of lymphoid follicles. Like Peyer's patches, the appendix is in an ideal position (1) to prevent bacteria (present in large numbers in the intestine) from breaching the intestinal wall, and (2) to generate many "memory" lymphocytes for long-term immunity.

Check Your Understanding

13. What is MALT? List several components of MALT.

For answers, see Answers Appendix.

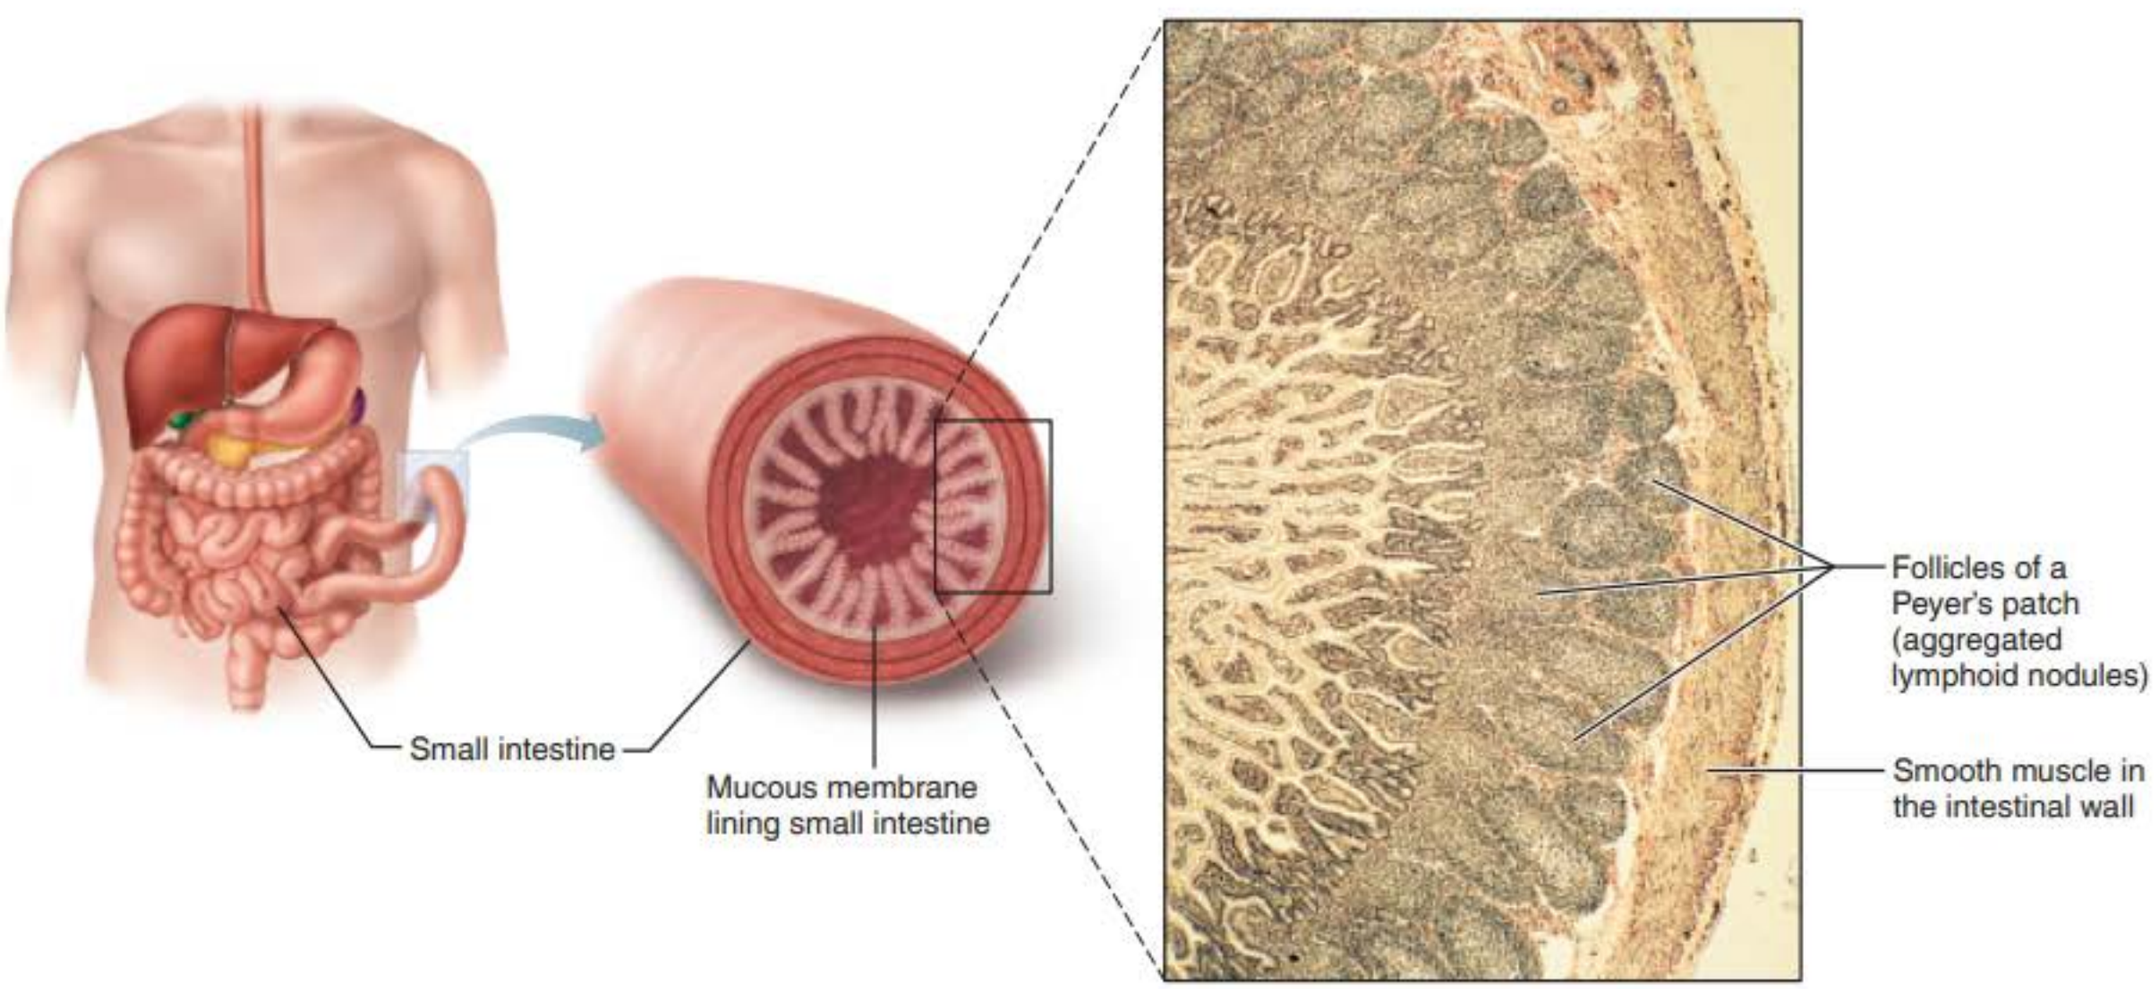

Figure 20.9 Peyer's patch (aggregated lymphoid nodules). Cross section of wall of the ileum of the small intestine (20×).

Practice Histology questions: MasteringA&P® > Study Area > Lab Tools > PAL

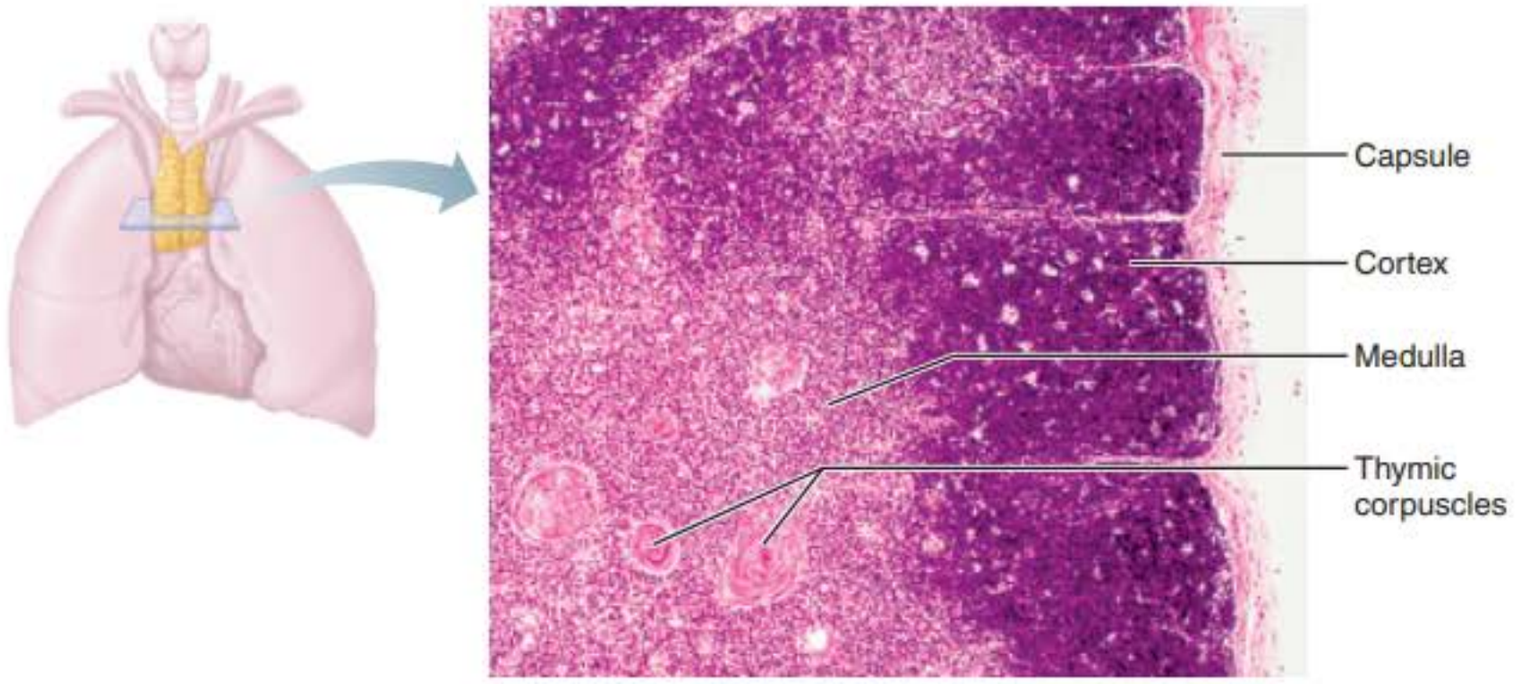

Figure 20.10 The thymus. The photomicrograph of a portion of the thymus shows part of a lobule with cortical and medullary regions (85×).

20.6 T lymphocytes mature in the thymus

Learning Outcome

▶ **Describe the structure and function of the thymus.**

The bilobed **thymus** (thi′mus) has important functions primarily during the early years of life. It is found in the inferior neck and extends into the superior thorax, where it partially overlies the heart deep to the sternum (see Figure 20.5 and **Figure 20.10**). In the thymus, T lymphocyte precursors mature to become immunocompetent lymphocytes. In other words, the thymus is where T lymphocytes become able to defend us against specific pathogens in the immune response.

Prominent in newborns, the thymus continues to increase in size during the first year, when it is highly active. After puberty, it gradually atrophies and by old age it has been replaced almost entirely by fibrous and fatty tissue and is difficult to distinguish from surrounding connective tissue. Even though it atrophies, the thymus continues to produce immunocompetent cells as we age, although at a declining rate.

To understand thymic histology, it helps to compare the thymus to a cauliflower head—the flowerets represent *thymic lobules*, each containing an outer cortex and an inner medulla (Figure 20.10). Most thymic cells are lymphocytes. In the cortical regions the rapidly dividing lymphocytes are densely packed, with a few macrophages scattered among them.

The lighter-staining medullary areas contain fewer lymphocytes plus some bizarre structures called **thymic corpuscles**. Consisting of concentric whorls of keratinized epithelial cells, they were thought to be sites of T cell destruction. Thymic corpuscles are involved in the development of *regulatory T cells*, a class of T lymphocytes that are important for preventing autoimmune responses.

The thymus is a primary lymphoid organ and differs from secondary lymphoid organs in three important ways:

- The thymus has no follicles because it lacks B cells.
- The thymus does not *directly* fight antigens. Instead, the thymus functions strictly as a maturation site for T lymphocyte precursors. These precursors must be kept isolated from foreign antigens to prevent their premature activation. In fact, there is a *blood thymus barrier* that keeps bloodborne antigens out of the thymus.
- The stroma of the thymus consists of epithelial cells rather than reticular fibers. These epithelial cells provide the physical and chemical environment in which T lymphocytes mature.

Table 20.1 summarizes the properties of the thymus and compares it with other lymphoid organs and tissues.

Check Your Understanding

14. MAKE CONNECTIONS T cells mature in the thymus. Where do B cells mature?

For answers, see Answers Appendix.

Developmental Aspects of the Lymphatic System and Lymphoid Organs and Tissues

By the fifth week of embryonic development, the beginnings of the lymphatic vessels and the main lymph node clusters are apparent. These usually arise as **lymph sacs** that bud from developing veins and form a branching system of lymphatic vessels throughout the thorax, upper extremities, and head. The two main connections to the venous system are retained and become the right lymphatic duct and, on the left, the superior part of the thoracic duct. Caudal lymphatics bud largely from the primitive inferior vena cava.

Except for the thymus, which is an endodermal derivative, the lymphoid organs develop from mesodermal mesenchymal cells that migrate to particular body sites and develop into reticular tissue. The thymus, the first lymphoid organ to appear, is an outgrowth of the primitive pharynx lining. It detaches and migrates caudally to the thorax where it is infiltrated with lymphocyte precursors. Shortly after birth, the other lymphoid organs become heavily populated by lymphocytes.

Table 20.1 Summary of Lymphoid Organs and Tissues*

	MAJOR FUNCTIONS	CAPSULE	CORTEX AND MEDULLA	LYMPHOID FOLLICLES	STROMA	SPECIAL FEATURES
Lymph nodes	• Cleanse lymph • Site for lymphocyte activation and proliferation	Yes	Yes	Yes (in cortex)	Reticular connective tissue	Both afferent and efferent lymphatic vessels
Spleen	• Cleanses blood and removes aged or defective red blood cells • Site for lymphocyte activation and proliferation • Stores platelets, moncytes, and iron	Yes	No	Yes (in white pulp)	Reticular connective tissue	Red and white pulp
MALT†	• Prevent pathogens from penetrating mucous membrane • Site for lymphocyte activation and proliferation	No	No	Yes	Reticular connective tissue	Diffuse lymphatic tissue in addition to follicles
Thymus	• Site of T cell maturation	Yes	Yes	No	Epithelial tissue	Thymic corpuscles

*Red bone marrow, a primary lymphoid organ, is not included. †MALT = mucosa-associated lymphoid tissues.

RELATED CLINICAL TERMS

Elephantiasis (el″lĕ-fan-ti′ah-sis) Typically a tropical disease in which the lymphatics (particularly those of the lower limbs and scrotum) become clogged with parasitic roundworms, an infectious condition called filariasis. Swelling (due to edema) reaches enormous proportions.

Hodgkin's lymphoma A malignancy of lymphoid tissue; symptoms include swollen, nonpainful lymph nodes, fatigue, and often intermittent fever and night sweats. Characterized by presence of giant malignantly transformed B cells called Reed-Sternberg cells. Infection with Epstein-Barr virus (see mononucleosis below) and genetic susceptibility appear to be predisposing factors. Treated with chemotherapy and radiation; high cure rate.

Lymphadenopathy (lim-fad″ĕ-nop′ah-the; *adeno* = a gland; *pathy* = disease) Any disease of the lymph nodes.

Lymphangiography (lim-fan″je-og′rah-fe) Diagnostic procedure in which the lymphatic vessels are injected with radiopaque dye and then visualized with X rays.

Lymphoma Any neoplasm (tumor) of the lymphoid tissue, whether benign or malignant.

Mononucleosis ◀ Chapter 17, p. 654.

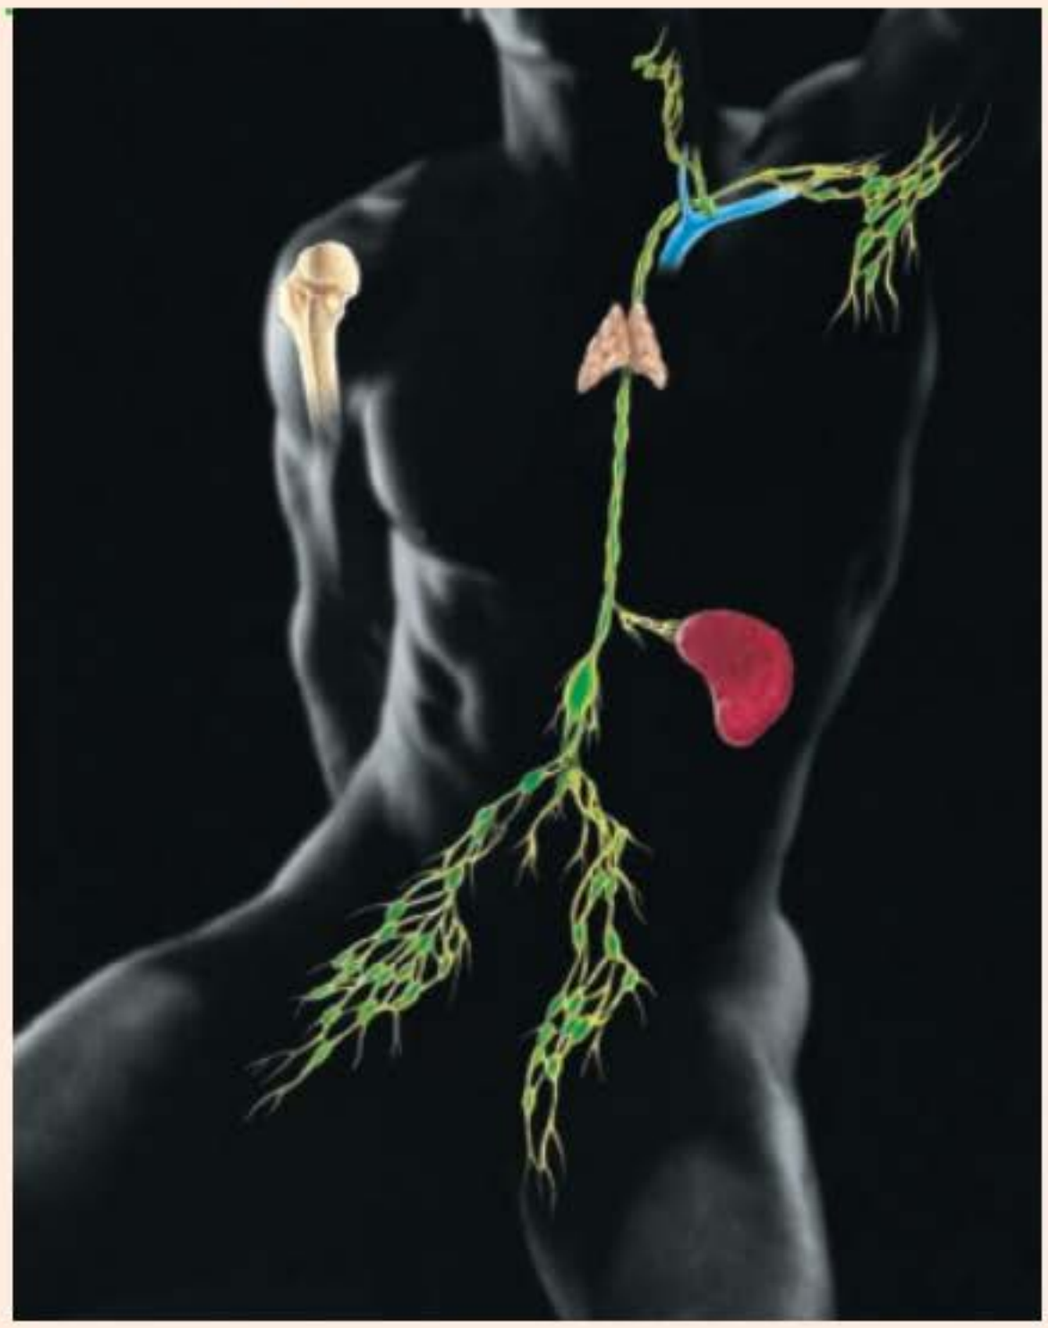
Non-Hodgkin's lymphoma Includes all cancers of lymphoid tissues except Hodgkin's lymphoma. Involves uncontrolled multiplication and metastasis of undifferentiated lymphocytes, with swelling of the lymph nodes, spleen, and Peyer's patches; other organs may eventually become involved. The seventh most common cancer. A rapidly progressing type, which primarily affects young people, grows quickly but responds to chemotherapy; up to an 88% 5-year survival rate. A slowly progressing type, which affects the elderly, resists chemotherapy and so is often fatal.

Sentinel node The first node that receives lymph drainage from a body area suspected of being cancerous. When examined for presence of cancer cells, this node gives the best indication of whether metastasis through the lymphatic vessels has occurred.

Splenomegaly (sple″no-meg′ah-le; *mega* = big) Enlargement of the spleen. May be due to accumulation of infectious microorganisms; typically caused by septicemia, mononucleosis, malaria, or leukemia.

Tonsillitis (ton″sĭ-li′tis; *itis* = inflammation) Inflammation of the tonsils, typically due to bacterial infection. Tonsils become red, swollen, and sore.

Homeostatic Interrelationships between the Lymphatic System/Immunity and Other Body Systems



Integumentary System Chapter 5

- Lymphatic vessels pick up leaked plasma fluid and proteins from the dermis; lymphocytes in lymphoid organs and tissues enhance the skin's protective role by defending against specific pathogens via the immune response
- The skin's keratinized epithelium provides a mechanical barrier to pathogens; epithelial dendritic cells and dermal macrophages act as antigen presenters in the immune response; acid pH of skin secretions inhibits growth of bacteria on the skin

Skeletal System Chapters 6–8

- Lymphatic vessels pick up leaked plasma fluid and proteins from the periostea; immune cells protect bones from pathogens
- The bones house hematopoietic tissue, which produces the lymphocytes (and macrophages) that populate lymphoid organs and provide immunity

Muscular System Chapters 9–10

- Lymphatic vessels pick up leaked fluids and proteins; immune cells protect muscles from pathogens
- The skeletal muscle "pump" aids the flow of lymph; shivering produces heat at the beginning of a fever

Nervous System Chapters 11–15

- Lymphatic vessels pick up leaked plasma fluid and proteins; immune cells protect nervous system structures from specific pathogens
- The nervous system innervates larger lymphatics; opiate neuropeptides influence immune functions; the brain helps regulate immune response

Endocrine System Chapter 16

- Lymphatic vessels pick up leaked fluids and proteins; lymph helps distribute hormones; immune cells protect endocrine organs
- Stress hormones depress immune activity; the thymus produces hormones and paracrines that are involved in the maturation of T cells

Cardiovascular System Chapters 17–19

- Lymphatic vessels pick up leaked plasma and proteins; spleen removes and destroys aged RBCs and debris, and stores iron, platelets, and monocytes; immune cells protect cardiovascular organs from specific pathogens
- Blood is the source of lymph; most lymphatics develop from veins; blood circulates immune elements

Respiratory System Chapter 22

- Lymphatic vessels pick up leaked fluids and proteins from respiratory organs; immune cells protect respiratory organs from specific pathogens; the tonsils and plasma cells in the respiratory mucosa (which secrete the antibody IgA) prevent pathogen invasion
- The lungs provide O_2 needed by lymphoid/immune cells and eliminate CO_2; the pharynx houses the tonsils; respiratory "pump" aids lymph flow

Digestive System Chapter 23

- Lymphatic vessels pick up leaked fluids and proteins from digestive organs; lymph transports some products of fat digestion to the blood; lymphoid follicles in the intestinal wall prevent invasion of pathogens
- The digestive system digests and absorbs nutrients needed by cells of lymphoid organs; gastric acidity inhibits pathogens' entry into blood

Urinary System Chapters 25–26

- Lymphatic vessels pick up leaked fluid and proteins from urinary organs; immune cells protect urinary organs from specific pathogens
- Urinary system eliminates wastes and maintains homeostatic balances of water, pH, and electrolytes in the blood for lymphoid/immune cell functioning; urine flushes some pathogens out of the urinary tract

Reproductive System Chapter 27

- Lymphatic vessels pick up leaked fluid and proteins; immune cells protect against pathogens
- Reproductive organs' hormones may influence immune functioning; acidity of vaginal secretions is bacteriostatic

CHAPTER SUMMARY

1. Lymphatic vessels, lymph nodes, and lymph make up the lymphatic system. Lymphatic vessels return fluids that have leaked from the blood vascular system back to the blood. Lymphoid organs and tissues protect the body by removing foreign material from the lymph and bloodstream, and provide a site for immune surveillance.

20.1 The lymphatic system includes lymphatic vessels, lymph, and lymph nodes (pp. 767–770)

1. Lymphatic vessels form a one-way network—lymphatic capillaries, collecting vessels, trunks, and ducts—in which fluid flows only toward the heart. The right lymphatic duct drains lymph from the right arm and right side of the upper body; the thoracic duct receives lymph from the rest of the body. These ducts empty into the blood vascular system at the junction of the internal jugular and subclavian veins in the neck.
2. Lymphatic capillaries are exceptionally permeable, admitting proteins and particulate matter from the interstitial space.
3. Lymphatic vessels carry pathogens to lymph nodes where they can be phagocytized and may activate lymphocytes.
4. Pathogens and cancer cells may spread through the body via the lymphatic stream.
5. The flow of lymphatic fluid is slow; it is maintained by skeletal muscle contraction, pressure changes in the thorax, and contractions of the lymphatic vessels. Valves prevent backflow.

20.2 Lymphoid cells and tissues are found in lymphoid organs and in connective tissue of other organs (pp. 770–771)

1. The cells in lymphoid tissues include lymphocytes (cells called T cells or B cells), plasma cells (antibody-producing offspring of B cells), macrophages and dendritic cells (cells that capture antigens and initiate an immune response), and reticular cells that form the lymphoid tissue stroma.
2. Lymphoid tissue is reticular connective tissue. It houses macrophages and a continuously changing population of lymphocytes. It is an important element of the immune system.
3. Lymphoid tissue may be diffuse or packaged into dense follicles. Follicles often display germinal centers (areas where B cells are proliferating).
4. Primary lymphoid organs—the red bone marrow and thymus—are sites where lymphocytes develop and mature. Secondary lymphoid organs include lymph nodes, the spleen, and MALT. They are sites where lymphocytes encounter their antigens and are activated.

20.3 Lymph nodes cleanse lymph and house lymphocytes (pp. 771–773)

1. Lymph nodes, the principal lymphoid organs, are clustered along lymphatic vessels. Lymph nodes "filter" lymph and help activate the immune system.
2. Each lymph node has a fibrous capsule, a cortex, and a medulla. The cortex contains mostly lymphocytes, which act in immune responses; the medulla contains macrophages, which engulf and destroy viruses, bacteria, and other foreign debris, as well as lymphocytes.
3. Lymph enters the lymph nodes via afferent lymphatic vessels and exits via efferent vessels. There are fewer efferent vessels; therefore, lymph flow stagnates within the lymph node, allowing time for its cleansing.

20.4 The spleen removes bloodborne pathogens and aged red blood cells (pp. 773–774)

1. The spleen provides a site for lymphocyte proliferation and immune function, and destroys aged or defective red blood cells and bloodborne pathogens. It also recycles the breakdown products of hemoglobin, stores platelets and monocytes, and may be a hematopoietic site in the fetus.

20.5 MALT guards the body's entryways against pathogens (pp. 774–775)

1. Peyer's patches of the intestinal wall, lymphoid follicles of the appendix, tonsils of the pharynx and oral cavity, and follicles in the genitourinary and respiratory tract mucosae are known as MALT (mucosa-associated lymphoid tissue). They prevent pathogens in these passages from penetrating mucous membrane lining.

20.6 T lymphocytes mature in the thymus (pp. 776–777)

1. The thymus provides the environment in which T lymphocytes mature and become immunocompetent. The thymus is most functional during youth.

Developmental Aspects of the Lymphatic System and Lymphoid Organs and Tissues (p. 777)

1. Lymphatics usually develop as outpocketings of developing veins. The thymus develops from endoderm; the other lymphoid organs derive from mesenchymal cells of mesoderm.
2. The thymus is the first lymphoid organ to develop.
3. Lymphoid organs are populated by lymphocytes, which arise from hematopoietic tissue.

REVIEW QUESTIONS

To access additional practice questions using your smartphone, tablet, or computer: MasteringA&P® > Study Area > Practice Tests & Quizzes

Level 1 Remember/Understand

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Lymphatic vessels **(a)** serve as sites for immune surveillance, **(b)** filter lymph, **(c)** transport leaked plasma proteins and fluids to the cardiovascular system, **(d)** are represented by vessels that resemble arteries, capillaries, and veins.
2. The sac that often forms the initial portion of the thoracic duct is the **(a)** lacteal, **(b)** right lymphatic duct, **(c)** cisterna chyli, **(d)** lymph sac.
3. Entry of lymph into the lymphatic capillaries is promoted by which of the following? **(a)** one-way minivalves formed by overlapping endothelial cells, **(b)** the respiratory pump, **(c)** the skeletal muscle pump, **(d)** greater fluid pressure in the interstitial space.

4. The structural framework of lymphoid organs is **(a)** areolar connective tissue, **(b)** hematopoietic tissue, **(c)** reticular tissue, **(d)** adipose tissue.
5. Lymph nodes are densely clustered in all of the following body areas *except* **(a)** the brain, **(b)** the axillae, **(c)** the groin, **(d)** the cervical region.
6. The germinal centers in lymph nodes are largely sites of **(a)** macrophages, **(b)** proliferating B lymphocytes, **(c)** T lymphocytes, **(d)** all of these.
7. The red pulp areas of the spleen are sites of **(a)** splenic sinusoids, macrophages, and red blood cells, **(b)** clustered lymphocytes, **(c)** connective tissue septa.
8. The lymphoid organ that functions primarily during youth and then begins to atrophy is the **(a)** spleen, **(b)** thymus, **(c)** palatine tonsils, **(d)** bone marrow.
9. Collections of lymphoid tissue (MALT) that guard mucosal surfaces include all of the following except **(a)** appendix follicles, **(b)** the tonsils, **(c)** Peyer's patches, **(d)** the thymus.

Level 2 Apply/Analyze

10. Compare and contrast blood, interstitial fluid, and lymph.
11. Compare the structure and functions of a lymph node to those of the spleen.
12. A friend tells you that she has tender, swollen "glands" along the left side of the front of her neck. You notice that she has a bandage on her left cheek that is not fully hiding a large infected cut there. Exactly what are her swollen "glands," and how did they become swollen?

Level 3 Evaluate/Synthesize

13. **(a)** Which anatomical characteristic ensures that the flow of lymph through a lymph node is slow? **(b)** Why is this desirable?
14. There are no lymphatic arteries. Why isn't this a problem?
15. Mrs. Jackson, a 59-year-old woman, has undergone a left radical mastectomy (removal of the left breast and left axillary lymph nodes and vessels). Her left arm is severely swollen and painful, and she is unable to raise it to more than shoulder height. **(a)** Explain her signs and symptoms. **(b)** Can she expect to have relief from these symptoms in time? How so?
16. Once almost a rite of childhood, tonsillectomy (surgical removal of the tonsils) is now rarely performed. Similarly, while ruptured spleens were once routinely removed, they are now conserved whenever possible. Why should these lymphoid organs be preserved when possible?

CLINICAL CASE STUDY

27-Year-Old Male with a Crushed Hand

Andrew Hutchinson, 27, had surgery to repair his right hand after it was crushed by his garage door. The routine complete blood count (CBC) performed on admission revealed both a dangerously low total leukocyte count and a low proportion of lymphocytes.

One day postsurgery, he complains of pain in his injured right ring finger. When examined, the affected finger and the dorsum of the right hand are red, warm, and edematous, and red streaks radiate proximally on his right forearm. High doses of antibiotics are prescribed, and a sling is applied to the affected arm. Nurses are instructed to wear gloves and gown for Andrew's protection (called reverse isolation) when tending to him.

Relative to these observations:

1. How might the low lymphocyte count, orders for antibiotic therapy, and reverse isolation be related? Why is it important that Andrew not move the affected arm excessively (i.e., why was the sling ordered)?
2. ✚ NCLEX-STYLE Which of the statements best explains the presence of red streaks on Andrew's forearm?
   a. The lymphatic vessels of his forearm are inflamed.
   b. The major arteries of his forearm are inflamed.
   c. The lymphatic vessels of his forearm are dilated.
   d. The major arteries of his forearm are dilated.
3. ✚ NCLEX-STYLE The day after Andrew's surgery, the lymph nodes in his right armpit become enlarged and tender. This was most likely caused by which of the following?
   a. This is due to an allergic reaction to his antibiotics.
   b. His low lymphocyte count has triggered lymphocyte proliferation in his right armpit lymph nodes.
   c. This is due to an infiltration of his lymph nodes by cancer cells.
   d. This is due to infection of his lymph nodes by bacteria.
4. Do you predict that Andrew's recovery will be uneventful or problematic? Why?

21 The Immune System: Innate and Adaptive Body Defenses

In this chapter, you will learn that

The immune system defends the body from disease-causing organisms and cancerous cells

by comparing

Part 1 Innate Defenses

Every second of every day, armies of hostile bacteria, fungi, and viruses swarm on our skin and yet we stay amazingly healthy most of the time. The body has evolved a single-minded approach to such foes—if you're not with us, you're against us! To implement that stance, it relies heavily on two intrinsic defense systems that act both independently and cooperatively to provide resistance to disease, or **immunity** (*immun* = free).

1. The **innate (nonspecific) defense system**, like a lowly foot soldier, is always prepared, responding within minutes to protect the body from foreign substances. This system has two "barricades." The *first line of defense* consists of surface barriers—intact skin and mucosae. The *second line of defense*, called into action whenever the first line has been penetrated, relies on internal defenses such as antimicrobial proteins, phagocytes, and other cells to inhibit the invaders' spread throughout the body. The hallmark of the second line of defense is *inflammation*.
2. The **adaptive (specific) defense system** functions like an elite fighting force equipped with high-tech weapons to attack *identified* foreign substances. The adaptive defense response, which provides the body's *third line of defense*, takes considerably longer to mount than the innate defense response.

Although we consider them separately, the innate and adaptive systems always work hand in hand. An overview of these two systems is shown in **Figure 21.1**. Small portions of this diagram will reappear in subsequent figures to let you know which part of the immune system we're dealing with.

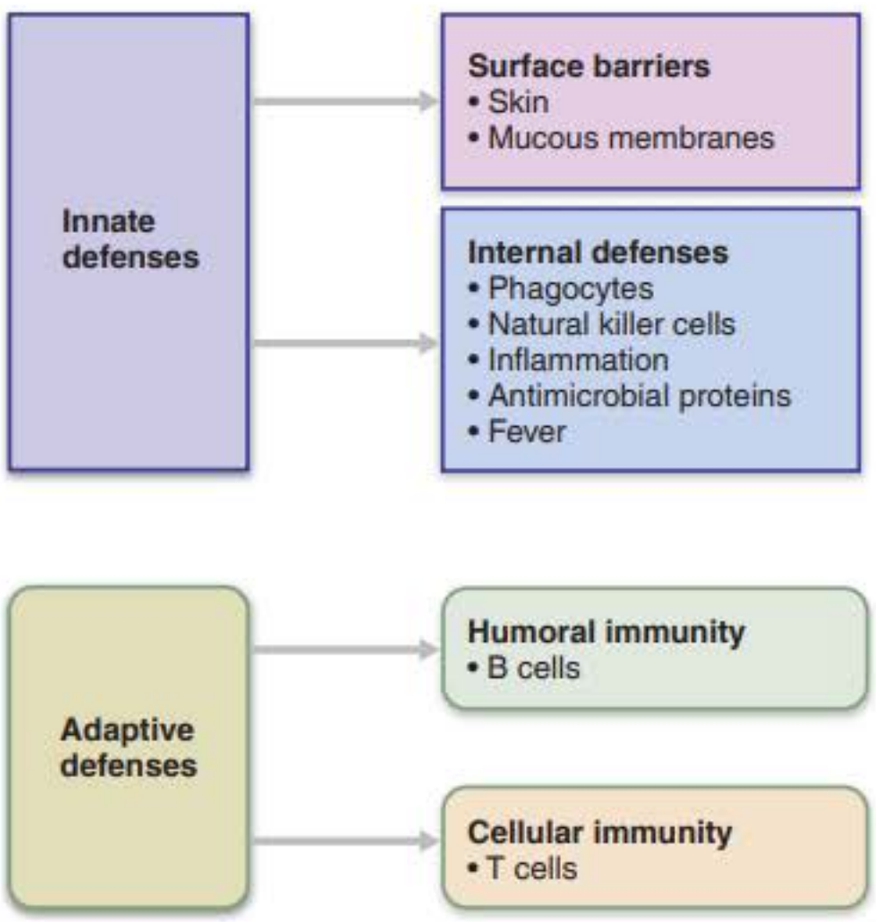

Figure 21.1 Simplified overview of innate and adaptive defenses. Humoral immunity (primarily involving B lymphocytes) and cellular immunity (involving T lymphocytes) are distinct but overlapping areas of adaptive immunity.

Although certain organs of the body (notably lymphoid organs) are intimately involved in the immune response, the **immune system** is a *functional system* rather than an organ system in an anatomical sense. Its "structures" are a diverse array of molecules plus trillions of immune cells (especially lymphocytes) that inhabit lymphoid tissues and circulate in body fluids.

Once, the term *immune system* was equated with the adaptive defense system only. However, we now know that the innate and adaptive defenses are deeply intertwined. Specifically:

- The innate and adaptive systems release and recognize (bind to) many of the same defensive molecules.
- The innate responses are not as nonspecific as once thought. Indeed, they have specific pathways to target certain foreign substances.
- Proteins released during innate responses alert cells of the adaptive system to the presence of specific foreign molecules in the body.

When the immune system is operating effectively, it protects the body from most infectious microorganisms, cancer cells, and (unfortunately) transplanted organs and grafts. It does this both directly, by cell attack, and indirectly, by releasing mobilizing chemicals and protective antibody molecules.

PART 1

INNATE DEFENSES

You could say we come fully equipped with innate defenses. The mechanical barriers that cover body surfaces and the cells and chemicals that act on the initial internal battlefronts are in place at birth, ready to ward off invading **pathogens** (harmful or disease-causing microorganisms).

Many times, our innate defenses alone ward off infection. In other cases, the adaptive immune system is called into action to reinforce and enhance the innate defenses. Either way, the innate defenses reduce the workload of the adaptive system by preventing the entry and spread of microorganisms in the body.

21.1 Surface barriers act as the first line of defense to keep invaders out of the body

Learning Outcome

- **Describe surface membrane barriers and their protective functions.**

The body's first line of defense—the *skin* and the *mucous membranes* (◀ p. 141), along with the secretions these membranes produce—is highly effective. As long as the epidermis is unbroken, this heavily keratinized epithelial membrane is a formidable physical barrier to most microorganisms. Keratin is also resistant to most weak acids and bases and to bacterial enzymes and toxins. Intact mucosae provide similar mechanical barriers within the body. Recall that mucous membranes line all body cavities that open to the exterior: the digestive, respiratory, urinary, and reproductive tracts.

Table 21.1 The First Line of Defense: Surface Membrane Barriers

CATEGORY/ASSOCIATED ELEMENTS	PROTECTIVE MECHANISM
Intact skin epidermis	Forms mechanical barrier that prevents entry of pathogens and other harmful substances into body
• Acid mantle of skin	Skin secretions (sweat and sebum) make epidermal surface acidic, which inhibits bacterial growth; also contain various bactericidal chemicals
• Keratin	Provides resistance against acids, alkalis, and bacterial enzymes
Intact mucous membranes	Form mechanical barrier that prevents entry of pathogens
• Mucus	Traps microorganisms in respiratory and digestive tracts
• Nasal hairs	Filter and trap microorganisms in nasal passages
• Cilia	Propel debris-laden mucus away from nasal cavity and lower respiratory passages
• Gastric juice	Contains concentrated hydrochloric acid and protein-digesting enzymes that destroy pathogens in stomach
• Acid mantle of vagina	Inhibits growth of most bacteria and fungi in female reproductive tract
• Lacrimal secretion (tears); saliva	Continuously lubricate and cleanse eyes (tears) and oral cavity (saliva); contain lysozyme, an enzyme that destroys microorganisms
• Urine	Normally acid pH inhibits bacterial growth; cleanses the lower urinary tract as it flushes from the body

Besides serving as physical barriers, skin and mucous membranes produce a variety of protective chemicals:

- **Acid.** The acidity of skin, vaginal, and stomach secretions—the *acid mantle*—inhibits bacterial growth.
- **Enzymes.** *Lysozyme*—found in saliva, respiratory mucus, and lacrimal fluid of the eye—destroys bacteria. Protein-digesting enzymes in the stomach kill many different microorganisms.
- **Mucin.** *Mucin* dissolved in water forms thick, sticky mucus that lines the digestive and respiratory passageways. This mucus traps many microorganisms. Likewise, the mucin in watery saliva traps microorganisms and washes them out of the mouth into the stomach where they are digested.
- **Defensins.** Mucous membranes and skin secrete small amounts of broad-spectrum antimicrobial peptides called *defensins*. Defensin output increases dramatically in response to inflammation when surface barriers are breached. Using various mechanisms, such as disruption of microbial membranes, defensins help to control bacterial and fungal colonization in the exposed areas.
- **Other chemicals.** In the skin, some lipids in sebum and *dermcidin* in eccrine sweat are toxic to bacteria.

The respiratory tract mucosae also have structural modifications that counteract potential invaders. Tiny mucus-coated hairs inside the nose trap inhaled particles, and cilia on the mucosa of the upper respiratory tract sweep dust- and bacteria-laden mucus toward the mouth, preventing it from entering the lower respiratory passages.

Although these surface barriers (summarized in **Table 21.1**) are quite effective, they are breached by everyday nicks and cuts, for example, when you brush your teeth or shave. When this happens and microorganisms invade deeper tissues, your *internal* innate defenses—the second line of defense—come into play.

Check Your Understanding

1. What distinguishes the innate defense system from the adaptive defense system?
2. What is the first line of defense against disease?

For answers, see Answers Appendix.

21.2 Innate internal defenses are cells and chemicals that act as the second line of defense

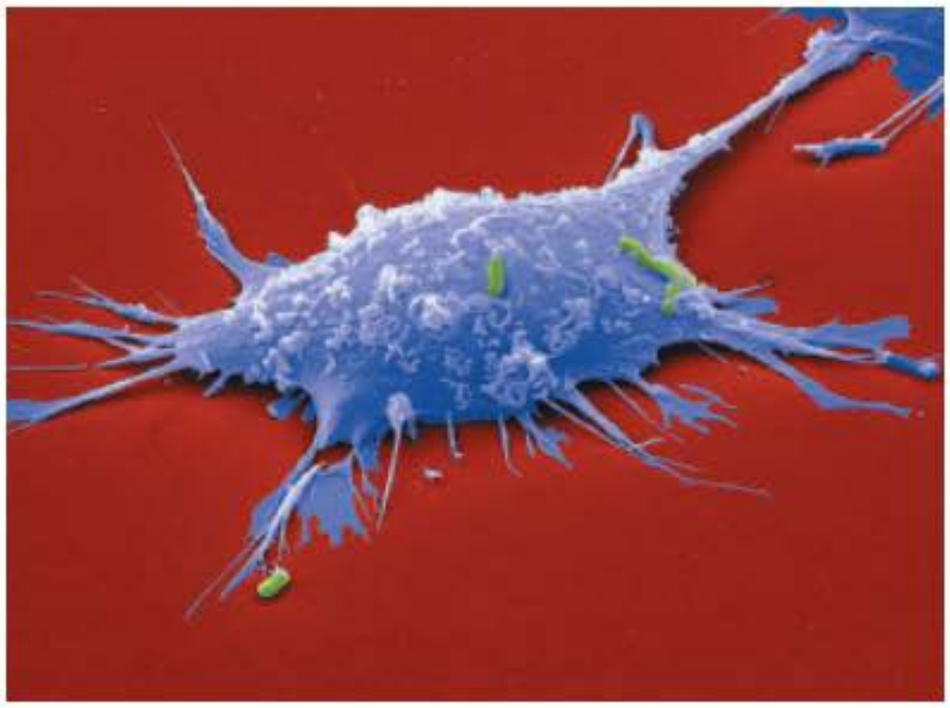
Learning Outcomes

- **Explain the importance of phagocytosis, natural killer cells, and fever in innate body defense.**
- **Describe the inflammatory process. Identify several inflammatory chemicals and indicate their specific roles.**
- **Name the body's antimicrobial substances and describe their functions.**

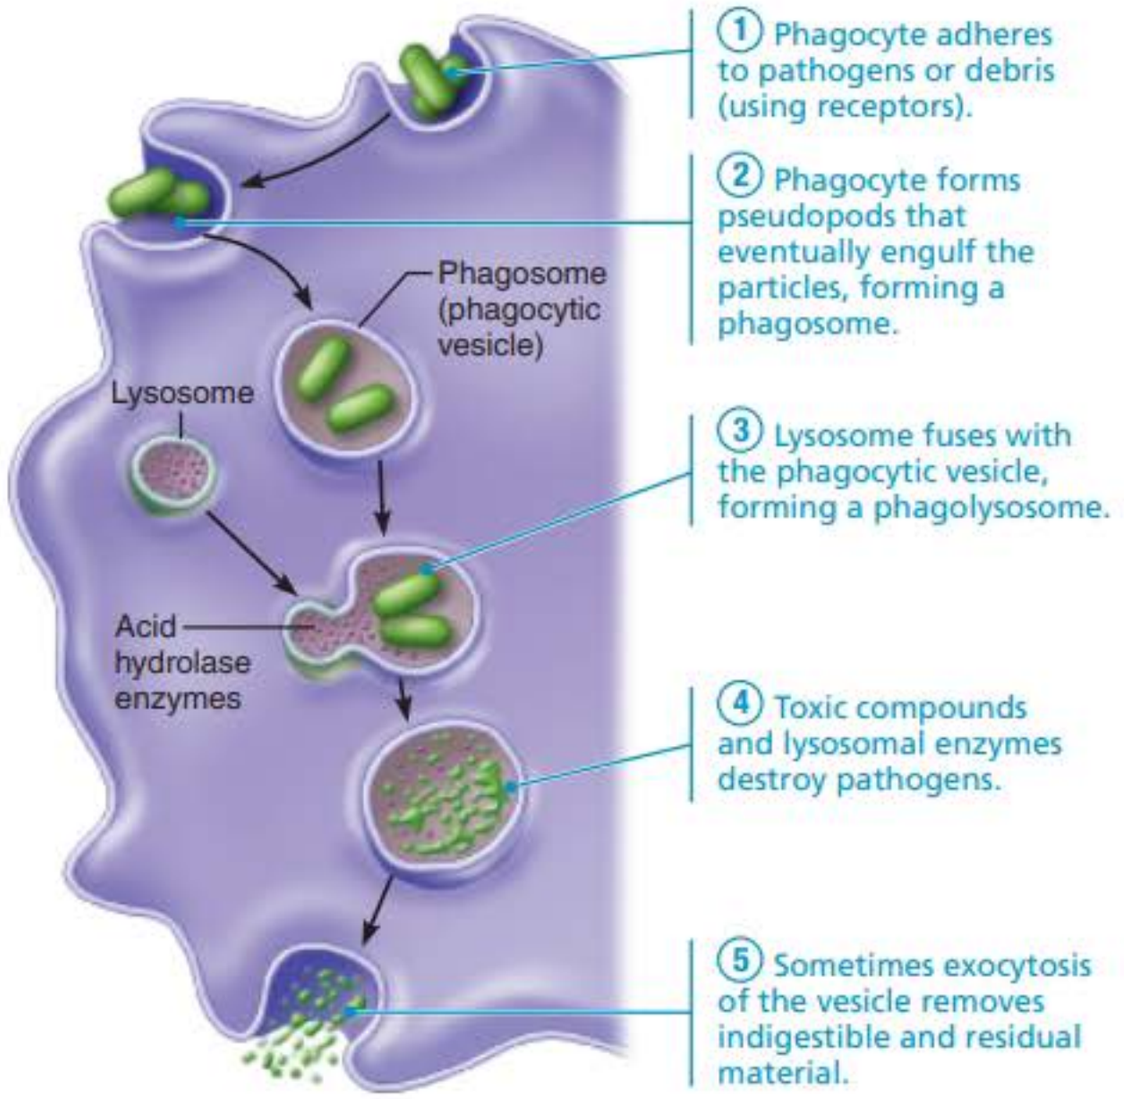
The body uses an enormous number of nonspecific cellular and chemical means to protect itself, including phagocytes, natural killer cells, antimicrobial proteins, and fever. The inflammatory response enlists macrophages, mast cells (◀ p. 129), all types of white blood cells, and dozens of chemicals that kill pathogens and help repair tissue. These protective tactics identify potentially harmful substances by recognizing (binding to) molecules with specific shapes that are part of infectious organisms (bacteria, viruses, fungi, and various parasites) but not normal human cells. The receptors that do this are called **pattern recognition receptors**.

One class of these receptors, called **Toll-like receptors (TLRs)**, plays a central role in triggering immune responses. There are 11 types of human TLRs, each recognizing a particular class of attacking microbe. For example, one type responds to a glycolipid in cell walls of the tuberculosis bacterium and

Innate defenses → Internal defenses



(a) A macrophage (purple) about to engulf rod-shaped bacteria (green). Scanning electron micrograph (2000×).



(b) Events of phagocytosis.

Figure 21.2 Phagocytosis.

another to a component of gram-negative bacteria such as *Salmonella*. A variety of cells have TLRs, including macrophages and cells of certain boundary tissues such as the epithelial cells lining the gastrointestinal and respiratory tracts. These pattern recognition receptors allow the cells to recognize invaders and sound a chemical "alarm" that initiates inflammation (which we will discuss shortly).

Phagocytes

Pathogens that get through the skin or mucosae into the underlying connective tissue are confronted by *phagocytes* (*phago* = eat). **Neutrophils**, the most abundant type of white blood cell, become phagocytic on encountering infectious material in the tissues. However, the most voracious phagocytes are **macrophages** ("big eaters"). Macrophages derive from white blood cells called **monocytes** that leave the bloodstream, enter the tissues, and develop into macrophages.

- *Free macrophages* wander throughout the tissue spaces in search of cellular debris or "foreign invaders."
- *Fixed macrophages*, such as *stellate macrophages* in the liver, are permanent residents of particular organs.

Phagocytosis

A phagocyte engulfs particulate matter much the way an amoeba ingests a food particle. Receptors on its flowing cytoplasmic extensions bind to the particle. The particle is then pulled inside, enclosed within a membrane-lined vesicle (**Figure 21.2a**). The resulting **phagosome** then fuses with a *lysosome* to form a **phagolysosome** (steps ①–③ in Figure 21.2b).

Neutrophils and macrophages generally kill ingested prey by acidifying the phagolysosome and digesting its contents with lysosomal enzymes. However, some pathogens such as the tuberculosis bacillus and certain parasites are resistant to lysosomal enzymes and can even multiply within the phagolysosome. In this case, other immune cells called helper T cells release chemicals that stimulate the macrophage. This activates additional enzymes that produce a lethal **respiratory burst**. The respiratory burst promotes killing of pathogens by:

- Liberating a deluge of highly destructive free radicals (◀ p. 86)
- Producing oxidizing chemicals (hydrogen peroxide and a substance identical to household bleach)
- Increasing the phagolysosome's pH and osmolarity, which activates other protein-digesting enzymes that digest the invader

Neutrophils also pierce the pathogen's membrane by using *defensins*, the antimicrobial peptides we mentioned earlier.

Phagocytic attempts are not always successful. In order for a phagocyte to ingest a pathogen, the phagocyte must first *adhere* to that pathogen, a feat made possible by recognizing the pathogen's carbohydrate "signature." Many bacteria have external capsules that conceal their carbohydrate signatures, allowing them to elude capture because phagocytes cannot bind to them.

Our immune systems get around this problem by coating pathogens with **opsonins**. Opsonins are complement proteins (discussed shortly) or antibodies. Both provide "handles" to which phagocyte receptors can bind. Any pathogen can be coated with opsonins, a process called **opsonization** ("to make tasty"), which greatly accelerates phagocytosis of that pathogen.

When phagocytes are unable to ingest their targets (because of size, for example), they can release their toxic chemicals into the extracellular fluid. Whether killing ingested or extracellular targets, neutrophils rapidly destroy themselves in the process. In contrast, macrophages are more robust and can survive to kill another day.

Natural Killer (NK) Cells

Natural killer (NK) cells, which "police" the body in blood and lymph, are a unique group of defensive cells that can kill cancer cells and virus-infected body cells before the adaptive immune system is activated. NK cells are part of a small group of *large granular lymphocytes*.

Unlike lymphocytes of the adaptive immune system, which only recognize and react against *specific* infected or tumor cells, NK cells are far less picky. They can eliminate a variety of infected or cancerous cells by detecting general abnormalities such as the lack of "self" cell-surface proteins called MHC, described on pp. 791–792. The name "natural" killer cells reflects their nonspecificity.

NK cells are not phagocytic. They kill by directly contacting the target cell, inducing it to undergo apoptosis (programmed cell death). This is the same method used by cytotoxic T cells (described on p. 807). NK cells also secrete potent chemicals that enhance the inflammatory response.

Inflammation: Tissue Response to Injury

Inflammation is a nonspecific response to any tissue injury. Causes include physical trauma, intense heat, irritating chemicals, or infection. Inflammation has several beneficial effects:

- It prevents the spread of damaging agents to nearby tissues.
- It disposes of cell debris and pathogens.
- It alerts the adaptive immune system.
- It sets the stage for repair.

How can you tell if inflammation is present? There are four *cardinal signs* (distinguishing indicators) of acute (short term) inflammation: *redness*, *heat* (*inflam* = set on fire), *swelling*, and *pain*. Some authorities consider *impaired function* to be a fifth cardinal sign. For instance, movement in an inflamed joint may be hampered temporarily, forcing it to rest, which aids healing. Inflammations are so common that many have specific names. Each name begins with the organ or tissue affected and ends with *-itis* (such as tonsillitis, appendicitis, and tendonitis).

Inflammatory Chemical Release

The inflammatory process begins with a chemical "alarm"—a flood of inflammatory chemicals released into the extracellular fluid. Inflammatory chemicals are released by injured or stressed tissue cells, and immune cells. For example, **mast cells** (◀ p. 129), a key component of the inflammatory response, release the potent inflammatory chemical **histamine** (his′tah-mēn). Inflammatory chemicals can also be formed from chemicals circulating in the blood (**Table 21.2**).

Other inflammatory chemicals include **kinins** (ki′ninz), **prostaglandins** (pros″tah-glan′dinz), and *cytokines* (a group of chemical mediators of immune responses that we will discuss later in the chapter). If pathogens provoked the inflammation, a group of plasma proteins known as **complement** is activated to form potent inflammatory chemicals.

All inflammatory chemicals dilate local arterioles and make local capillaries leakier. Many also attract phagocytes to the injured area. (We will see the importance of these effects next.) In addition, some have individual inflammatory roles, such as mobilizing lymphocytes and other elements of adaptive immunity.

Vasodilation and Increased Vascular Permeability

Vasodilation of local arterioles causes local **hyperemia** (increased blood flow). Hyperemia brings more cells and chemicals of the immune system to the injured area. It accounts for two of the cardinal signs of inflammation: the *redness* and *heat* of an inflamed region.

Inflammatory chemicals also increase the permeability of local capillaries and venules. Consequently, **exudate**—fluid containing clotting factors and antibodies—seeps from the

Table 21.2 Inflammatory Chemicals

CHEMICAL	SOURCE	PHYSIOLOGICAL EFFECTS
Histamine	Granules of mast cells and basophils (◀ p. 653). Released in response to mechanical injury, presence of certain microorganisms, and chemicals released by neutrophils.	Promotes vasodilation of local arterioles, increasing blood flow to injured area. Increases permeability of local capillaries, promoting formation of exudate.
Kinins (bradykinin and others)	A plasma protein, kininogen, is split by the enzyme kallikrein found in plasma, urine, saliva, and in lysosomes of neutrophils and other types of cells. Splitting releases active kinin peptides.	Same as for histamine. Also induce chemotaxis of leukocytes and prompt neutrophils to release lysosomal enzymes, thereby enhancing generation of more kinins. Induce pain.
Prostaglandins (◀ p. 48)	Fatty acid molecules produced from arachidonic acid found in all cell membranes; generated by enzymes of neutrophils, basophils, mast cells, and others.	Same as for histamine. Also induce neutrophil chemotaxis. Induce pain. (Some prostaglandins are anti-inflammatory.)
Complement	See Table 21.3 (p. 790).	
Cytokines	See Table 21.7 (p. 805).	

blood into the tissue spaces. This influx of protein-rich fluids into the tissue spaces sweeps foreign material into the lymphatic vessels so it can be processed in the lymph nodes. It also delivers important proteins such as complement and clotting factors to the interstitial fluid. The clotting factors form a gel-like fibrin mesh (a clot; ◀ p. 658) that acts as a scaffold for permanent repair. The mesh also isolates the injured area and prevents bacteria and other harmful agents from spreading. Walling off the injured area is such an important defense strategy that some bacteria (such as *Streptococcus*) have evolved enzymes that break down the clot, allowing them to invade surrounding tissues.

The increased tissue fluid causes the local *swelling* (edema) that presses on adjacent nerve endings, contributing to a sensation of *pain*. Pain also results from the release of bacterial toxins, and the sensitizing effects of released prostaglandins and kinins. (Aspirin and some other anti-inflammatory drugs reduce pain by inhibiting prostaglandin synthesis.)

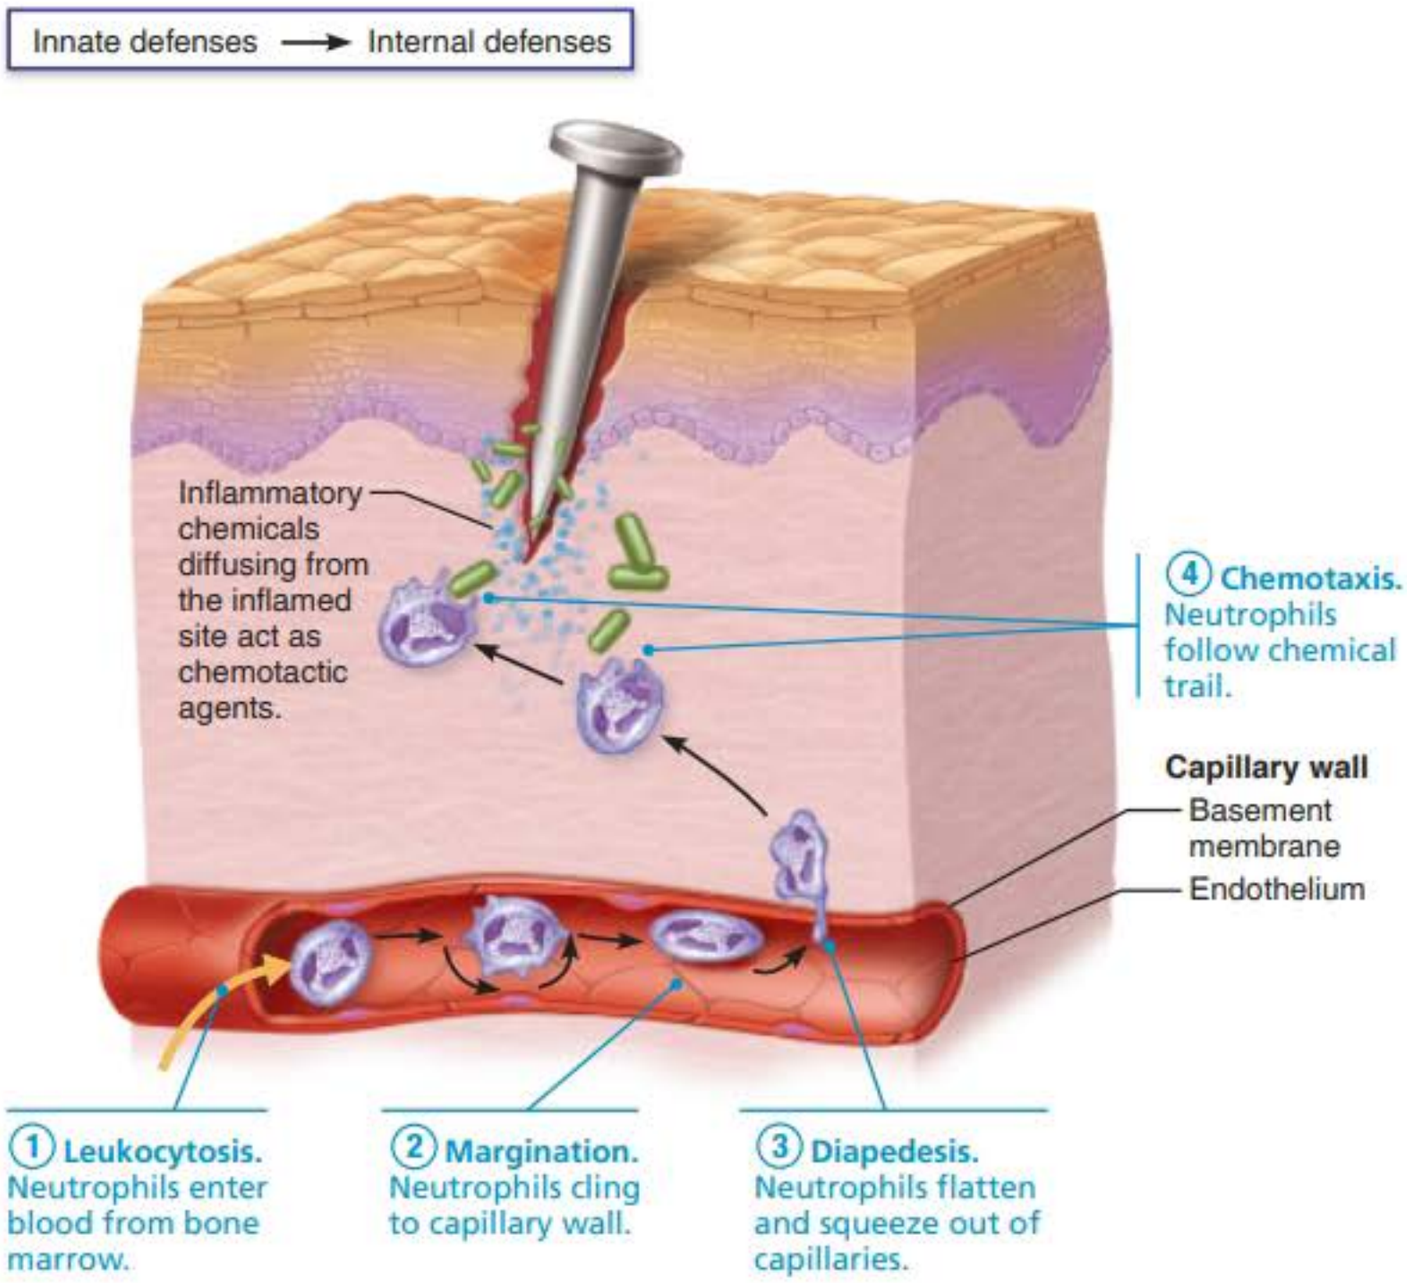


Figure 21.3 Phagocyte mobilization.

Phagocyte Mobilization

Soon after inflammation begins, phagocytes flood the damaged area. Neutrophils lead, followed by macrophages. **Figure 21.3** illustrates the four steps in which phagocytes are mobilized to infiltrate the injured site.

① **Leukocytosis.** Injured cells release chemicals called **leukocytosis-inducing factors**. In response, neutrophils enter blood from red bone marrow and within a few hours, the number of neutrophils in blood increases four- to five-fold. This **leukocytosis**, the increase in white blood cells (WBCs), is characteristic of inflammation.

② **Margination.** **Margination** refers to the phenomenon of phagocytes clinging to the inner walls (margins) of the capillaries and postcapillary venules. Inflamed endothelial cells sprout cell adhesion molecules (CAMs, ◀ p. 81) that signal "this is the place." As neutrophils encounter these CAMs, they bind briefly. This causes them to slow and roll along the inner surface of the blood vessel so they can be activated by inflammatory chemicals. Once activated, neutrophils sprout additional CAMs on their own plasma membranes. This allows the neutrophils to bind endothelial cells tightly, creating an initial foothold.

③ **Diapedesis.** Continued chemical signaling prompts the neutrophils to flatten and squeeze between the endothelial cells of the capillary walls—a process called **diapedesis**.

④ **Chemotaxis.** Inflammatory chemicals act as homing devices, or more precisely **chemotactic agents**. Neutrophils and other WBCs migrate up the gradient of chemotactic agents to the site of injury. Within an hour after the inflammatory response has begun, neutrophils have collected at the site and are devouring any foreign material present.

As the body's counterattack continues, monocytes follow neutrophils into the injured area. Monocytes are fairly poor phagocytes, but within 12 hours of leaving the blood and entering the tissues, they swell and develop large numbers of lysosomes, becoming macrophages with insatiable appetites. These late-arriving macrophages replace the neutrophils on the battlefield.

Macrophages are the central actors in the final disposal of cell debris as acute inflammation subsides, and they predominate at sites of chronic inflammation. The ultimate goal of an inflammatory response is to clear the injured area of pathogens, dead tissue cells, and any other debris so that tissue can be repaired. Once this is accomplished, healing usually occurs quickly.

The inflammatory response is summarized in **Figure 21.4**.

HOMEOSTATIC IMBALANCE 21.1 CLINICAL

In severely infected areas, the battle takes a considerable toll on both sides, and creamy yellow **pus** (a mixture of dead or dying neutrophils, broken-down tissue cells, and living and dead pathogens) may accumulate in the wound. If the inflammatory mechanism fails to clear the area of debris, collagen fibers may

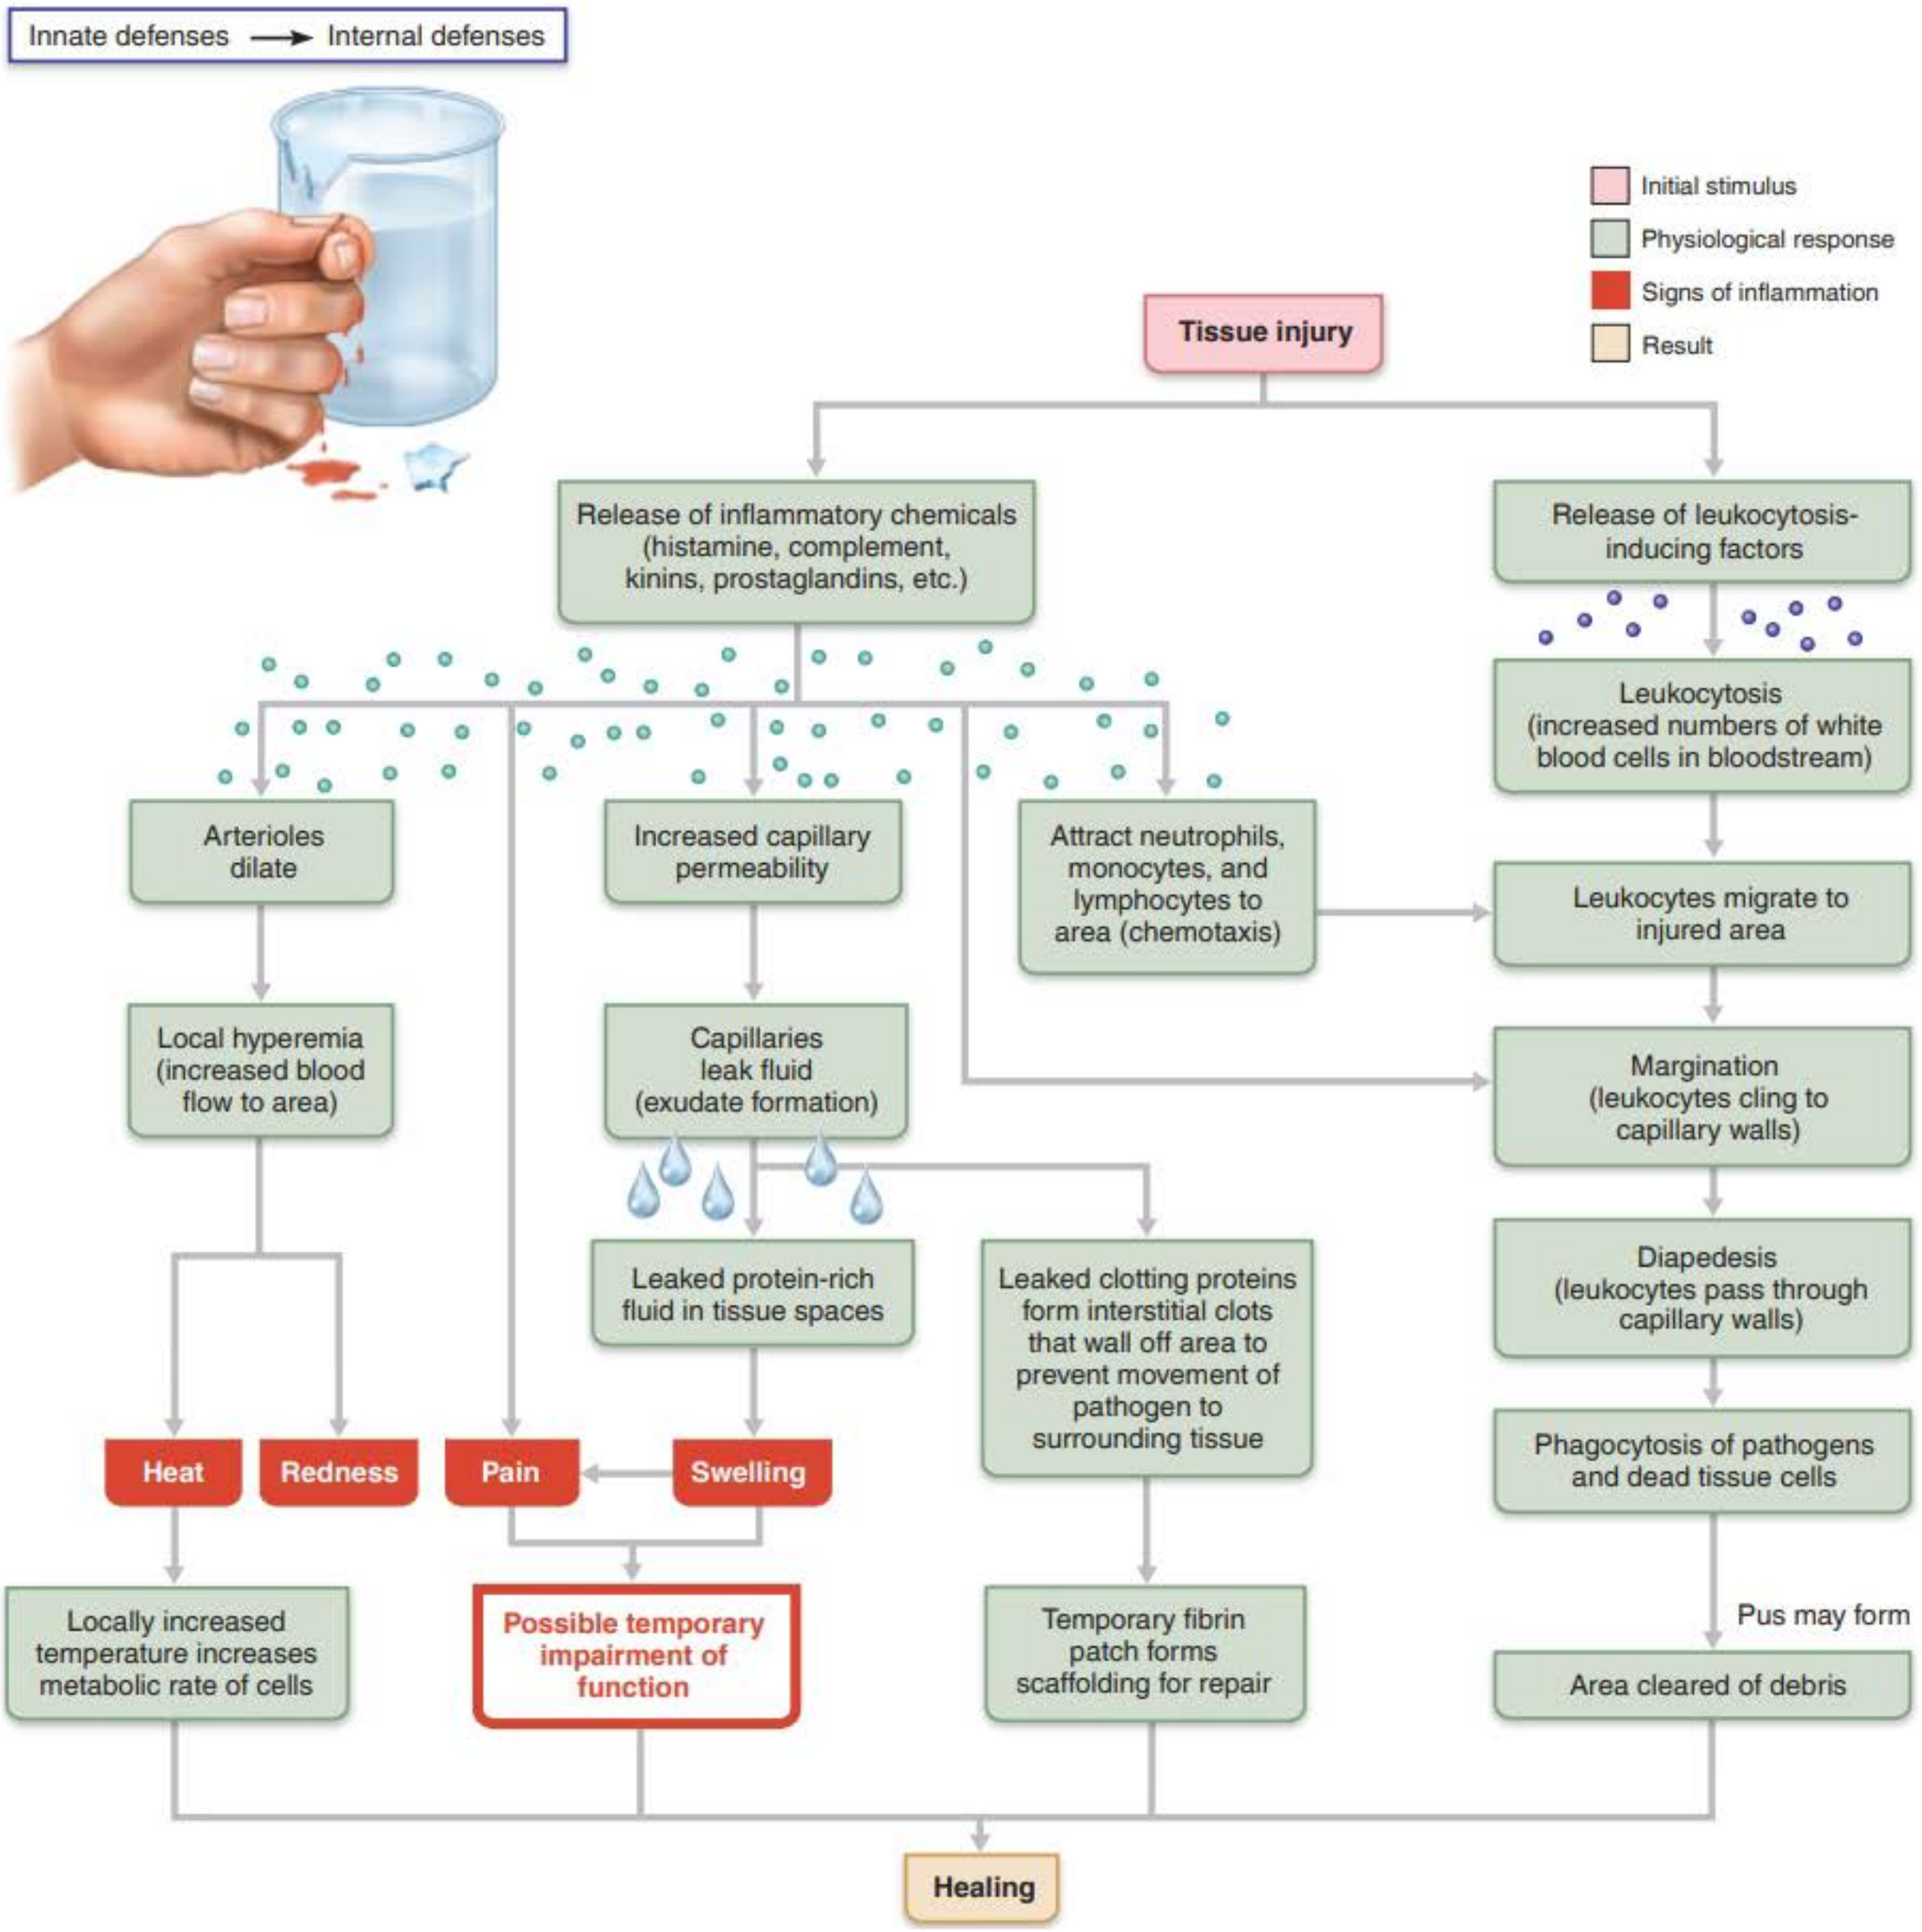

Figure 21.4 Events of acute inflammation. The four cardinal signs are shown in red boxes, as is impaired function, which in some cases constitutes a fifth cardinal sign.

be laid down, which walls off the sac of pus, forming an *abscess*. The abscess may need to be surgically drained before healing can occur.

Some bacteria, such as tuberculosis bacilli, resist digestion by the macrophages that engulf them. They escape the effects of prescription antibiotics by remaining snugly enclosed within their macrophage hosts. In such cases, *granulomas* form. These tumorlike growths contain a central region of infected macrophages surrounded by uninfected macrophages and an outer fibrous capsule.

A person may harbor pathogens walled off in granulomas for years without displaying any symptoms. However, if the person's resistance to infection is ever compromised, the bacteria may be activated and break free, leading to clinical disease symptoms.

Antimicrobial Proteins

A variety of **antimicrobial proteins** enhance our innate defenses by attacking microorganisms directly or by hindering their ability to reproduce. The most important antimicrobial proteins are interferons and complement proteins (**Table 21.3** on p. 790).

Interferons

Viruses—essentially nucleic acids surrounded by a protein envelope—lack the cellular machinery to generate ATP or synthesize proteins. They do their "dirty work" in the body by invading tissue cells and taking over the cellular metabolic machinery needed to reproduce themselves.

Infected cells can do little to save themselves, but some can secrete small proteins called **interferons (IFNs)** (in″ter-fēr′onz) to help protect cells that have not yet been infected. The IFNs diffuse to nearby cells, which they stimulate to synthesize proteins that block further protein synthesis and degrade viral RNA. In this way, they "interfere" with viral replication (**Figure 21.5**). Because IFN protection is *not* virus-specific, IFNs produced against a particular virus protect against other viruses, too.

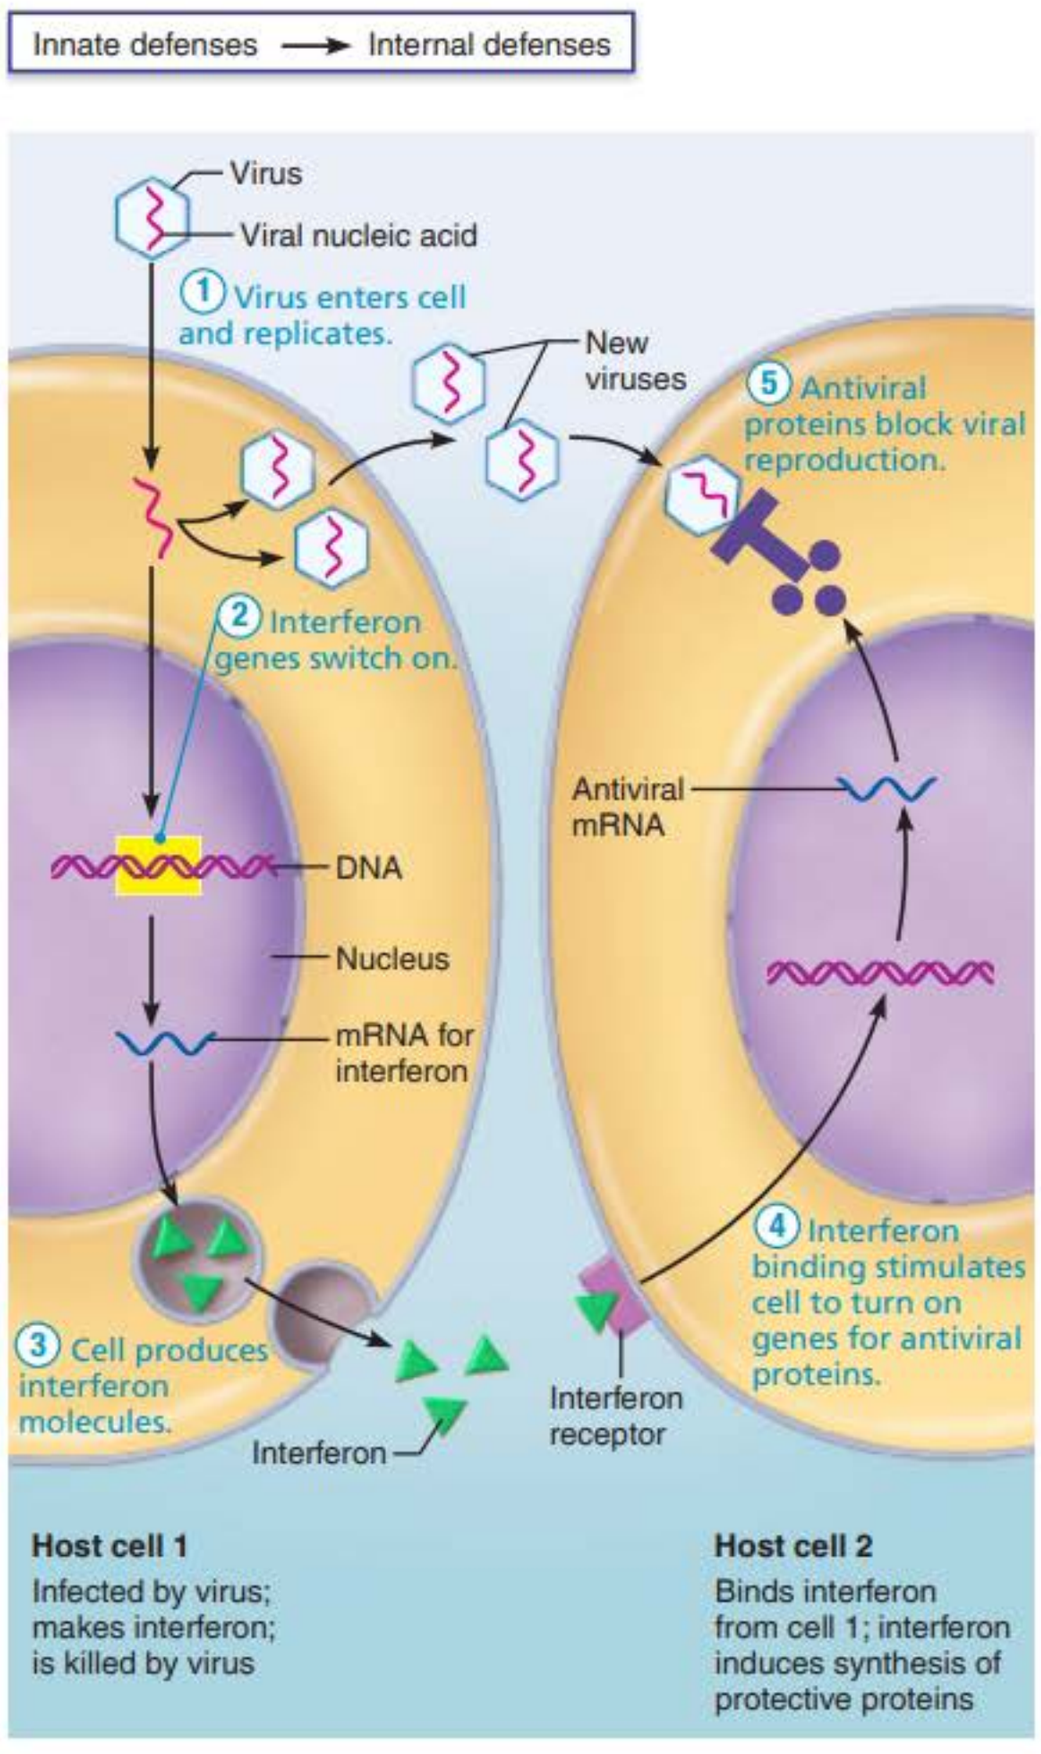

Figure 21.5 The interferon mechanism against viruses.

The IFNs are a family of immune modulating proteins produced by a variety of body cells, each having a slightly different physiological effect. IFN alpha (α) and beta (β) have the antiviral effects that we've just described and also activate NK cells. Another interferon, IFN gamma (γ), or immune interferon, is secreted by lymphocytes and has widespread immune mobilizing effects, such as activating macrophages. Because both macrophages and NK cells can also act directly against cancerous cells, the interferons have an indirect role in fighting cancer. IFNs are used to treat several disorders including hepatitis C, genital warts, and multiple sclerosis.

Complement

The term **complement system**, or simply **complement**, refers to a group of at least 20 plasma proteins that normally circulate in the blood in an inactive state. These proteins include those numbered C1 through C9 plus several others that act as regulatory proteins and other factors.

Complement provides a major mechanism for destroying foreign substances in the body. Its activation unleashes inflammatory chemicals that amplify virtually all aspects of the inflammatory process. Activated complement also lyses and kills certain bacteria and other cell types. (Luckily our own cells are equipped with proteins that normally inhibit complement activation.) Although complement is a nonspecific defensive mechanism, it "complements" (enhances) the effectiveness of *both* innate and adaptive defenses.

Figure 21.6 outlines the three pathways by which complement can be activated.

- The **classical pathway** involves *antibodies*, water-soluble protein molecules that the adaptive immune system produces to fight off foreign invaders. When antibodies bind to pathogens, they can also bind complement components. This double binding is the first step in this complement activation pathway. (We describe this in more detail on pp. 800–801.)
- The **lectin pathway** involves *lectins*, water-soluble protein molecules that the innate immune system produces to recognize foreign invaders. When lectins bind specific sugars on the surface of microorganisms, they can then bind and activate complement.
- The **alternative pathway** is triggered when spontaneously activated C3 and other complement factors interact on the surface of microorganisms. These microorganisms lack the complement activation inhibitors our own cells have.

Like the blood clotting cascade, complement activation by any of these pathways involves a cascade in which proteins are activated in an orderly sequence—each step catalyzing the next. The three pathways converge at C3, which is split into C3a and C3b. Splitting C3 initiates a common terminal pathway that enhances inflammation, promotes phagocytosis, and can cause cell lysis.

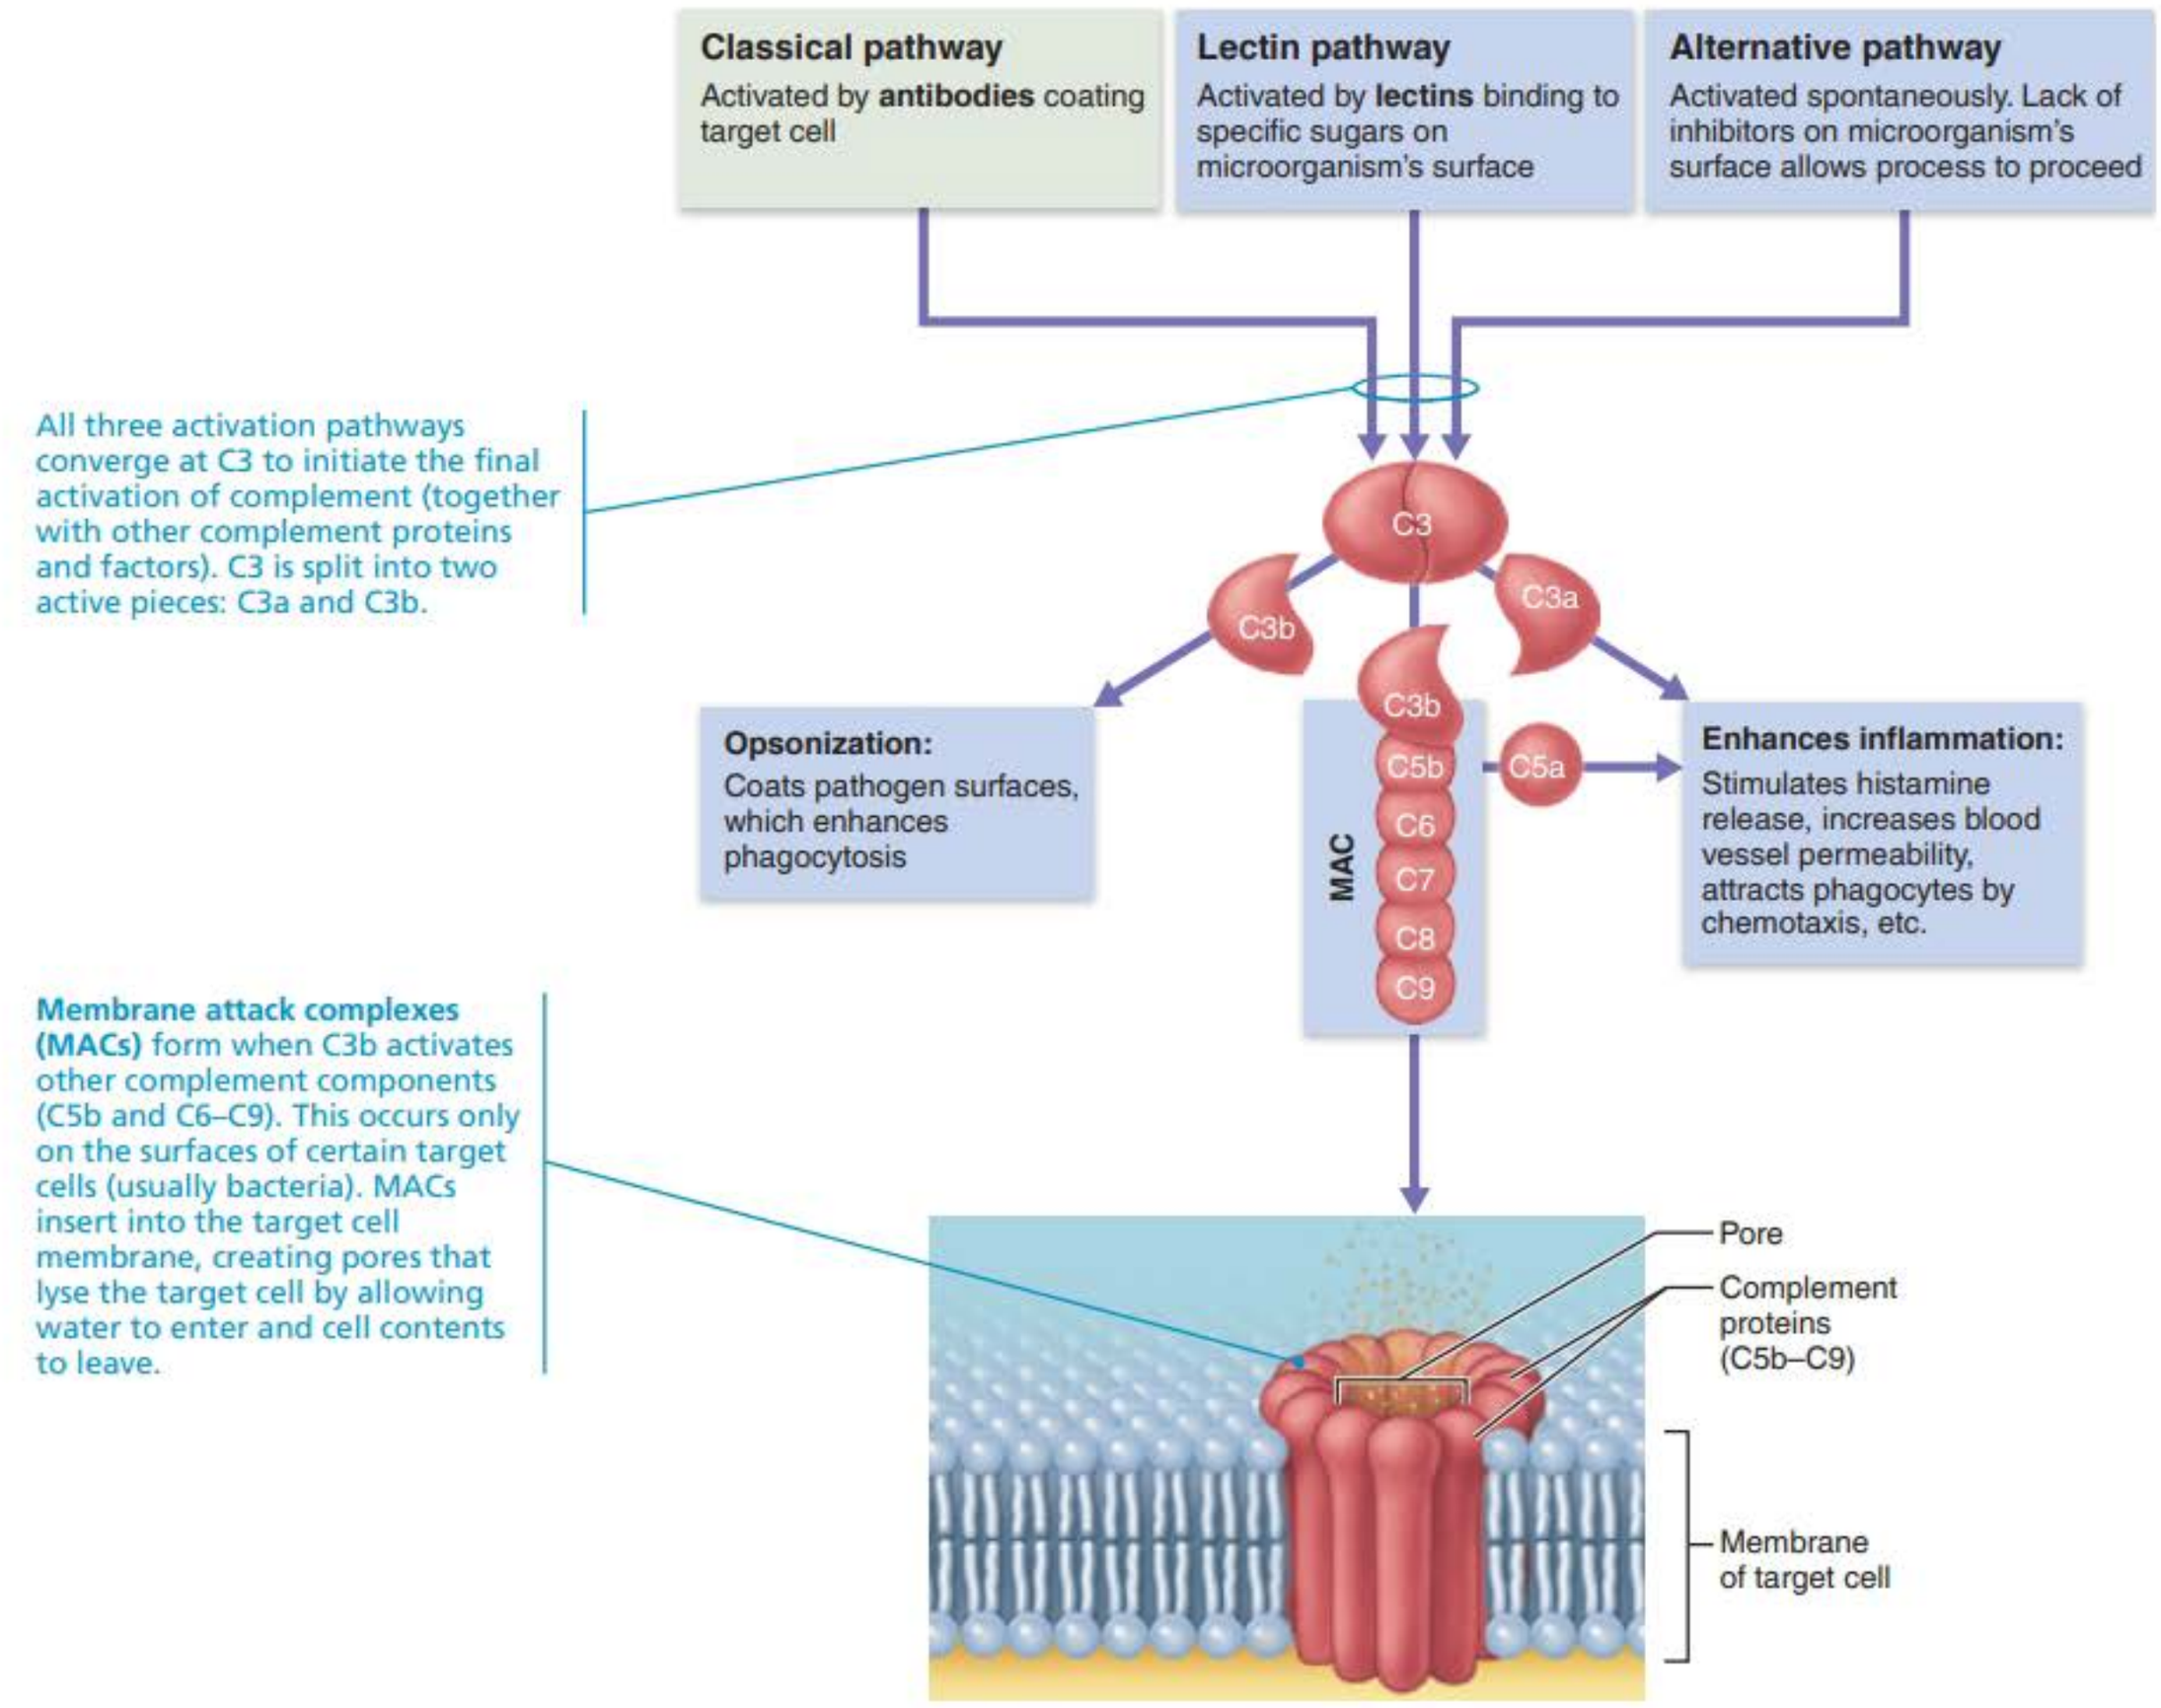

Figure 21.6 Complement activation.

Cell lysis begins when C3b binds to the target cell's surface and triggers the insertion of a group of complement proteins called **MAC (membrane attack complex)** into the cell's membrane. MAC forms and stabilizes a hole in the membrane that allows a massive influx of water, lysing the target cell.

The C3b molecules also act as *opsonins*. As previously described, opsonins coat the microorganism, providing "handles" that receptors on macrophages and neutrophils can adhere to. This allows them to engulf the particle more rapidly. C3a and other molecules formed during complement activation amplify the inflammatory response by stimulating mast cells and basophils to release histamine and by attracting neutrophils and other inflammatory cells to the area.

Fever

Inflammation is a localized response to infection, but sometimes the body's response to the invasion of microorganisms is more widespread. **Fever**, an abnormally high body temperature, is a systemic response to invading microorganisms.

When leukocytes and macrophages are exposed to foreign substances in the body, they release chemicals called **pyrogens** (*pyro* = fire). These pyrogens act on the body's thermostat—a cluster of neurons in the hypothalamus—raising the body's temperature above normal [37°C (98.6°F)].

Fever seems to benefit the body, but exactly how it does so is unclear. Fever causes the liver and spleen to sequester iron and zinc, which may make them less available to support bacterial growth. Additionally, fever increases the metabolic rate of tissue cells, and may speed up repair processes.

Check Your Understanding

3. What is opsonization and how does it help phagocytes? Give an example of a molecule that acts as an opsonin.
4. Under what circumstances might NK cells kill our own cells?

In summary, the adaptive immune response has four key characteristics that set it appart from the innate defenses:

- **It involves lymphocytes called B and T lymphocytes.** These lymphocytes are not involved in innate immunity.
- **It is specific.** It recognizes and targets *identified* pathogens or foreign substances that initiate the immune response.
- **It is systemic.** Adaptive immunity is not restricted to the initial infection site.
- **It has "memory."** After an initial exposure, it recognizes and mounts even stronger attacks on previously encountered pathogens.

Before describing the humoral and cellular responses, we will first consider the central role of *antigens*.

21.3 Antigens are substances that trigger the body's adaptive defenses

Learning Outcomes

- **Define antigen and describe how antigens affect the adaptive defenses.**
- **Define complete antigen, hapten, and antigenic determinant.**

Antigens (an′tĭ-jenz) are substances that can mobilize the adaptive defenses. They are the ultimate targets of all adaptive immune responses. (*Antigen* is a contraction of "*anti*body *gen*erating.") Most antigens are large, complex molecules (natural or synthetic) that are *foreign* (not normally present in the body). Consequently, as far as our immune system is concerned, they are intruders, or **nonself**.

Complete Antigens and Haptens

Antigens can be *complete* or *incomplete*. **Complete antigens** have two important functional properties:

- **Immunogenicity**, which is the ability to stimulate specific lymphocytes to proliferate (multiply).
- **Reactivity**, which is the ability to react with the activated lymphocytes and the antibodies released by immunogenic reactions.

An almost limitless variety of foreign molecules can act as complete antigens, including virtually all foreign proteins, many large polysaccharides, and some lipids and nucleic acids. Of these, proteins are the strongest antigens. Pollen grains and microorganisms—such as bacteria, fungi, and virus particles—are all immunogenic because their surfaces bear many different foreign macromolecules.

As a rule, small molecules—such as peptides, nucleotides, and many hormones—are not immunogenic. But if they link up with the body's own proteins, the adaptive immune system may recognize the *combination* as foreign and mount an attack that is harmful rather than protective. (We describe these reactions, called *hypersensitivities*, later in the chapter.) In such cases, the troublesome small molecule is called a **hapten** (hap′ten; *haptein* = grasp) or **incomplete antigen**. Unless attached to protein carriers, haptens have reactivity but not immunogenicity. Besides certain drugs (particularly penicillin), chemicals that act as haptens are found in poison ivy, animal dander, detergents, cosmetics, and a number of common household and industrial products.

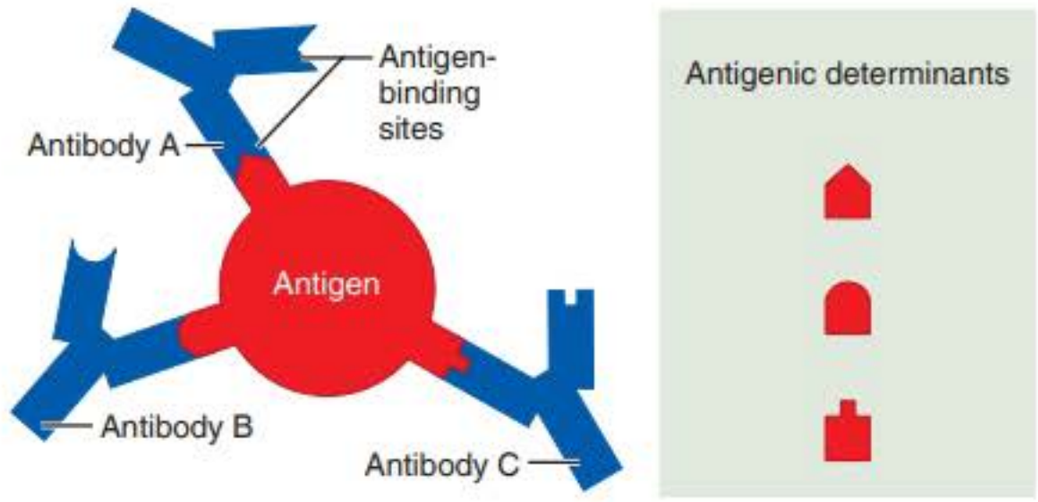

Figure 21.7 Most antigens have several different antigenic determinants. Antibodies (and related receptors on lymphocytes) bind to small areas on the antigen surface called antigenic determinants. In this example, three different types of antibodies react with different antigenic determinants on the same antigen molecule.

Antigenic Determinants

The ability of a molecule to act as an antigen depends on both its size and its complexity. Only certain parts of the antigen, called **antigenic determinants**, are immunogenic. Antibodies or lymphocyte receptors bind to these antigenic determinants in much the same manner that an enzyme binds to a substrate.

Most naturally occurring antigens have a variety of antigenic determinants on their surfaces, some more potent than others in provoking an immune response (**Figure 21.7**). Different lymphocytes "recognize" different antigenic determinants, so a single antigen may mobilize several lymphocyte populations and stimulate formation of many kinds of antibodies.

Large proteins have hundreds of chemically different antigenic determinants, which accounts for their high immunogenicity and reactivity. However, large simple molecules such as plastics, which have many identical, regularly repeating units, have little or no immunogenicity. Such substances are used to make artificial implants because the substances are not seen as foreign and rejected by the body.

Self-Antigens: MHC Proteins

A huge variety of protein molecules dot the external surfaces of all our cells. Assuming your immune system has been properly "programmed," your **self-antigens** are not foreign or antigenic to you, but they are strongly antigenic to other individuals. (This is the basis of transfusion reactions and graft rejection.)

Among the cell surface proteins that identify a cell as *self* is a group of glycoproteins called **MHC proteins**. Genes of the

major histocompatibility complex (MHC) code for these proteins. Because millions of combinations of these genes are possible, it is unlikely that any two people except identical twins have the same MHC proteins. Each MHC protein has a deep groove that holds a peptide, either a self-antigen or a foreign antigen. As we will describe shortly, T lymphocytes can only bind antigens that are presented (displayed to them) on MHC proteins.

Check Your Understanding

7. Name four key characteristics of adaptive immunity.
8. What is the difference between a complete antigen and a hapten?
9. What marks a cell as "self" as opposed to "nonself"?

For answers, see Answers Appendix.

21.4 B and T lymphocytes and antigen-presenting cells are cells of the adaptive immune response

Learning Outcomes

- **Compare and contrast the origin, maturation process, and general function of B and T lymphocytes.**
- **Define immunocompetence and self-tolerance, and describe their development in B and T lymphocytes.**
- **Name several antigen-presenting cells and describe their roles in adaptive defenses.**

The adaptive immune system involves three crucial types of cells: two distinct populations of lymphocytes, plus *antigen-presenting cells* (*APCs*).

- **B lymphocytes (B cells)** oversee humoral immunity.
- **T lymphocytes (T cells)** are non-antibody-producing lymphocytes that constitute the cellular arm of adaptive immunity.
- APCs do not respond to specific antigens as lymphocytes do. Instead, they play essential auxiliary roles. As we will see, T cells cannot recognize their antigens without APCs.

Lymphocytes

Despite their differences, B and T lymphocytes share a common pattern of development and common steps in their life cycles. Let's take a look.

Lymphocyte Development, Maturation, and Activation

The development, maturation, and activation of B and T cells share the five general steps shown in **Figure 21.8**.

① **Origin.** Like all blood cells, lymphocytes originate in red bone marrow from hematopoietic stem cells.

② **Maturation.** Lymphocytes are "educated" (go through a rigorous selection process) as they mature. The aim of this education is twofold:

- **Immunocompetence.** Each lymphocyte must become able (competent) to recognize its one specific antigen by binding to it. This ability is called **immunocompetence**. When B or T cells become immunocompetent, they display a unique type of receptor on their surface. These receptors (some 10^5 per cell) enable the lymphocyte to recognize and bind a specific antigen. Once these receptors appear, the lymphocyte is committed to react to one (and only one) distinct antigenic determinant because *all* of its antigen receptors are the same. The receptors on B cells are in fact membrane-bound antibodies. The receptors on T cells are not antibodies but are products of the same gene superfamily and have similar functions.
- **Self-tolerance.** Each lymphocyte must be relatively unresponsive to self-antigens so that it does not attack the body's own cells. This is called **self-tolerance**.

Maturation is a two- to three-day process that occurs in the red bone marrow for B cells and in the thymus for T cells. Recall from Chapter 20 that the lymphoid organs where lymphocytes mature—thymus and red bone marrow—are called **primary lymphoid organs**. All other lymphoid organs are referred to as **secondary lymphoid organs**. We will examine the selection process that underlies lymphocyte maturation on p. 794.

③ **Seeding secondary lymphoid organs and circulation.** Immunocompetent B and T cells that have not yet been exposed to antigen are called **naive**. Naive B cells and T cells are exported from the primary lymphoid organs to seed (colonize) the secondary lymphoid organs—lymph nodes, spleen, and so on—where they are likely to encounter antigens.

Lymphocytes, especially the T cells (which account for 65–85% of bloodborne lymphocytes), circulate continuously throughout the body. Circulating greatly increases a lymphocyte's chance of coming into contact with antigens located in different parts of the body, as well as with other lymphocytes and antigen-presenting cells. For example, a T cell circulates through lymph and blood and back to a lymph node about once a day. Although lymphocyte circulation appears to be random, lymphocyte movement into the tissues is highly specific, regulated by homing signals (CAMs) displayed on vascular endothelial cells.

④ **Antigen encounter and activation.** The first encounter between an immunocompetent but naive lymphocyte and an invading antigen usually takes place in a lymph node or the spleen, but it may happen in any secondary lymphoid organ. Immune cells in lymph nodes are in a strategic position to encounter a large variety of antigens because lymphatic capillaries pick up proteins and pathogens from nearly all body tissues.

When an antigen binds to the particular lymphocyte that has a receptor for it, the antigen selects that lymphocyte for further development. This is called **clonal selection**. If the proper signals (which we describe later) are present, the selected lymphocyte will activate to complete its differentiation.

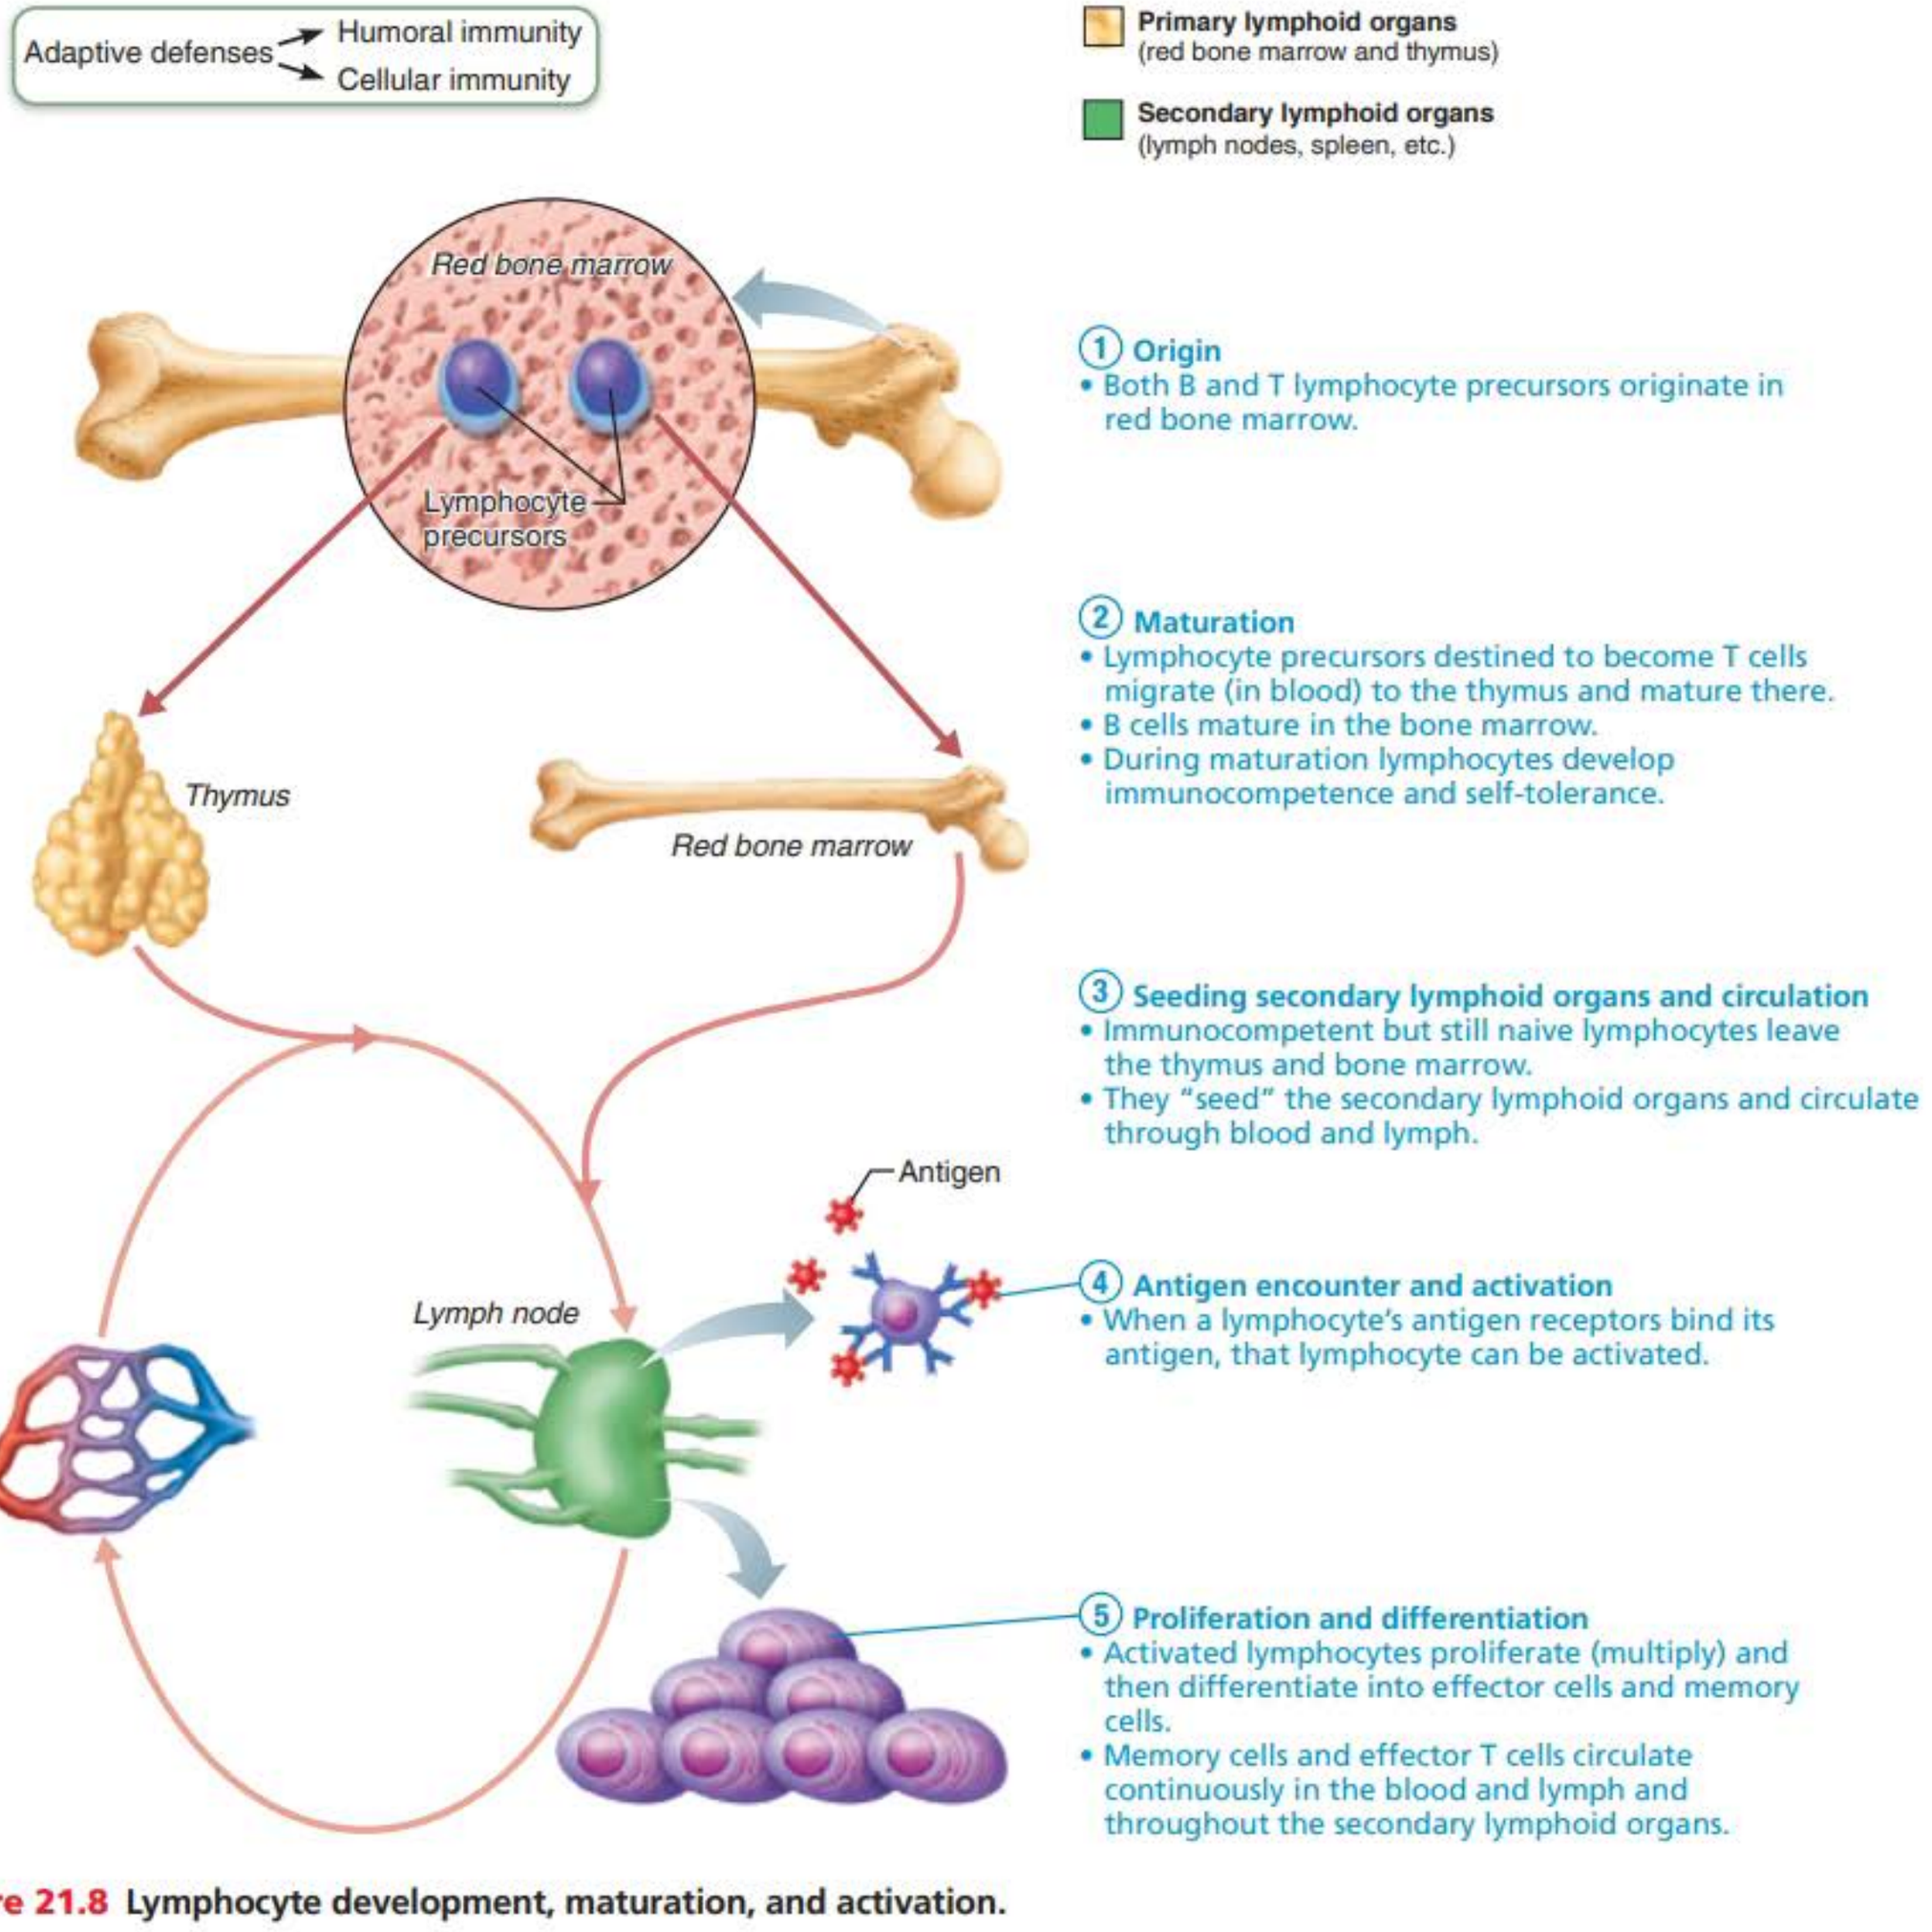

Figure 21.8 Lymphocyte development, maturation, and activation.

⑤ **Proliferation and differentiation.** Once activated, the lymphocyte rapidly proliferates (multiplies) to form an army of cells exactly like itself and having the same antigen specificity. This army of identical cells, all descended from the *same* ancestor cell, is called a **clone**.

Most members of the clone become **effector cells**, the cells that actually do the work of fighting infection. A few members of the clone become **memory cells** that are able to respond quickly after any subsequent encounter with the same antigen. B and T memory cells and effector T cells circulate throughout the body on continuous patrol.

How Does Antigen Receptor Diversity in Lymphocytes Come About?

We know that lymphocytes become immunocompetent *before* meeting the antigens they may later attack. *Our genes, not antigens we encounter, determine which specific foreign substances our immune system will be able to recognize and resist.* In other words, the immune cell receptors represent our genetically acquired knowledge of the microbes that are likely to be in our environment. An antigen simply determines which existing T or B cells will proliferate and mount the attack against it.

Only some of the antigens our lymphocytes are programmed to resist will ever invade our bodies. Consequently, only some

members of our army of immunocompetent cells are mobilized in our lifetime. The others are forever idle.

Our lymphocytes make up to a billion different types of antigen receptors. These receptors, like all other proteins, are specified by genes, so you might think that an individual must have billions of genes. Not so; each body cell only contains about 20,000 genes that code for all the proteins the cell must make.

How can a limited number of genes generate a seemingly limitless number of different antigen receptors? Molecular genetic studies have shown that the genes that dictate the structure of each antigen receptor are not present as such in lymphocyte stem cells. Instead of a complete set of "antigen receptor genes," stem cells contain a few hundred genetic bits and pieces that can be thought of as a "Lego® set" for antigen receptor genes. As each lymphocyte becomes immunocompetent, these gene segments are shuffled and combined in different ways, a process called *somatic recombination*. The information of the newly assembled genes is then expressed as the surface receptors of B and T cells and as the antibodies later released by the B cell's "offspring."

How Are Lymphocytes Educated during Maturation?

The selection process (education) that lymphocytes undergo during maturation is best understood in T cells. T cell education consists of positive and negative selection in the thymus (**Figure 21.9**).

1. **Positive selection** is the first of two tests a developing T lymphocyte must pass. It ensures that *only* T cells with receptors that are able to recognize self-MHC proteins survive. Remember that T cells cannot bind antigens unless the antigens are presented on self-MHC proteins. T cells that are unable to recognize self-MHC are eliminated by apoptosis.
2. **Negative selection**, the second test, ensures that T cells do not recognize self-antigens displayed on self-MHC. If they do, they are eliminated by apoptosis. Negative selection is the basis for immunological self-tolerance, making sure that T cells don't attack the body's own cells, which would cause autoimmune disorders. Because the self-reactive lymphocyte and all of its potential progeny are eliminated, this is called *clonal deletion*.

This education of T cells is expensive indeed—only about 2% of T cells survive it and continue to become successful immunocompetent, self-tolerant T cells.

Less is known about the factors that control B cell maturation. Like T cells, only immunocompetent B cells are allowed to mature. But selection is not perfect for either B or T cells—some self-reactive lymphocytes survive.

Antigen-Presenting Cells (APCs)

Antigen-presenting cells (APCs) engulf antigens and then present fragments of them, like signal flags, on their own surfaces where T cells can recognize them. Naive T cells can only be activated by antigens that are presented to them on MHC proteins by APCs. In other words, APCs *present antigens* to the cells that will deal with the antigens. The major types of cells acting as APCs are *dendritic cells*, *macrophages*, and *B lymphocytes*.

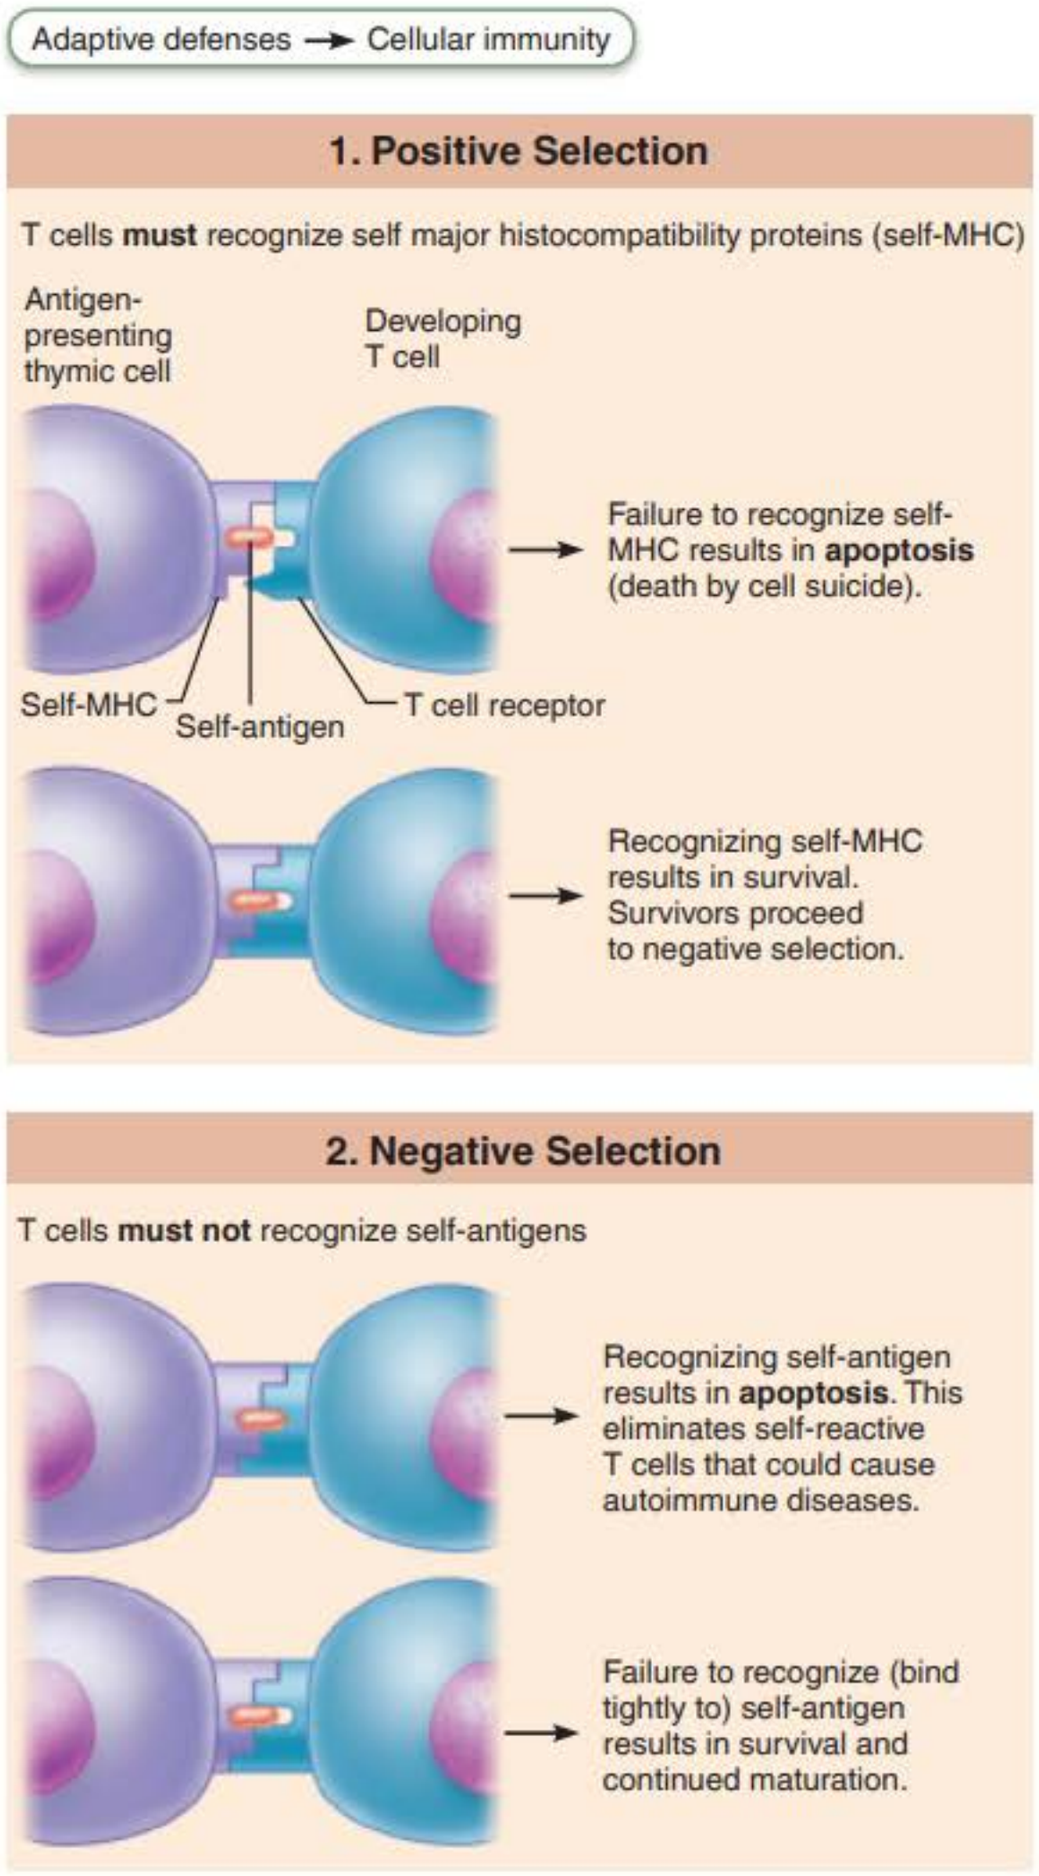

Figure 21.9 T cell education in the thymus.

Dendritic Cells

Dendritic cells are found at the body's frontiers (skin, for example) where they act as mobile sentinels. With their long, wispy extensions, dendritic cells are very efficient antigen catchers (**Figure 21.10**). Once they have internalized antigens by phagocytosis, they enter nearby lymphatics to get to a lymph node where they will present the antigens to T cells.

Migration of dendritic cells to secondary lymphoid organs is now recognized as the most important way of ensuring that lymphocytes encounter invading antigens. Indeed, dendritic cells are the most effective antigen presenter known—it's their only job. This early alert spares the body a good deal of tissue damage that might otherwise occur.

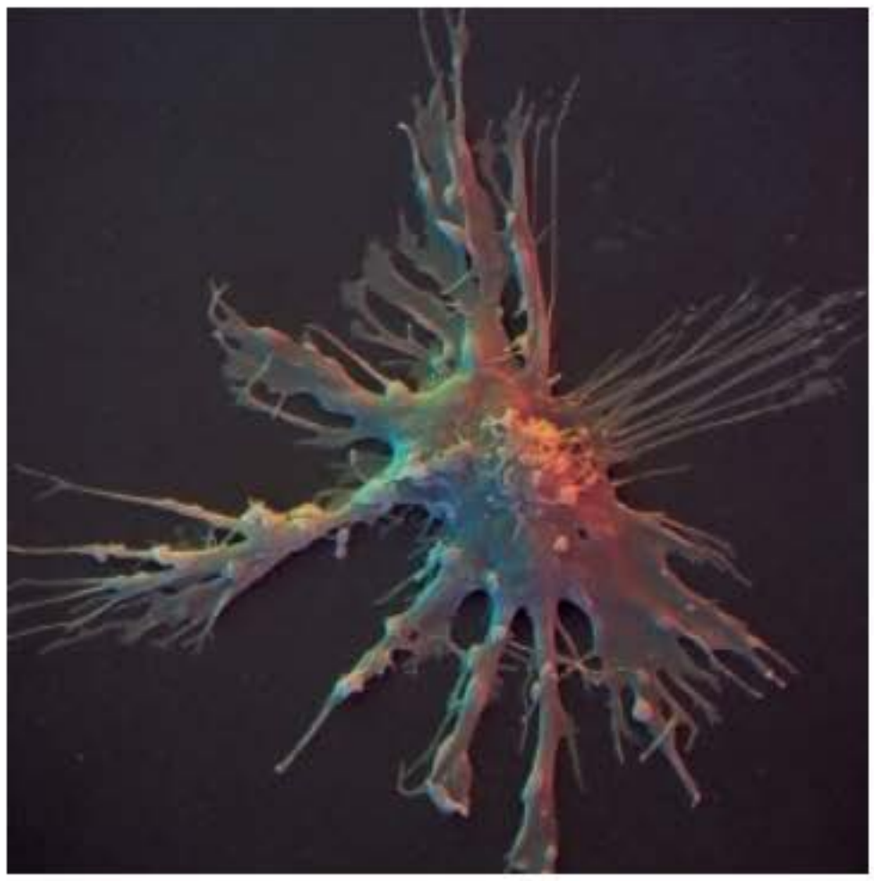

Figure 21.10 Dendritic cell. Scanning electron micrograph (1050×).

Dendritic cells are one of the key links between innate and adaptive immunity. They initiate adaptive immune responses tailored to the type of pathogen they have encountered.

Macrophages

Macrophages are widely distributed throughout the lymphoid organs and connective tissues. Although macrophages, like dendritic cells, can activate naive T cells, macrophages often present antigens to T cells for other reasons—to maintain T cell activation or to be activated themselves. Certain effector T cells release chemicals that prod macrophages to become *activated macrophages*. Activated macrophages are true "killers"—insatiable phagocytes that also trigger powerful inflammatory responses and recruit additional defenses.

B Lymphocytes

Unlike dendritic cells and macrophages, B cells do not activate naive T cells. Instead, they present antigens to a certain kind of T cell (a helper T cell) in order to obtain "help" in their own activation. We will discuss this more on p. 806.

Check Your Understanding

10. What event (or observation) signals that a B or T cell has achieved immunocompetence?

11. Name three different APCs. Which is most important for T lymphocyte activation?

12. In clonal selection, "who" does the selecting? What is being selected?

13. PREDICT Which of the following T cells would survive education in the thymus? (a) one that recognizes neither MHC nor self-antigen, (b) one that recognizes both MHC and self-antigen, (c) one that recognizes MHC but not self-antigen, (d) one that recognizes self-antigen but not MHC.

For answers, see Answers Appendix.

In summary, the two-fisted adaptive immune system uses lymphocytes, APCs, and specific molecules to identify and destroy all substances—both living and nonliving—that are in the body but not recognized as self. The system's response to such threats depends on the ability of its cells to (1) recognize antigens by binding to them and (2) communicate with one another so that the whole system mounts a response specific to those antigens. As you will see, interactions between various lymphocytes, and between lymphocytes and APCs, underlie virtually all phases of the adaptive immune response.

Table 21.4 outlines major similarities and differences between B and T lymphocytes. This will help orient you as you delve into the details of humoral and cellular immunity in the next two modules.

Table 21.4 Overview of B and T Lymphocytes

	B LYMPHOCYTES	T LYMPHOCYTES
Type of immune response	Humoral	Cellular
Antibody secretion	Yes	No
Primary targets	Extracellular pathogens (e.g., bacteria, fungi, parasites, some viruses in extracellular fluid)	Intracellular pathogens (e.g., virus-infected cells) and cancer cells*
Site of origin	Red bone marrow	Red bone marrow
Site of maturation	Red bone marrow	Thymus
Effector cells	Plasma cells	Cytotoxic T (T_C) cells Helper T (T_H) cells Regulatory T (T_{Reg}) cells
Memory cell formation	Yes	Yes

*In addition, helper T cells coordinate both B and T lymphocyte responses.

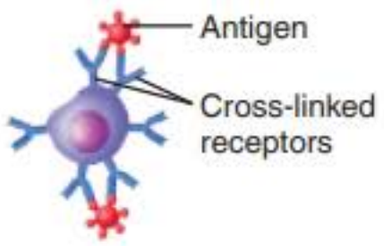
21.5 In humoral immunity, antibodies are produced that target extracellular antigens

Learning Outcomes

- **Define humoral immunity.**
- **Describe the process of clonal selection of a B cell and recount the roles of plasma cells and memory cells in humoral immunity.**
- **Compare and contrast active and passive humoral immunity.**
- **Describe the structure and functions of antibodies and name the five antibody classes.**

Now that you understand the common steps in lymphocyte maturation and activation, let's examine how this basic pattern applies to B lymphocytes. When a B cell encounters its antigen, that antigen provokes the *humoral immune response*, in which antibodies specific for that antigen are made.

Activation and Differentiation of B Cells



An immunocompetent but naive B lymphocyte is *activated* when matching antigens bind to its surface receptors and cross-link adjacent receptors together. Antigen binding is quickly followed by receptor-mediated endocytosis of the cross-linked antigen-receptor complexes. As we described previously, this is called *clonal selection* and is followed by proliferation and differentiation into effector cells (**Figure 21.11**). (As we will see shortly, interactions with T cells are usually required to help B cells achieve full activation.)

Most cells of the clone differentiate into **plasma cells**, the antibody-secreting *effector cells* of the humoral response.

Adaptive defenses → Humoral immunity

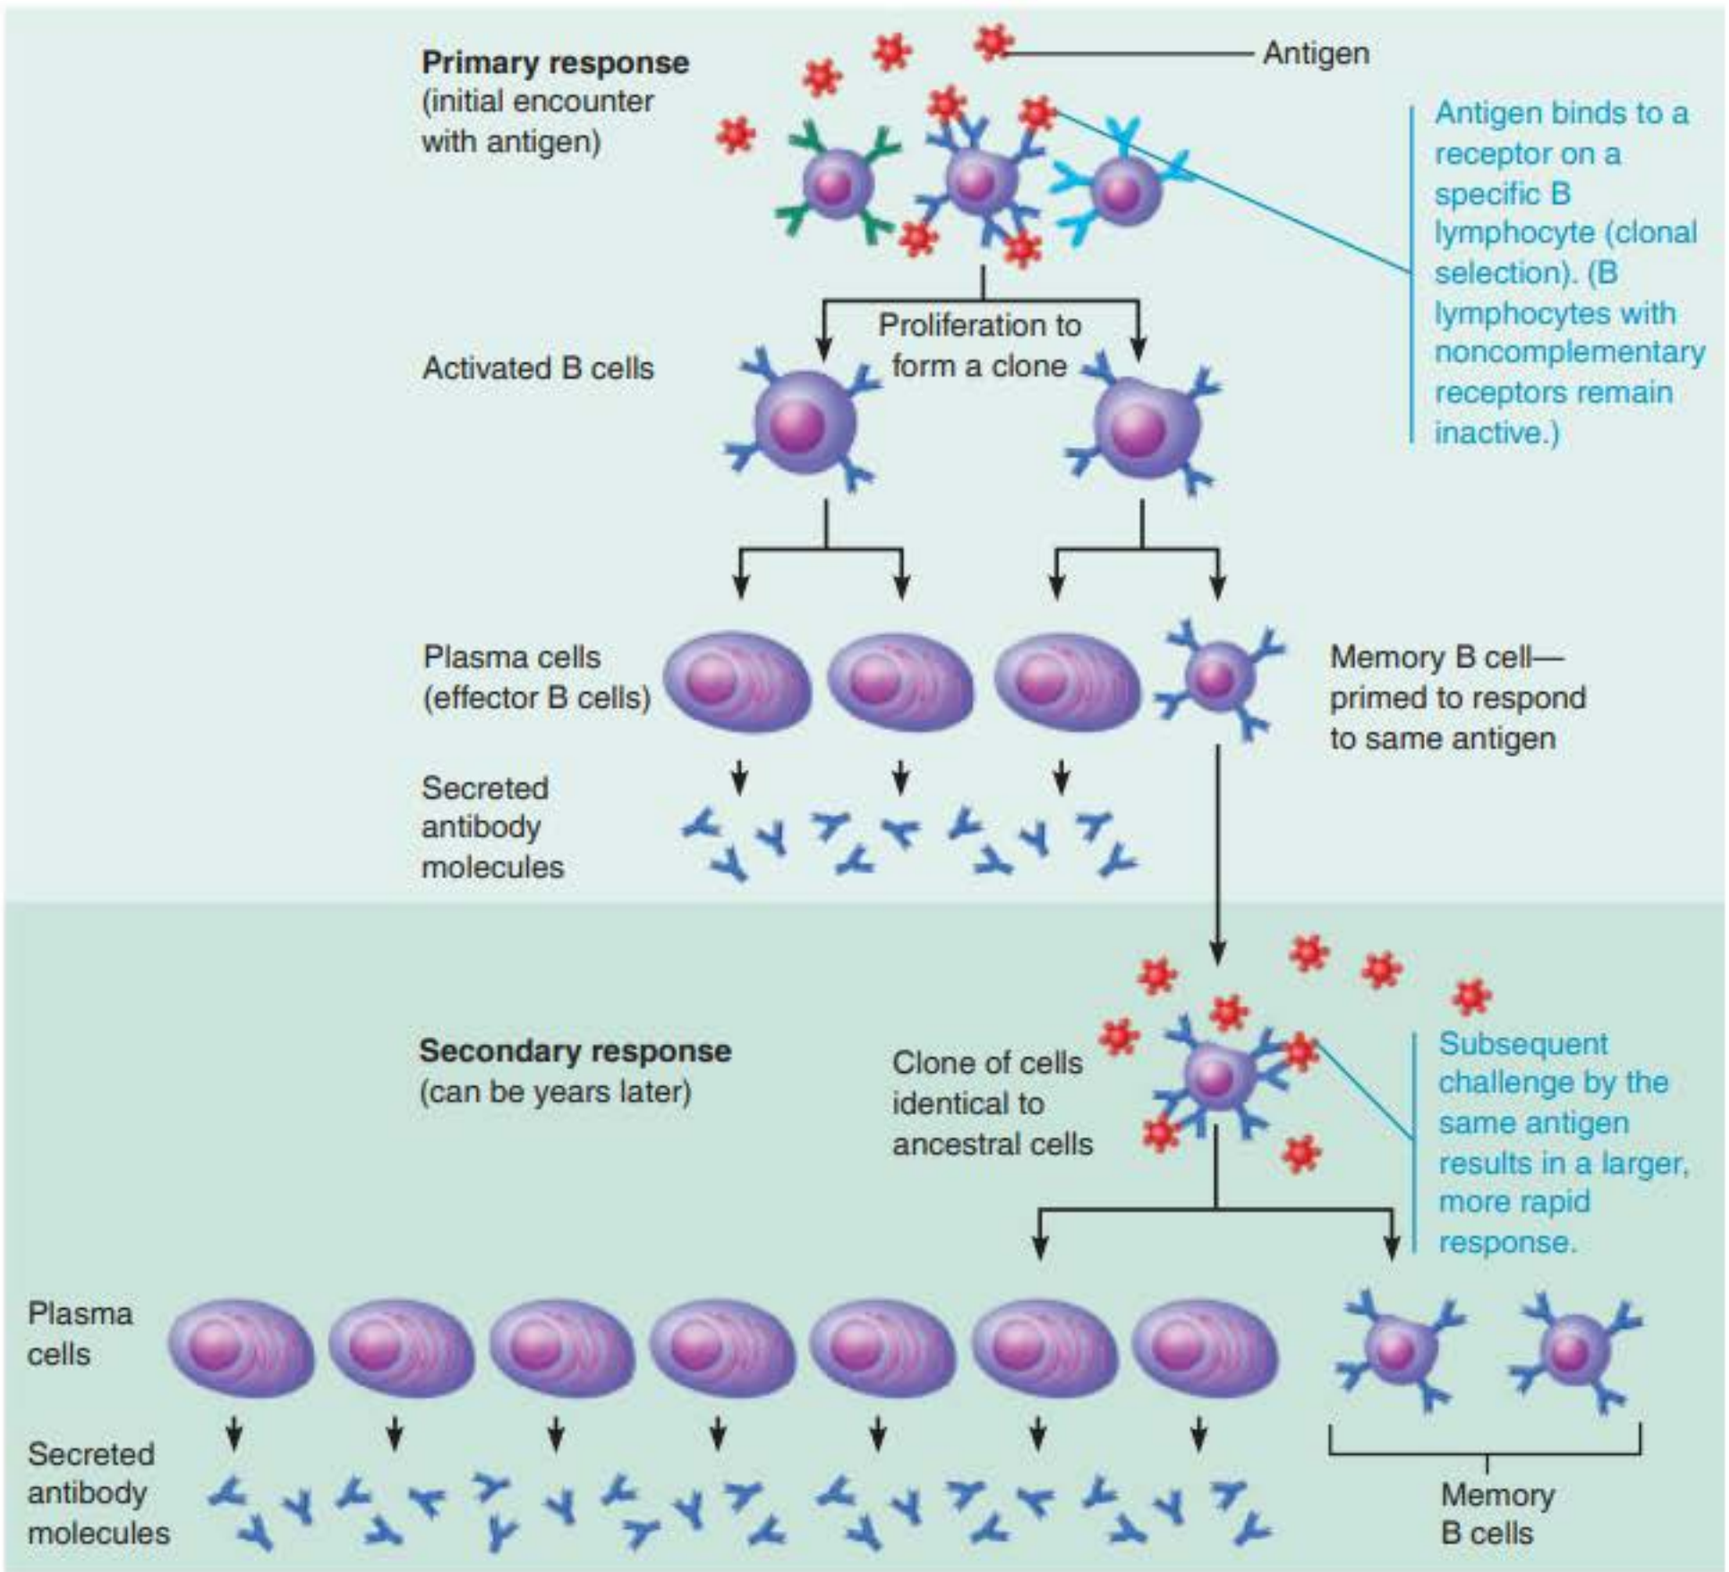


Figure 21.11 Clonal selection of a B cell.

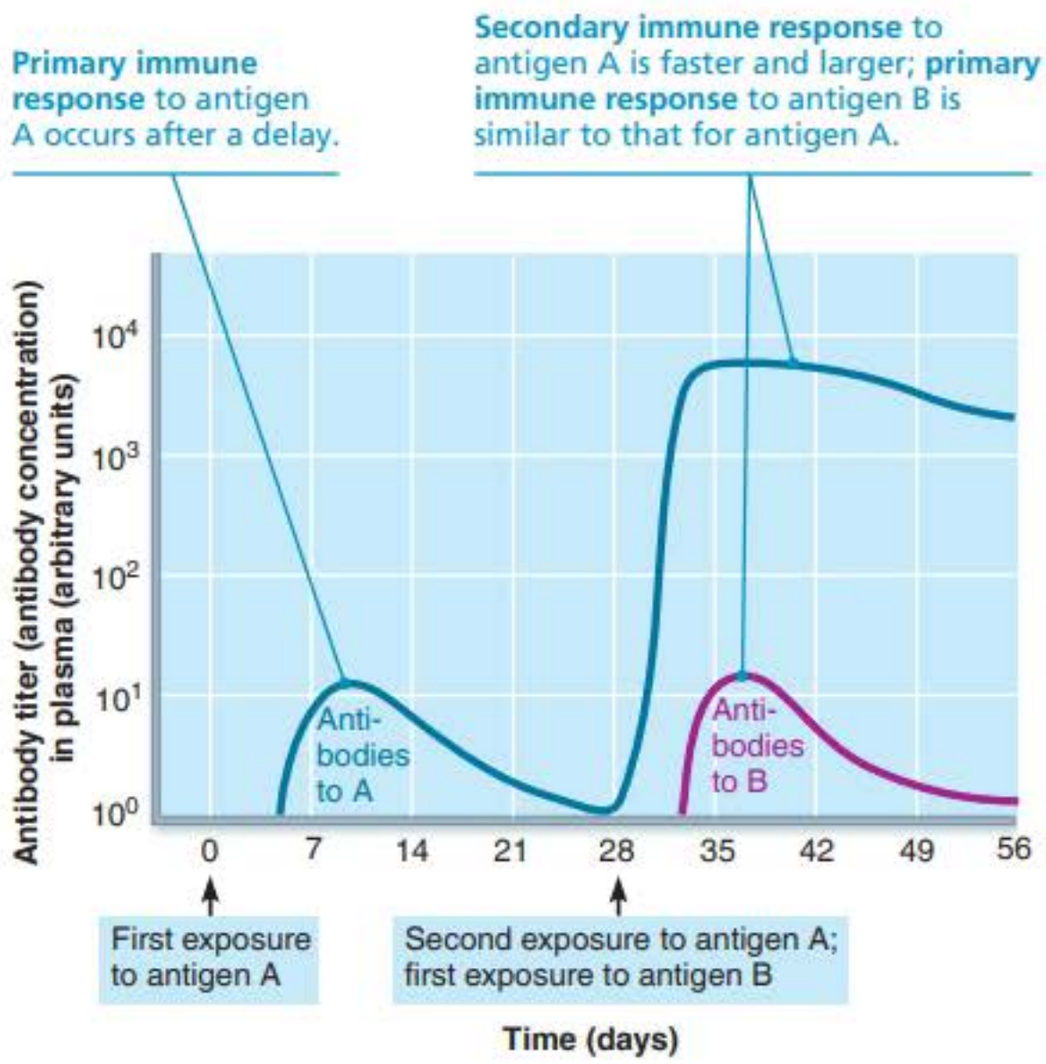

Figure 21.12 Primary and secondary humoral responses. The primary response to antigen A generates memory cells that give rise to the enhanced secondary response to antigen A. The response to antigen B is independent of the response to antigen A.

Plasma cells develop the elaborate internal machinery (largely rough endoplasmic reticulum) needed to secrete antibodies at the unbelievable rate of about 2000 molecules per second. Each plasma cell functions at this breakneck pace for 4 to 5 days and then dies. The secreted antibodies, each with the same antigen-binding properties as the receptor molecules on the surface of the parent B cell, circulate in the blood or lymph. There they bind to free antigens and mark them for destruction by other innate or adaptive mechanisms.

Clone cells that do not become plasma cells become long-lived **memory cells**. They can mount an almost immediate humoral response if they encounter the same antigen again in the future (Figure 21.11, bottom).

Immunological Memory

The cellular proliferation and differentiation we have just described constitute the **primary immune response**, which occurs on first exposure to a particular antigen. The primary response typically has a lag period of 3 to 6 days after the antigen encounter. This lag period mirrors the time required for the few B cells specific for that antigen to proliferate (about 12 generations) and for their offspring to differentiate into plasma cells. After the mobilization period, plasma antibody levels rise, reach peak levels in about 10 days, and then decline (**Figure 21.12**).

If (and when) someone is reexposed to the same antigen, whether it's the second or twenty-second time, a **secondary immune response** occurs. Secondary immune responses are faster, more prolonged, and more effective, because the immune system has already been primed to the antigen, and sensitized memory cells are already "on alert." These memory cells provide **immunological memory**.

Within hours after recognizing the "old enemy" antigen, a new army of plasma cells is being generated. Within 2 to 3 days the antibody concentration in the plasma, called the *antibody titer*, rises steeply to reach much higher levels than in the primary response. Secondary response antibodies not only bind with greater affinity (more tightly), but their blood levels remain high for weeks to months. (When the appropriate chemical signals are present, plasma cells can keep functioning for much longer than the 4 to 5 days seen in primary responses.) Memory cells persist for long periods and many retain their capacity to produce powerful secondary humoral responses for life.

The same general events occur in the cellular immune response: A primary response sets up a pool of effector cells (in this case, T cells) and generates memory cells that can then mount secondary responses.

Active and Passive Humoral Immunity

When your B cells encounter antigens and produce antibodies against them, you are exhibiting **active humoral immunity**. Active immunity is acquired in two ways (**Figure 21.13**). It is (1) *naturally acquired* when you get a bacterial or viral infection, during which time you may develop symptoms of the disease and suffer a little (or a lot), and (2) *artificially acquired* when you receive a **vaccine**. Indeed, once researchers realized that secondary responses are so much more vigorous than primary responses, the race was on to develop vaccines to "prime" the immune response by providing a first encounter with the antigen.

Most vaccines contain pathogens that are dead or *attenuated* (living, but extremely weakened), or their components. Vaccines provide two benefits:

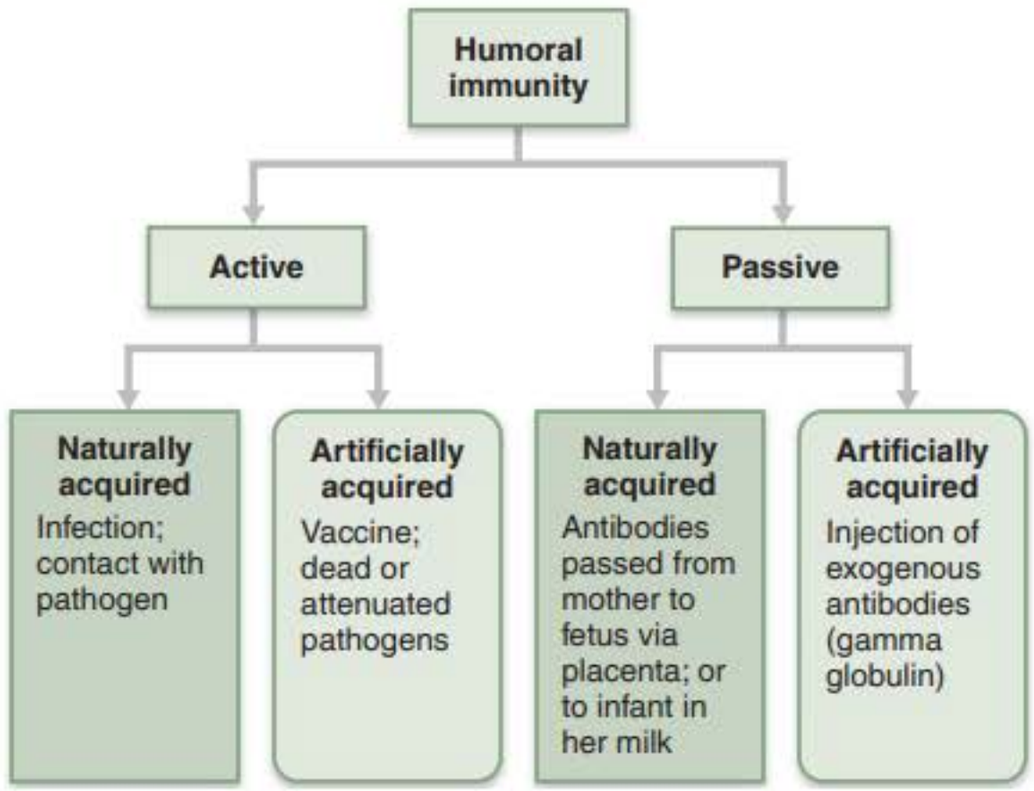

Figure 21.13 Active and passive humoral immunity. Active immunity establishes immunological memory; passive immunity never does.

- Their weakened antigens provide functional antigenic determinants that are both immunogenic and reactive.
- They spare us most of the symptoms and discomfort of the disease that would otherwise occur during the primary response.

Vaccine *booster shots* are used in some cases to intensify the immune response at later encounters with the same antigen.

Vaccines have wiped out smallpox and have substantially lessened the illness caused by such former childhood killers as whooping cough, polio, and measles. Although vaccines have dramatically reduced hepatitis B, tetanus, influenza, and pneumonia in adults, immunization of adults in the U.S. has a much lower priority than that of children. As a result more than 65,000 Americans die each year from preventable infections.

Conventional vaccines have shortcomings. The biggest shortcoming is that they are not always as effective or long-lasting as we would like. In some individuals, contaminating proteins (for example, egg albumin) cause allergic responses to the vaccine.

Passive humoral immunity differs from active immunity, both in the antibody source and in the degree of protection it provides (Figure 21.13). Instead of being made by your plasma cells, ready-made antibodies are introduced into your body. As a result, your B cells are not challenged by antigens, immunological memory does not occur, and the protection provided by the "borrowed" antibodies ends when they naturally degrade in the body.

Passive immunity is conferred *naturally* on a fetus or infant when the mother's antibodies cross the placenta or are ingested with the mother's milk. For several months after birth, the baby is protected from all the antigens to which the mother has been exposed.

Passive immunity can also be conferred *artificially* by administering exogenous antibodies (from outside your own body) as *gamma globulin*, harvested from the plasma of an immune donor. Exogenous antibodies are used to prevent hepatitis A (antiserum) and treat poisonous snake bites (antivenom), botulism, rabies, and tetanus (antitoxin) because these rapidly fatal diseases would kill a person before active immunity could be established. The donated antibodies provide immediate protection, but their effect is short-lived (two to three weeks).

Antibodies

Antibodies, also called **immunoglobulins (Igs)** (im″u-no-glob′u-linz), constitute the **gamma globulin** part of blood proteins. As we mentioned earlier, antibodies are proteins secreted in response to an antigen by effector B cells called plasma cells, and the antibodies bind specifically with that antigen. They are formed in response to an incredible number of different antigens. Despite their variety, all antibodies can be grouped into

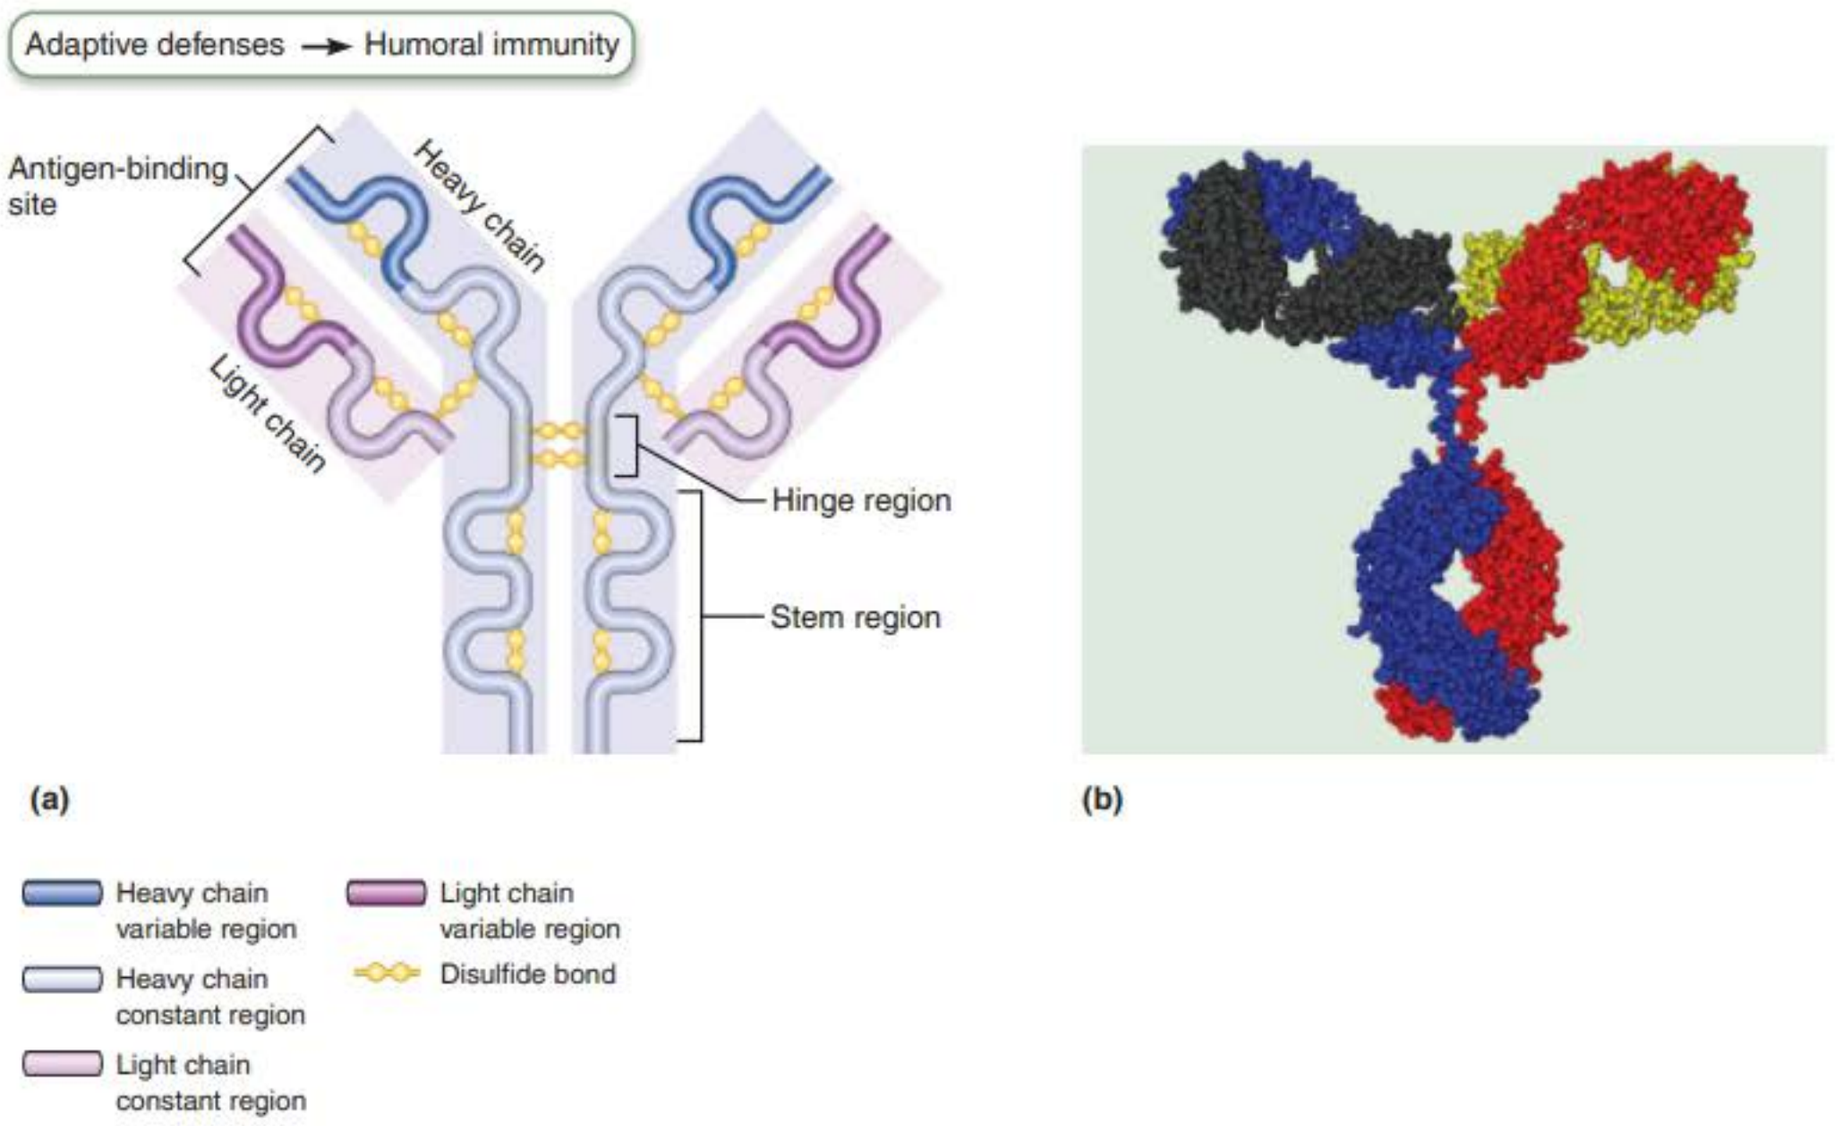

Figure 21.14 Antibody structure. **(a)** Schematic antibody structure (based on IgG) consists of four polypeptides—two short *light chains* and two long *heavy chains* joined together by covalent bonds between sulfur atoms called disulfide bonds (S–S). Each chain has a variable (V) region (which differs in antibodies made by different cells) and a constant (C) region (essentially identical in different antibodies of the same class). Together, the variable regions form the antigen-binding sites—two per antibody monomer. **(b)** Computer-generated image of antibody structure.

one of five Ig classes. Before seeing how these Ig classes differ from one another, let's look at how all antibodies are alike.

Basic Antibody Structure

Regardless of its class, each antibody consists of four looping polypeptide chains linked together by disulfide (sulfur-to-sulfur) bonds. The four chains combined form a molecule, called an **antibody monomer** (mon′o-mer), with two identical halves. The molecule as a whole is T or Y shaped (**Figure 21.14**).

Two of the chains, called the **heavy (H) chains**, are identical to each other (blue chains in Figure 21.14a). The other two chains, called the **light (L) chains** (pink), are also identical to each other, but they are only about half as long as each H chain. The heavy chains have a flexible *hinge* region at their approximate "middles." The "loops" on each chain are created by disulfide bonds that cause the intervening parts of the polypeptide chains to loop out.

Each chain forming an antibody has a **variable (V) region** at one end and a **constant (C) region** at the other end. Antibodies responding to different antigens have very different V regions, but their C regions are the same (or nearly so) in all antibodies of a given class. In each arm of the monomer, the V regions of the heavy and light chains combine to form an **antigen-binding site** shaped to "fit" a specific antigenic determinant. Consequently, each antibody monomer has two such antigen-binding regions.

The C regions that form the *stem* of the antibody monomer determine the antibody class and serve common functions in all antibodies: These are the *effector regions* of the antibody that dictate (1) the cells and chemicals of the body the antibody can bind to, and (2) how the antibody class functions to eliminate antigens. For example, some antibodies activate complement, some circulate in blood while others are found primarily in body secretions, some cross the placental barrier, and so on.

Antibody Classes

The five major immunoglobulin classes are designated IgM, IgA, IgD, IgG, and IgE, on the basis of the C regions in their heavy chains. (Remember the name MADGE to recall the five Ig types.)

The antibodies of each class have different characteristics, biological roles, and locations in the body, as shown in **Table 21.5**. IgM in plasma is huge compared to the other antibodies. It is constructed from five Y-shaped units, or *monomers*, linked together to form a *pentamer* (*penta* = five). IgA occurs in both monomer and *dimer* (two linked monomers) forms. IgD, IgG, and IgE are monomers and have the same basic Y-shaped structure.

B cells usually switch from making one class of antibody to another as they become plasma cells. As a result, two or more different antibody classes having the same antigen specificity are produced. For example, the first antibody released in the primary response is IgM, and then later plasma cells begin to secrete IgG. During secondary responses, almost all of the Ig protein is IgG. Switching from IgM to IgA or IgE also occurs.

Table 21.5 Immunoglobulin Classes*

 IgM (pentamer)	• The first immunoglobulin class secreted by plasma cells during the primary response. (This fact is diagnostically useful because presence of IgM in plasma usually indicates current infection by the pathogen eliciting IgM's formation.) • Readily activates complement. • Exists in monomer and pentamer (five united monomers) forms. • The monomer serves as an antigen receptor on the B cell surface. • The pentamer circulates in blood plasma. • Numerous antigen-binding sites make it a potent agglutinating agent.
IgA (dimer)	• The dimer, referred to as **secretory IgA**, is found in body secretions such as saliva, sweat, intestinal juice, and milk. • Secretory IgA helps stop pathogens from attaching to epithelial cell surfaces (including mucous membranes and the epidermis). • The monomer exists in limited amounts in plasma.
IgD (monomer)	• Found on the B cell surface. • Functions as a B cell antigen receptor (as does IgM).
IgG (monomer)	• The most abundant antibody in plasma, accounting for 75–85% of circulating antibodies. • The main antibody of both secondary and late primary responses. • Readily activates complement. • Protects against bacteria, viruses, and toxins circulating in blood and lymph. • Crosses the placenta and confers passive immunity from the mother to the fetus.
IgE (monomer)	• Stem end binds to mast cells or basophils. Antigen binding to its receptor end triggers these cells to release histamine and other chemicals that mediate inflammation and an allergic reaction. • Secreted by plasma cells in skin, mucosae of the gastrointestinal and respiratory tracts, and tonsils. • Only traces of IgE are found in plasma. • Levels rise during severe allergic attacks or chronic parasitic infections of the gastrointestinal tract.

*Key characteristics are listed in blue type.

Antibody Targets and Functions

Though antibodies themselves cannot destroy antigens, they can inactivate antigens and tag them for destruction (**Figure 21.15**). The common event in all antibody-antigen interactions is formation of **antigen-antibody** (or **immune**) **complexes**. Defensive mechanisms used by antibodies include neutralization, agglutination, precipitation, and complement activation, with the first two most important.

Neutralization **Neutralization**, the simplest defensive mechanism, occurs when antibodies block specific sites on viruses or bacterial exotoxins (toxic chemicals secreted by bacteria). As a result, the virus or exotoxin cannot bind to receptors on tissue cells. Phagocytes eventually destroy the antigen-antibody complexes.

Agglutination Because antibodies have more than one antigen-binding site, they can bind to the same determinant on more than one antigen at a time. Consequently, antigen-antibody complexes can be cross-linked into large lattices. When cell-bound antigens are cross-linked, the process causes clumping, or **agglutination**, of the foreign cells. IgM, with 10 antigen-binding sites, is an especially potent agglutinating agent (see Table 21.5). Recall from Chapter 17 that agglutination occurs when mismatched blood is transfused (the foreign red blood cells clump) and is the basis of tests used for blood typing.

Precipitation In **precipitation**, soluble molecules (instead of cells) are cross-linked into large complexes that settle out of solution. Like agglutinated bacteria, precipitated antigen molecules are much easier for phagocytes to capture and engulf than are freely moving antigens.

Complement Activation Complement activation is the chief antibody defense used against cellular antigens, such as bacteria or mismatched red blood cells. When several antibodies bind close together on the same cell, the complement-binding sites

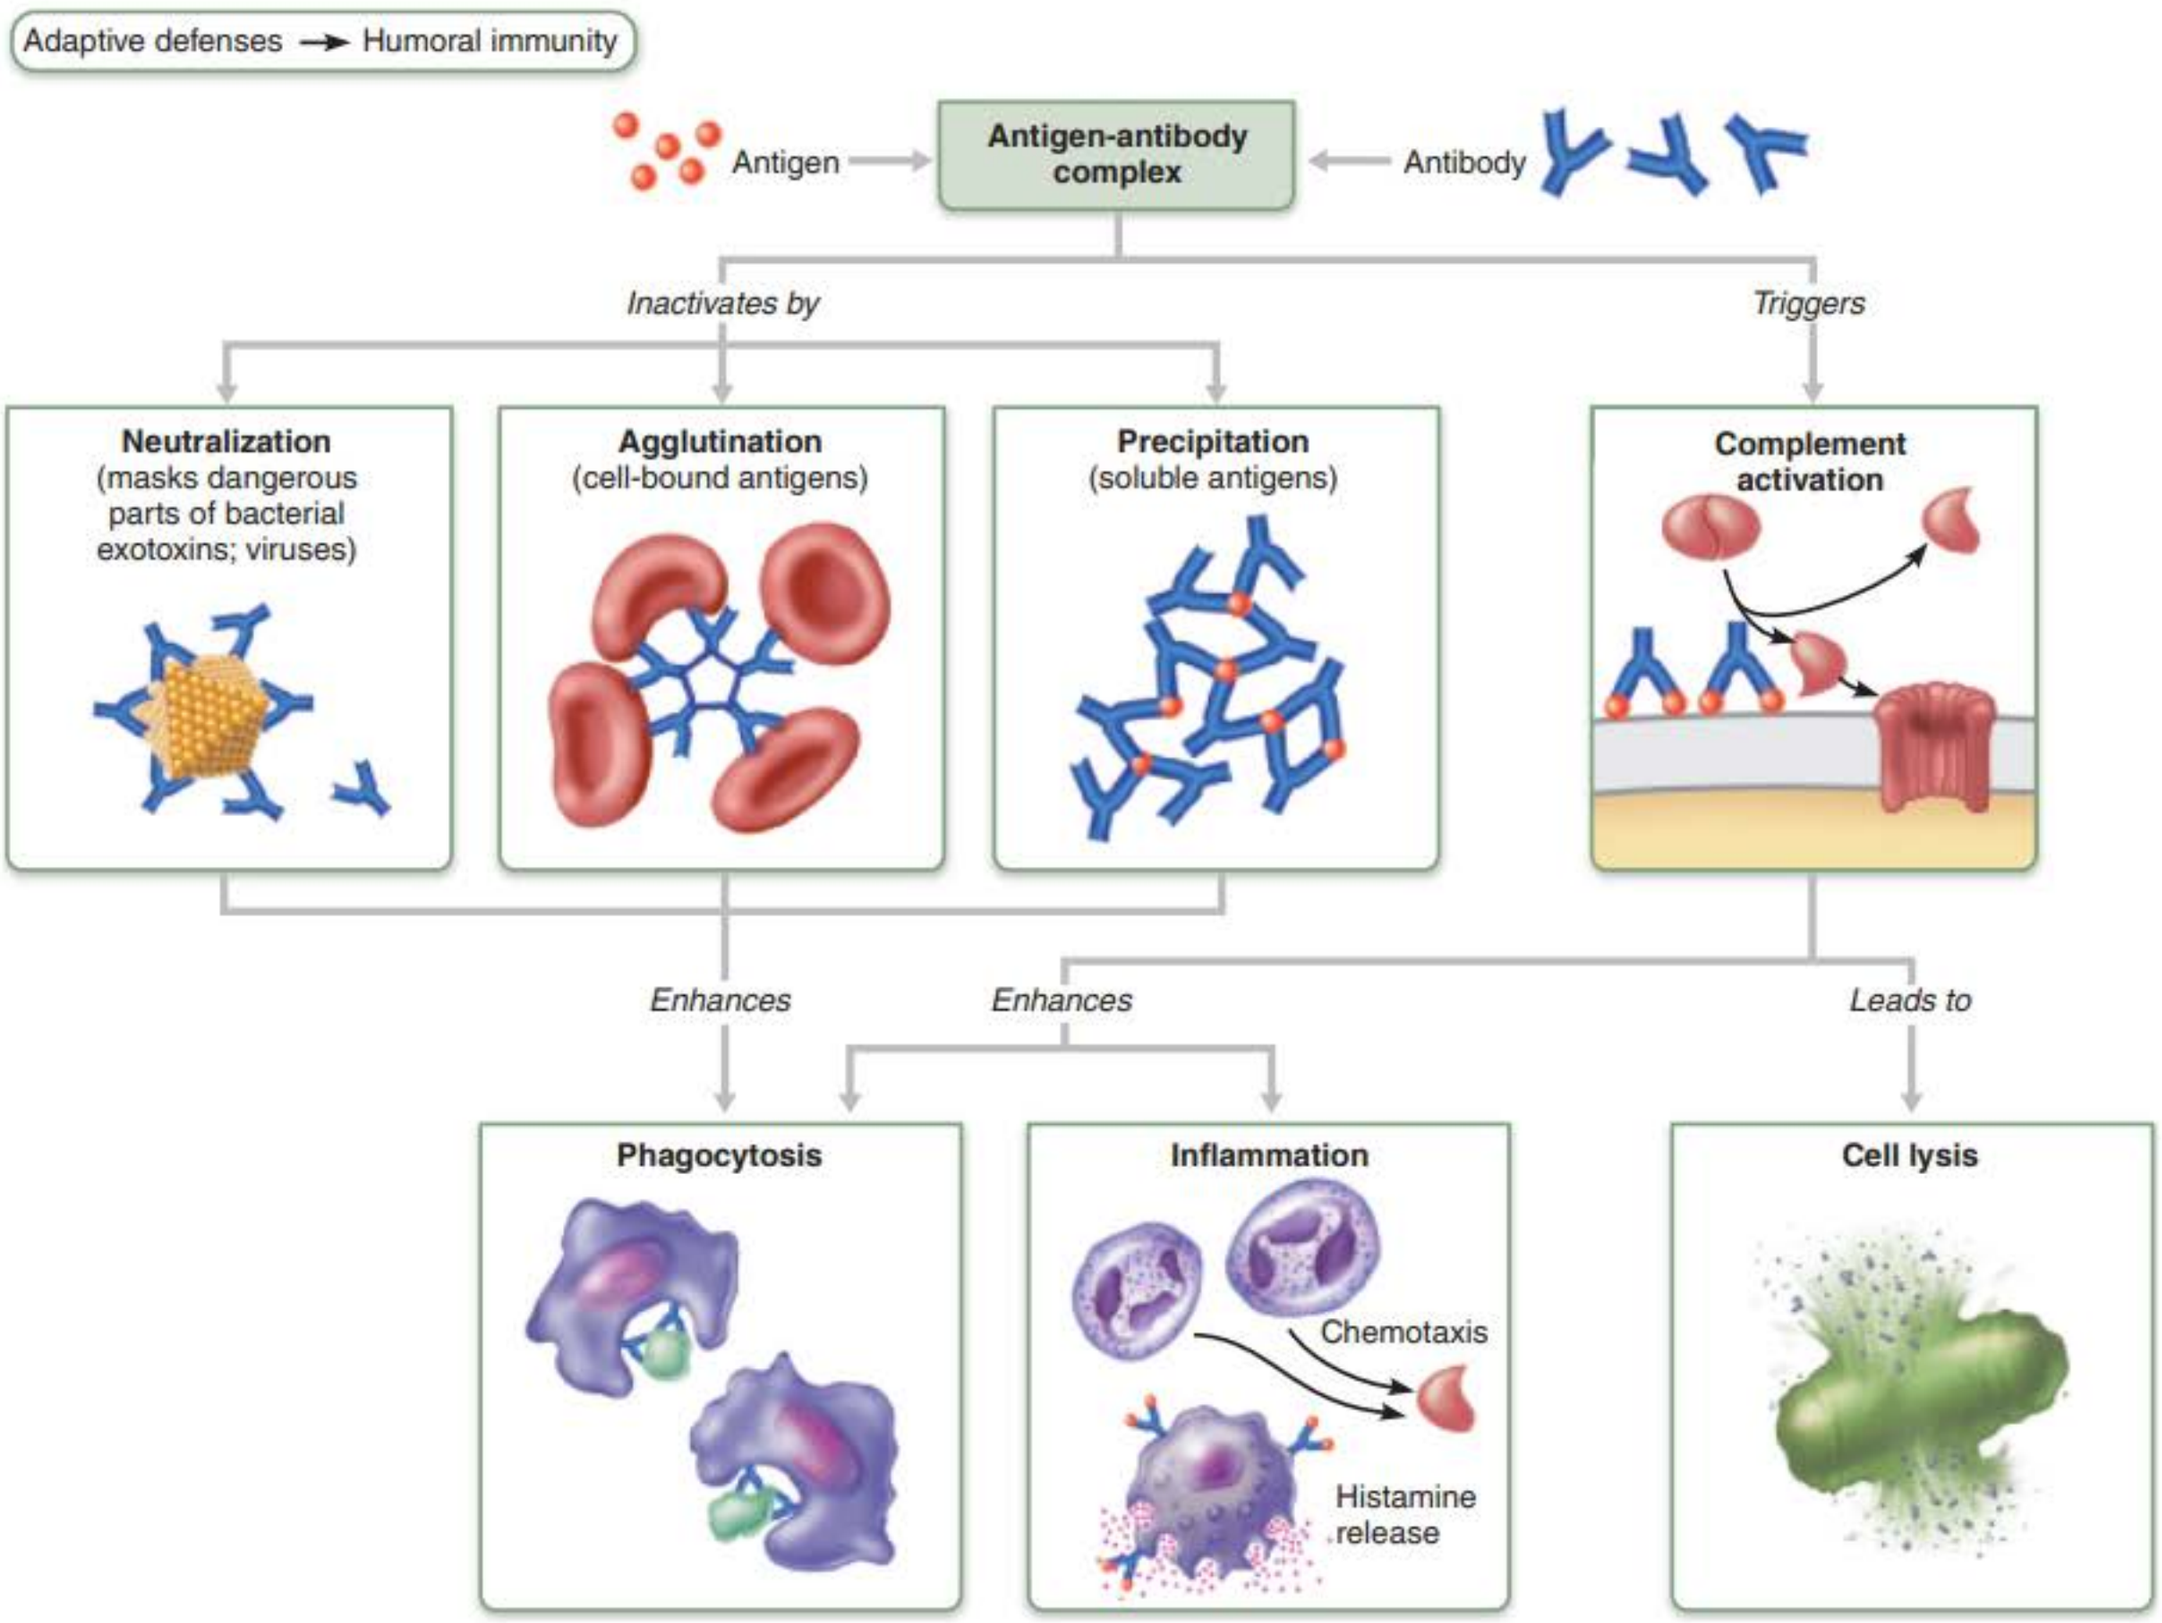

Figure 21.15 Mechanisms of antibody action. Antibodies act against free viruses, red blood cell antigens, bacterial toxins, intact bacteria, fungi, and parasitic worms.

on their stem regions align and complement is activated (◀ p. 788). Membrane attack complexes may insert into the antigenic cell's surface, triggering cell lysis.

Additionally, as we described earlier, molecules released during complement activation tremendously amplify the inflammatory response and promote phagocytosis by opsonizing pathogens. This sets into motion a positive feedback cycle that enlists more and more defensive elements.

A quick and dirty way to remember how antibodies work is to remember they have a PLAN of action—**p**recipitation, **l**ysis (by complement), **a**gglutination, and **n**eutralization.

HOMEOSTATIC IMBALANCE 21.2 — CLINICAL

Around the world, billions of people are infected by parasitic worms such as *Ascaris* and *Schistosoma*. These large pathogens are difficult for our immune systems to deal with and "PLAN" is insufficient.

Nevertheless, antibodies still play a critical role in the worm's destruction. IgE antibodies coat the surface of parasitic worms, marking them for destruction by eosinophils (◀ p. 652). When eosinophils encounter antibody-coated worms, they bind to the exposed stems of the IgE. This triggers the eosinophils to release the toxic contents of their large cytoplasmic granules all over their prey.

Monoclonal Antibodies as Clinical and Research Tools

Monoclonal antibodies are pure antibody preparations specific for a single antigenic determinant. They are produced by descendants of a single cell. Commercially prepared monoclonal antibodies are essential in research, clinical testing, and treatment.

Monoclonal antibodies are used to diagnose pregnancy, certain sexually transmitted infections, some cancers, hepatitis, and rabies. These monoclonal antibody tests are more specific, sensitive, and rapid than other tests. Monoclonal antibodies are also used to treat leukemia and lymphomas, cancers that are present in the circulation and so are easily accessible to injected antibodies. They also serve as "guided missiles" to deliver anticancer drugs only to cancerous tissue, and to treat certain autoimmune diseases (as we will discuss later).

Summary of Antibody Actions

At the most basic level, the race between antibody production and pathogen multiplication determines whether or not you become sick. Remember, however, that forming antigen-antibody complexes does *not* destroy the antigens. Instead, it prepares them for destruction by innate defenses.

Antibodies produced by plasma cells are in many ways the simplest, most versatile ammunition of the immune response. Nevertheless, they provide only partial immunity. Their prey are *extracellular pathogens*—intact bacteria, free viruses, and soluble foreign molecules—in other words, pathogens that are free in body secretions and tissue fluid and circulating in blood and lymph. Antibodies never invade solid tissues unless inflammation is present.

Until recently, the accepted dogma was that antibodies *only* act extracellularly. Remarkably, we now know that antibodies can act intracellularly as well. Antibodies that are attached to a virus before that virus infects a cell can "hang on" to the virus as it slips inside the cell. There, the antibodies activate intracellular mechanisms that destroy the virus. Even so, antibodies are not very effective against pathogens like viruses and tuberculosis bacilli that quickly slip inside body cells to multiply there. For these intracellular pathogens, the cellular arm of adaptive immunity comes into play.

Check Your Understanding

14. Why is the secondary response to an antigen so much faster than the primary response?

15. Which class of antibody is shown at right? Which is most abundant in blood? Which is secreted first in a primary immune response? Which is most abundant in secretions?

16. List four ways in which antibodies can bring about destruction of a pathogen.

17. APPLY How do vaccines protect against common childhood illnesses such as chicken pox, measles, and mumps?

18. DRAW Draw an antibody. Label the antigen-binding sites, and the hinge and stem regions. Which region determines the antibody's class?

19. MAKE CONNECTIONS What is the function of the abundant endoplasmic reticulum in plasma cells? What other organelle(s) (described in Chapter 3) would be especially abundant in plasma cells? Why?

For answers, see Answers Appendix.

21.6 Cellular immunity consists of T lymphocytes that direct adaptive immunity or attack cellular targets

Learning Outcomes

- **Define cellular immunity and describe the process of activation and clonal selection of T cells.**
- **Describe the roles of different types of T cells.**
- **Describe T cell functions in the body.**

T cells are best suited for cell-to-cell interactions. When antigens are presented to a T lymphocyte, they provoke a cellular immune response. Some activated T cells directly kill body cells that are:

- Infected by viruses or bacteria
- Cancerous or abnormal
- Foreign cells (e.g., transplanted cells)

Other T cells release chemicals that regulate the immune response.

T cells are a diverse lot, much more complex than B cells in both classification and function. There are two major populations of T cells based on which of two structurally related *cell differentiation glycoproteins*—CD4 or CD8—a mature T cell displays. The CD4 and CD8 glycoproteins are surface receptors but

Adaptive defenses → Cellular immunity

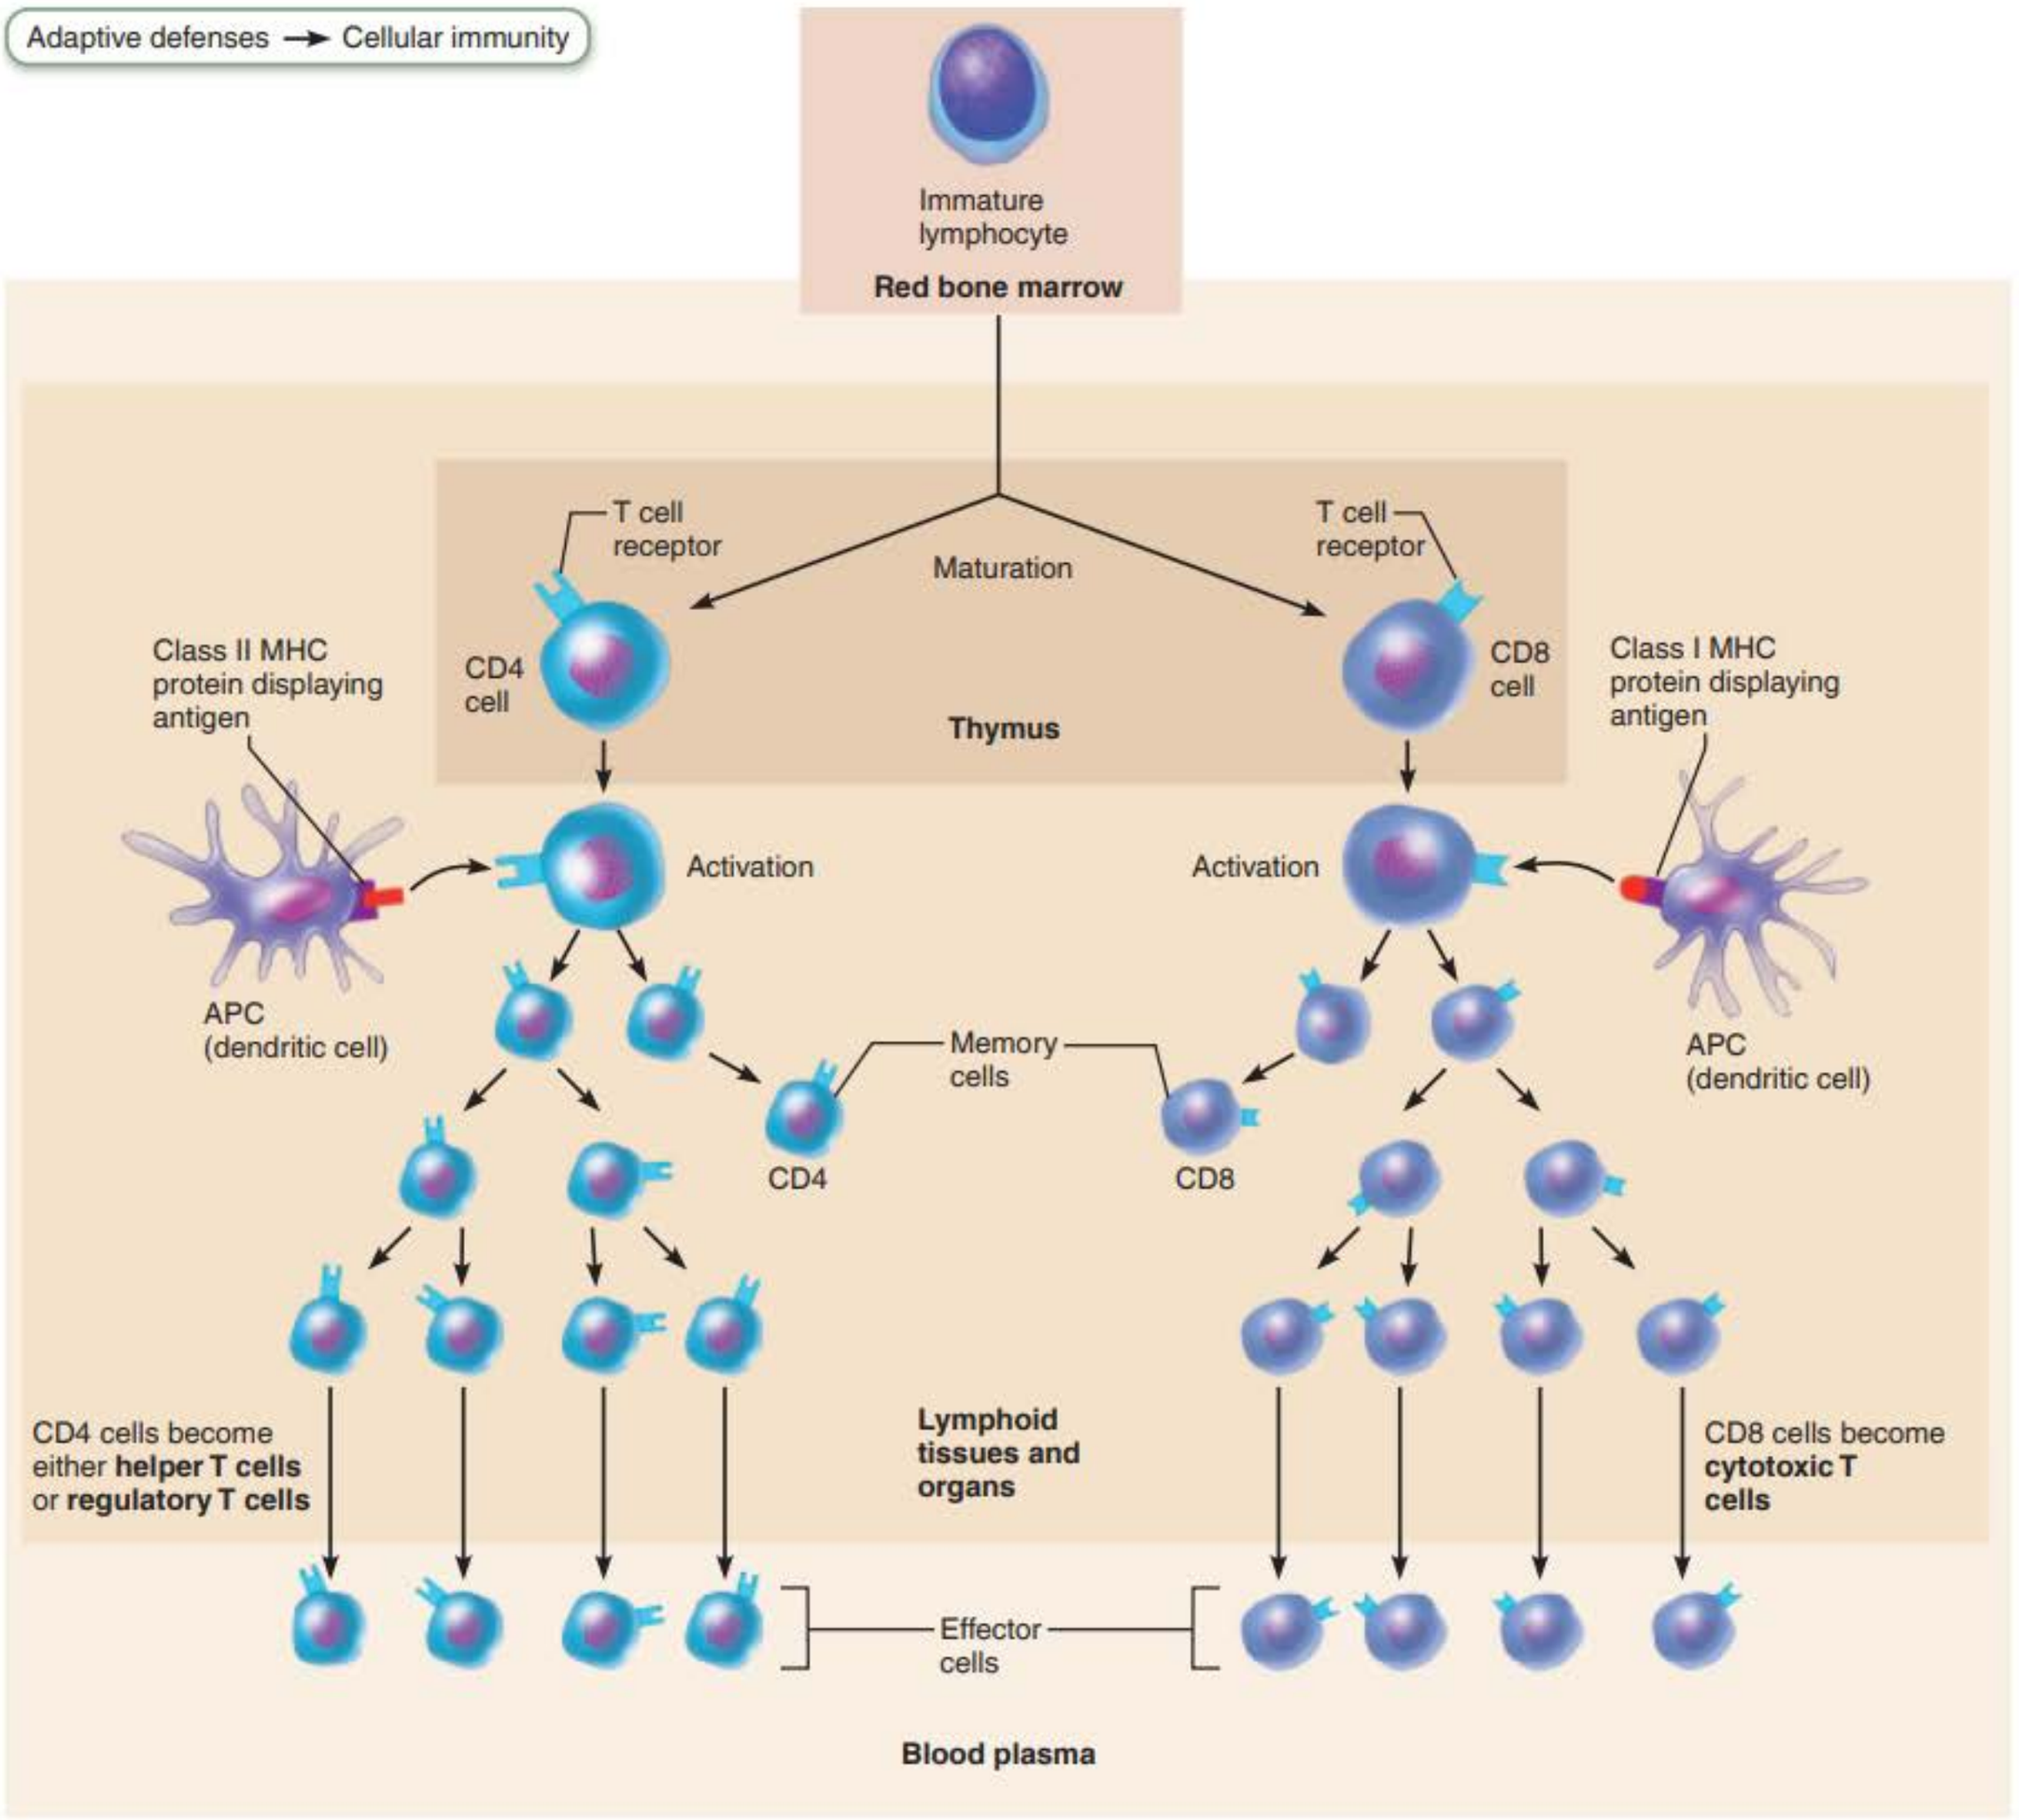

Figure 21.16 Major types of T cells.

are distinct from the T cell antigen receptors. They play a role in interactions between T cells and other cells.

When activated, CD4 and CD8 cells differentiate into the three major kinds of *effector cells* of cellular immunity (**Figure 21.16**).

- **CD4 cells** usually become *helper T (T_H) cells* that help activate B cells, other T cells, and macrophages, and direct the adaptive immune response.
- **CD8 cells** become *cytotoxic T (T_C) cells* that destroy cells in the body that harbor anything foreign.
- Some CD4 cells become *regulatory T (T_{Reg}) cells*, which moderate the immune response.

Activated CD4 and CD8 cells can also become memory T cells. Note that the names of the effector cells (helper, cytotoxic, regulatory) are reserved for *activated* T cells, while naive T cells are simply called CD4 or CD8 cells.

MHC Proteins and Antigen Presentation

Unlike B cells and antibodies, T cells cannot "see" either free antigens or antigens that are in their natural state. T cells can recognize and respond only to *processed* fragments of protein antigens displayed on surfaces of body cells (APCs and others).

Antigen presentation is necessary for both activation of naive T cells and the normal functioning of effector T cells.

As previously noted, the cell surface proteins on which antigens are presented to T cells are the major histocompatibility complex (MHC) proteins. It is important to understand how these critical players in antigen presentation work before we can understand how T cells work. There are two classes of MHC proteins—class I and class II—summarized in **Table 21.6**.

Class I MHC Proteins

Class I MHC proteins are found on the surface of virtually *all* body cells except red blood cells. Each class I MHC protein has a groove that holds an antigen—in this case, a protein fragment (of 8 or 9 amino acids).

Where do these protein fragments come from? All antigens displayed on class I MHC proteins are **endogenous antigens**—fragments of proteins synthesized *inside the cell*. In a healthy cell, endogenous antigens are all self-antigens, generally bits of digested cellular proteins. But in an infected cell, endogenous antigens may also include fragments of foreign antigens that are synthesized within the infected cell but "belong to" the pathogen. In a cancerous cell, endogenous antigens can include altered (cancer) proteins.

How do these endogenous antigens end up attached to class I MHCs on the outside of our cells? As proteases (protein-digesting enzymes) degrade cytoplasmic proteins as part of their natural recycling, a random sample of the resulting protein fragments is transported into the endoplasmic reticulum. Inside the ER, these peptides bind to newly synthesized class I MHC proteins. Transport vesicles then export the "loaded" class I MHC proteins to the cell surface.

Class I MHC proteins are crucial for both activating naive CD8 cells and "informing" cytotoxic T cells that infectious microorganisms are hiding in body cells. Without them, viruses and certain bacteria that thrive in cells could multiply unnoticed and unbothered.

When class I MHC proteins display fragments of our own proteins (self-antigens), cytotoxic T cells passing by get the signal "Leave this cell alone, it's ours!" and ignore them. But when class I MHC proteins display foreign antigens, they "sound a molecular alarm" that signals invasion. In this signaling, the class I MHC proteins both (1) act as antigen holders and (2) form the self part of the self-nonself complexes that cytotoxic T cells must recognize in order to kill.

Class II MHC Proteins

This second type of MHC protein is less widespread. **Class II MHC proteins** are typically found *only on the surfaces of cells that present antigens to CD4 cells*: dendritic cells, macrophages, and B cells. Like their class I MHC counterparts, class II MHC proteins are synthesized at the ER and bind to peptide fragments. However, the peptides they bind are longer (14–17 amino acids) and come from **exogenous antigens**—antigens from *outside* the cell that have been engulfed by the cell that displays them.

The engulfed exogenous antigens are broken down by proteases inside a phagolysosome. Vesicles from the ER containing class II MHC proteins fuse with the phagolysosome, and the antigen fragments bind to the groove of the MHC proteins. The vesicle is then exported to the cell surface, where the class II MHC protein displays its prize for CD4 cells to recognize.

Class II MHC proteins loaded with foreign antigens generally signal CD4 cells that help is required. It's as if they are showing the CD4 cells what the foreign invader "looks like." Most

Table 21.6 Role of MHC Proteins in Cellular Immunity

	CLASS I MHC PROTEINS	CLASS II MHC PROTEINS
Displayed by	All nucleated cells 	APCs (dendritic cells, macrophages, B cells) Recognized by	Naive CD8 cells and cytotoxic T cells 	Naive CD4 cells and helper T cells Foreign antigens on MHC are	Endogenous (intracellular pathogens or proteins made by cancerous cells)*	Exogenous (phagocytized extracellular pathogens)
Cells displaying foreign antigens on MHC send this message	**If the cell is an APC:** "I belong to self, but have captured a foreign invader. This is what it looks like. Kill any cell that displays it." **If the cell is not an APC:** "I belong to self, but have been invaded or become cancerous. Kill me!"	"I belong to self, but have captured a foreign invader. This is what it looks like. Help me mount a defense against it."

* Dendritic cells are an exception because they can present ***another cell's*** endogenous antigens on their class I MHC proteins to activate CD8 cells.

often, the result is that the CD4 cell will help mount a defense against the antigen.

MHC Restriction

CD4 and CD8 cells have different requirements for the class of MHC protein that presents antigens to them. This constraint, acquired during the education process in the thymus, is called *MHC restriction*.

- CD4 cells (which usually become helper T cells) are restricted to binding antigens only on class II MHC proteins, which are typically displayed on antigen-presenting cell (APC) surfaces.
- CD8 cells (which become cytotoxic T cells) are activated by antigen fragments on class I MHC proteins, also found on the surface of APCs. Once activated, cytotoxic T cells look for this same antigen presented on class I MHC proteins located on any cell in the body.

The MHC restriction for CD8 cells presents a problem for APCs. As a rule, class I MHC proteins display endogenous antigens—those that originate inside that cell. How do APCs obtain endogenous antigens from another cell and display them on class I MHCs to activate CD8 cells? Dendritic cells have the special ability to do this. They obtain other cells' endogenous antigens either by engulfing dying virus-infected or tumor cells, or by importing antigens through temporary gap junctions with infected cells. Dendritic cells then display these antigens on *both* class I and class II MHCs.

Activation and Differentiation of T Cells

T cells can *only* be activated by APCs and this activation is actually a two-step process involving antigen binding and co-stimulation. Both steps usually occur on the surface of the same APC, and both steps are required for *clonal selection*.

Antigen Binding

This first step mostly entails what we have already described: T cell antigen receptors (**TCRs**) bind to an antigen-MHC complex on the surface of an APC. As you will recall from our discussion of T cell education, TCRs must perform *double recognition*: They must recognize both MHC (self-antigen) and the foreign antigen it displays.

The TCR that recognizes (by binding) the nonself-self complex triggers multiple intracellular signaling pathways that lead to T cell activation. Other T cell surface proteins also play a role in T cell activation. For example, the CD4 and CD8 proteins that distinguish the two major T cell groups are adhesion molecules that help bind cells together during antigen recognition.

Co-stimulation

The story isn't over yet because step 2 comes next. Once antigen binding has occurred, the T cell is stimulated but is still "idling," like a car that has been started but not put into gear. Before an "idling" T cell can be "put into gear" and proliferate to form a clone, it must also bind one or more **co-stimulatory signals** (Figure 21.17 2b). These signals are yet other molecules that appear on the surfaces of APCs in tissues that are damaged or invaded by pathogens. For example, dendritic cells and macrophages sprout co-stimulatory molecules on their surfaces when the innate defenses are being mobilized. The binding of these molecules to specific receptors on a T cell is a crucial co-stimulatory signal.

What happens if a T cell binds to antigen without receiving the co-stimulatory signal? In this case, the T cell becomes tolerant to that antigen and is unable to respond. This state of unresponsiveness to antigen is called **anergy**.

The two-signal sequence acts as a kind of "double-handshake," a safeguard to prevent the immune system from destroying healthy cells. Without this safeguard, class I MHC proteins, which occur on all body cells and which display peptides from within the cell, could activate cytotoxic T cells, leading to widespread damage of healthy cells.

The important thing to understand is that along with antigen binding, co-stimulation is crucial for T cell activation. To

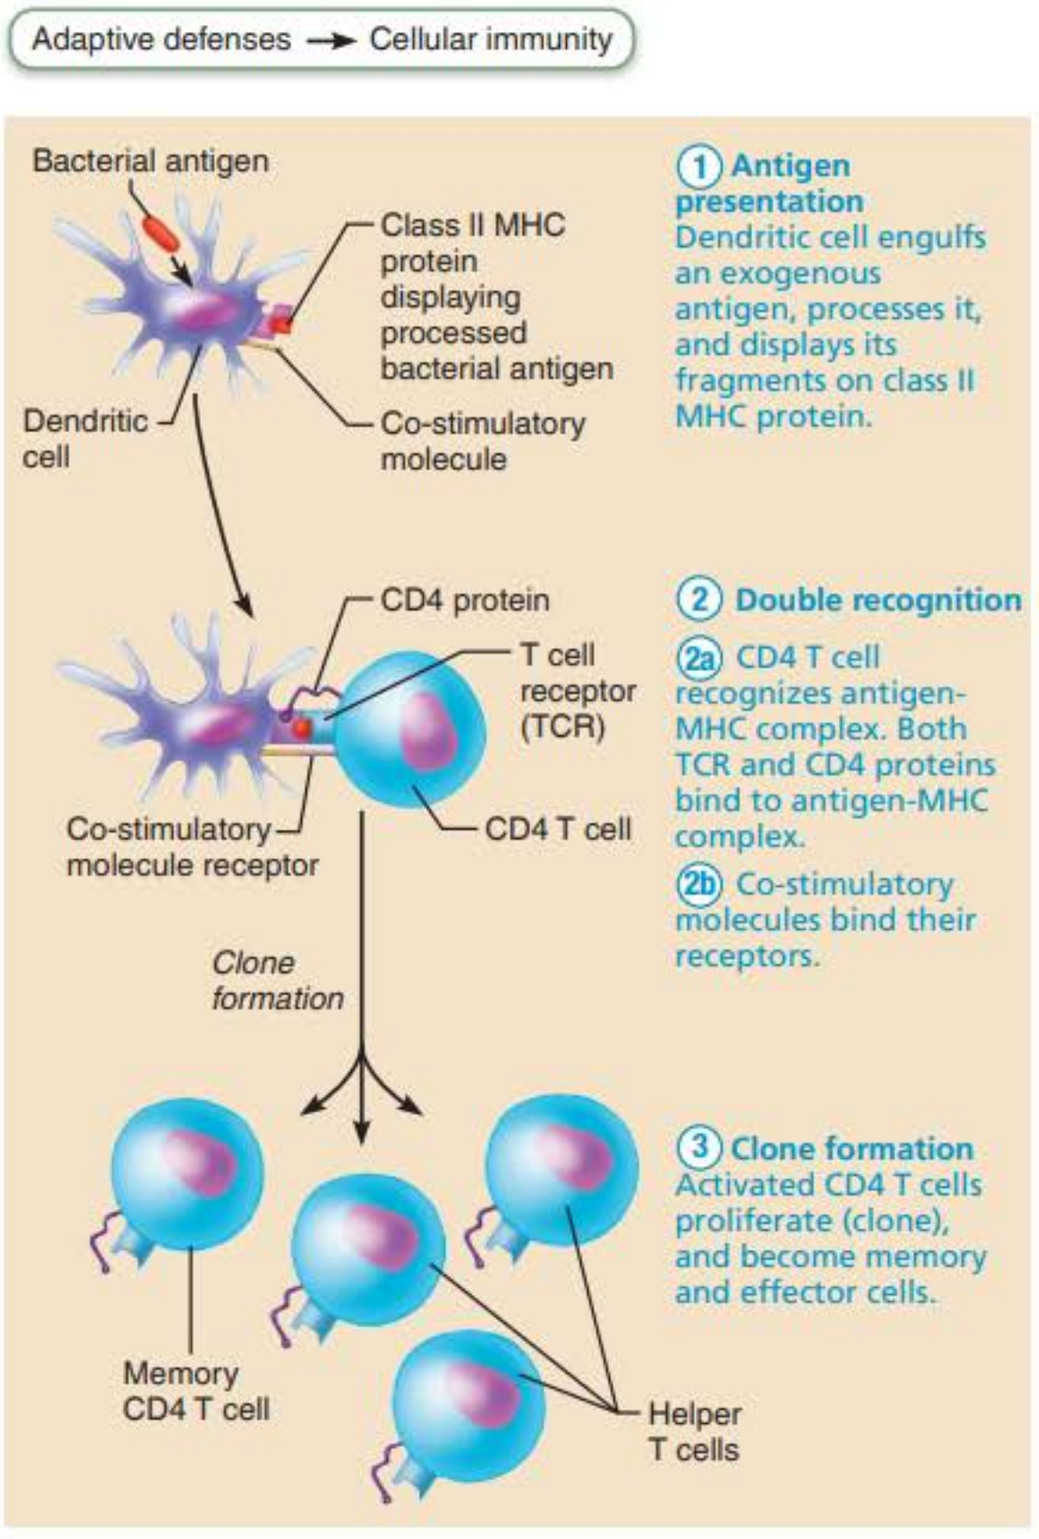

Figure 21.17 Clonal selection of T cells involves simultaneous recognition of self and nonself. Activation of CD4 cells is shown here, but activation of CD8 cells is similar.

Table 21.7 Selected Cytokines

CYTOKINE	FUNCTION IN IMMUNE RESPONSE
Interferons (IFNs)	
• Alpha (α) and beta (β)	Secreted by many cells. Have antiviral effects; activate NK cells.
• Gamma (γ)	Secreted by lymphocytes. Activates macrophages; stimulates synthesis and expression of more class I and II MHC proteins; promotes differentiation of T_H cells into T_H1.
Interleukins (ILs)	
• IL-1	Secreted by activated macrophages. Promotes inflammation and T cell activation; causes fever (acts as a pyrogen that resets the thermostat of the hypothalamus).
• IL-2	Secreted by T_H cells. Stimulates T and B cell proliferation, T_{Reg} cell development, and NK cell activation.
• IL-4	Secreted by some T_H cells. Promotes differentiation to T_H2; promotes B cell activation; switches antibody production to IgE.
• IL-5	Secreted by some T_H cells and mast cells. Attracts and activates eosinophils; causes plasma cells to secrete IgA antibodies.
• IL-10	Secreted by macrophages, T_H, and T_{Reg} cells. Inhibits macrophages and dendritic cells; turns down cellular and innate immune response.
• IL-12	Secreted by dendritic cells and macrophages. Stimulates T_C and NK cell activity; promotes T_H1 differentiation.
• IL-17	Secreted by T_H17 cells. Important in innate and adaptive immunity and recruiting neutrophils. Involved in inflammation in many autoimmune diseases.
Suppressor factors	A generic term for a number of cytokines that suppress the immune system, for example TGF-β and IL-10.
Transforming growth factor beta (TGF-β)	A suppressor factor similar to IL-10; stimulates T_{Reg} and T_H17 cell development.
Tumor necrosis factors (TNFs)	Produced by lymphocytes and in large amounts by macrophages. Promote inflammation; enhance phagocyte chemotaxis and nonspecific killing; slow tumor growth by selectively damaging tumor blood vessels; promote cell death by apoptosis.

go back to our idling car analogy, the car will not go anywhere unless it has been both (1) started and (2) put into gear.

Proliferation and Differentiation

Once activated by antigen binding and co-stimulation, a T cell enlarges and proliferates. Cytokines (which we will discuss next) released by APCs or T cells themselves promote this process. Cells of the resulting clone differentiate to perform functions according to their T cell class. This primary response peaks within a week of exposure to the triggering antigen. A period of apoptosis then occurs between days 7 and 30, during which time the activated T cells die off and effector activity wanes as the amount of antigen declines.

This wholesale disposal of T cells has a critical protective role because activated T cells that are no longer needed are potential hazards. They produce huge amounts of inflammatory cytokines, which contribute to increased cell division, and may promote cancer in chronically inflamed tissue. Thousands of clone members become memory T cells, persisting perhaps for life, and providing a reservoir of T cells that can later mediate secondary responses to the same antigen.

Cytokines

The chemical messengers involved in cellular immunity belong to a group of molecules called **cytokines**, a general term for mediators that influence cell development, differentiation, and responses in the immune system. Cytokines include interferons and interleukins. In **Table 21.7**, you can see some of the large variety of these molecules and their myriad effects on target cells.

Cytokines include hormone-like or paracrine-like glycoproteins released by a variety of cells. Some cytokines promote T cell proliferation. For example, **interleukin 1 (IL-1)**, released by macrophages, stimulates T cells to liberate **interleukin 2 (IL-2)** and to synthesize more IL-2 receptors. IL-2 is a key growth factor. Acting on the cells that release it (as well as other T cells), it sets up a positive feedback cycle that encourages activated T cells to divide even more rapidly.

Additionally, all activated T cells secrete one or more other cytokines that help amplify and regulate a variety of adaptive and innate immune responses. For example, some are inflammatory chemicals and others (such as *gamma interferon*) enhance the killing power of macrophages.

Roles of Specific Effector T Cells

Activated T cells (like B cells) can become either effector cells or memory cells. Next, we will focus on the three major groups of effector T cells: helper, cytotoxic, and regulatory T cells.

Adaptive defenses → Humoral immunity
Adaptive defenses → Cellular immunity

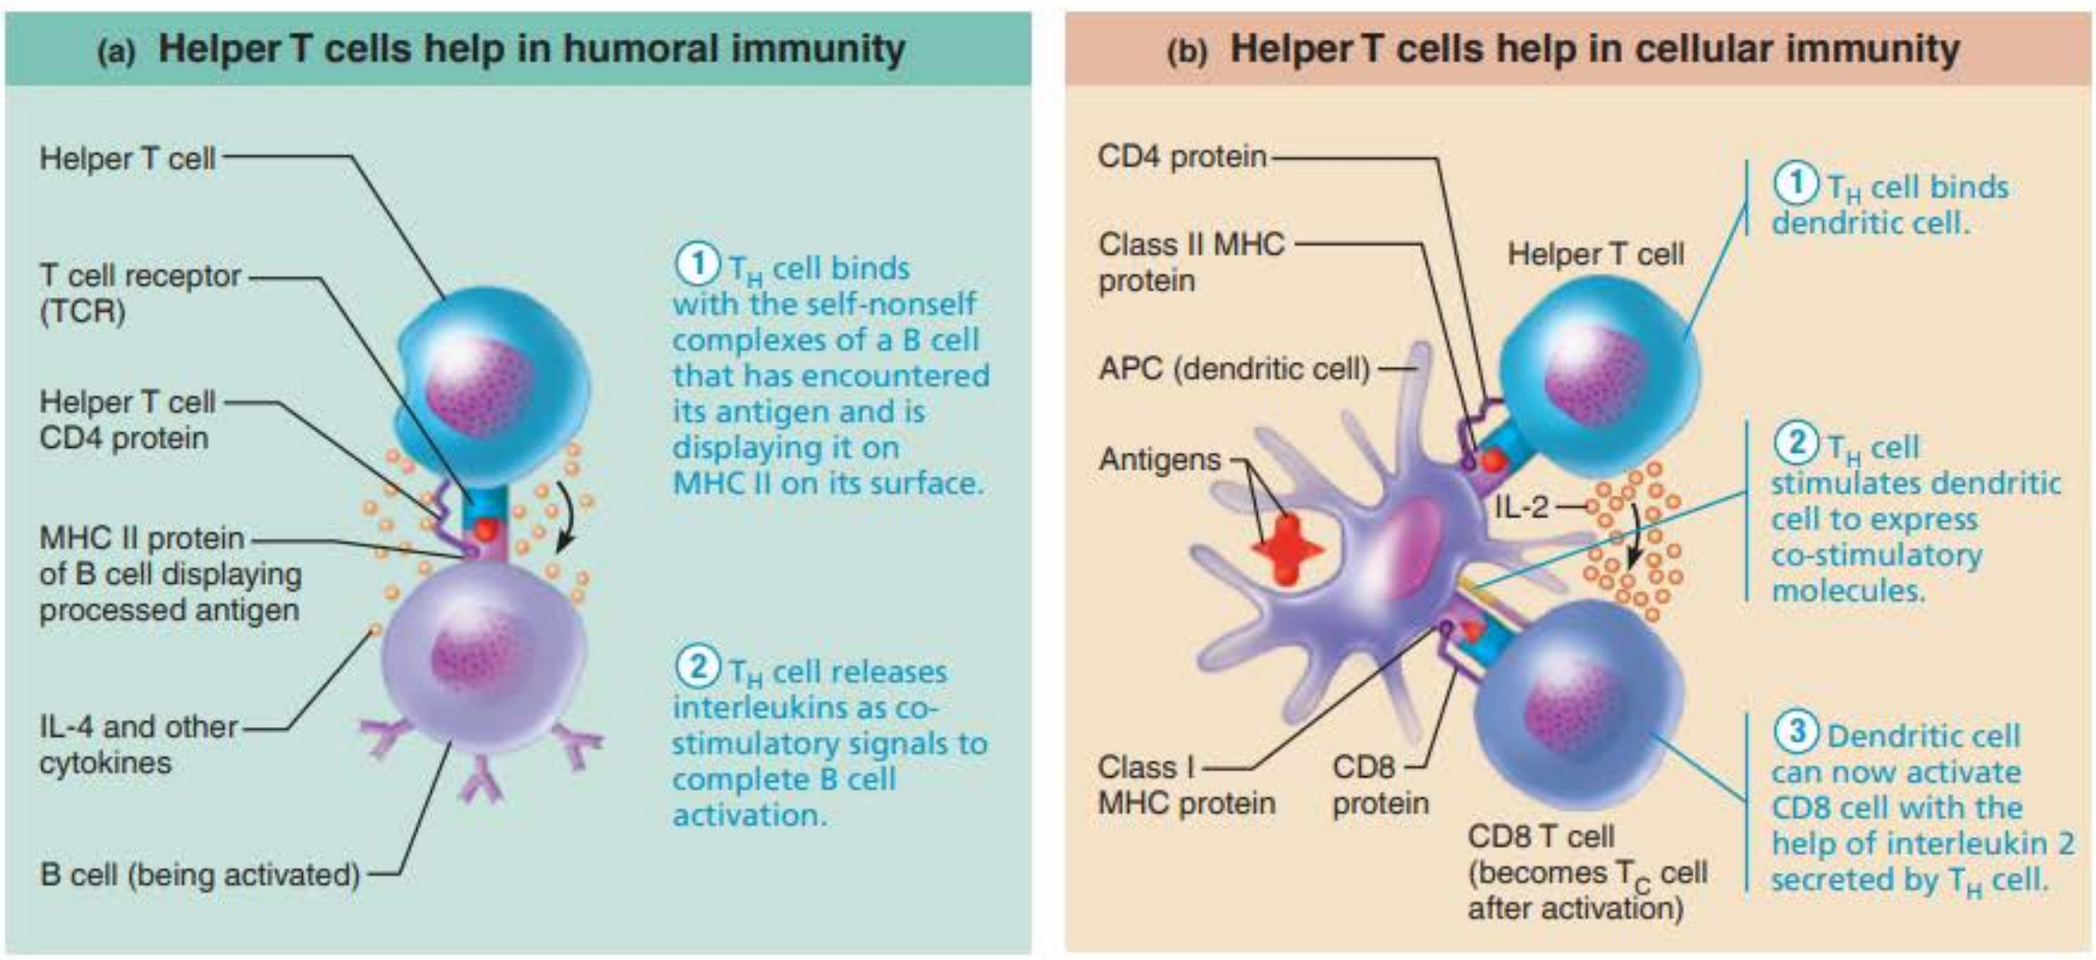

Figure 21.18 The central role of helper T cells in mobilizing both humoral and cellular immunity. (a) T_H and B cells usually must interact directly for full B cell activation. **(b)** In response to T_H cell binding, dendritic cells express co-stimulatory molecules required to activate CD8 T cells. (Some types of antigens induce these co-stimulatory molecules themselves, in which case T_H cell help may not be needed.) The T_H cell also produces interleukin 2, which causes the CD8 cell to proliferate and differentiate into a T_C cell.

Helper T Cells

Helper T (T_H) cells play a central role in adaptive immunity, mobilizing both its humoral and cellular arms (**Figure 21.18**). Once activated by APC presentation of antigen, T_H cells help activate B and T cells, and induce B and T cells to proliferate. In fact, without the help of "director" T_H cells, there is *no* adaptive immune response. Their cytokines furnish the chemical help needed to recruit other immune cells. The crucial role of T_H cells in immunity is painfully evident when they are destroyed, as in AIDS (see p. 811).

Activation of B Cells Helper T cells interact directly with B cells displaying antigen fragments bound to class II MHC receptors (Figure 21.18a). Whenever a T_H cell binds to a B cell, the T_H cell releases cytokines that prod the B cells into dividing more rapidly. Then, like the boss of an assembly line, the T_H cell signals for antibody formation to begin. B cells continue to divide as long as T_H stimulation continues. In this way, helper T cells activate B cells to help unleash their protective potential.

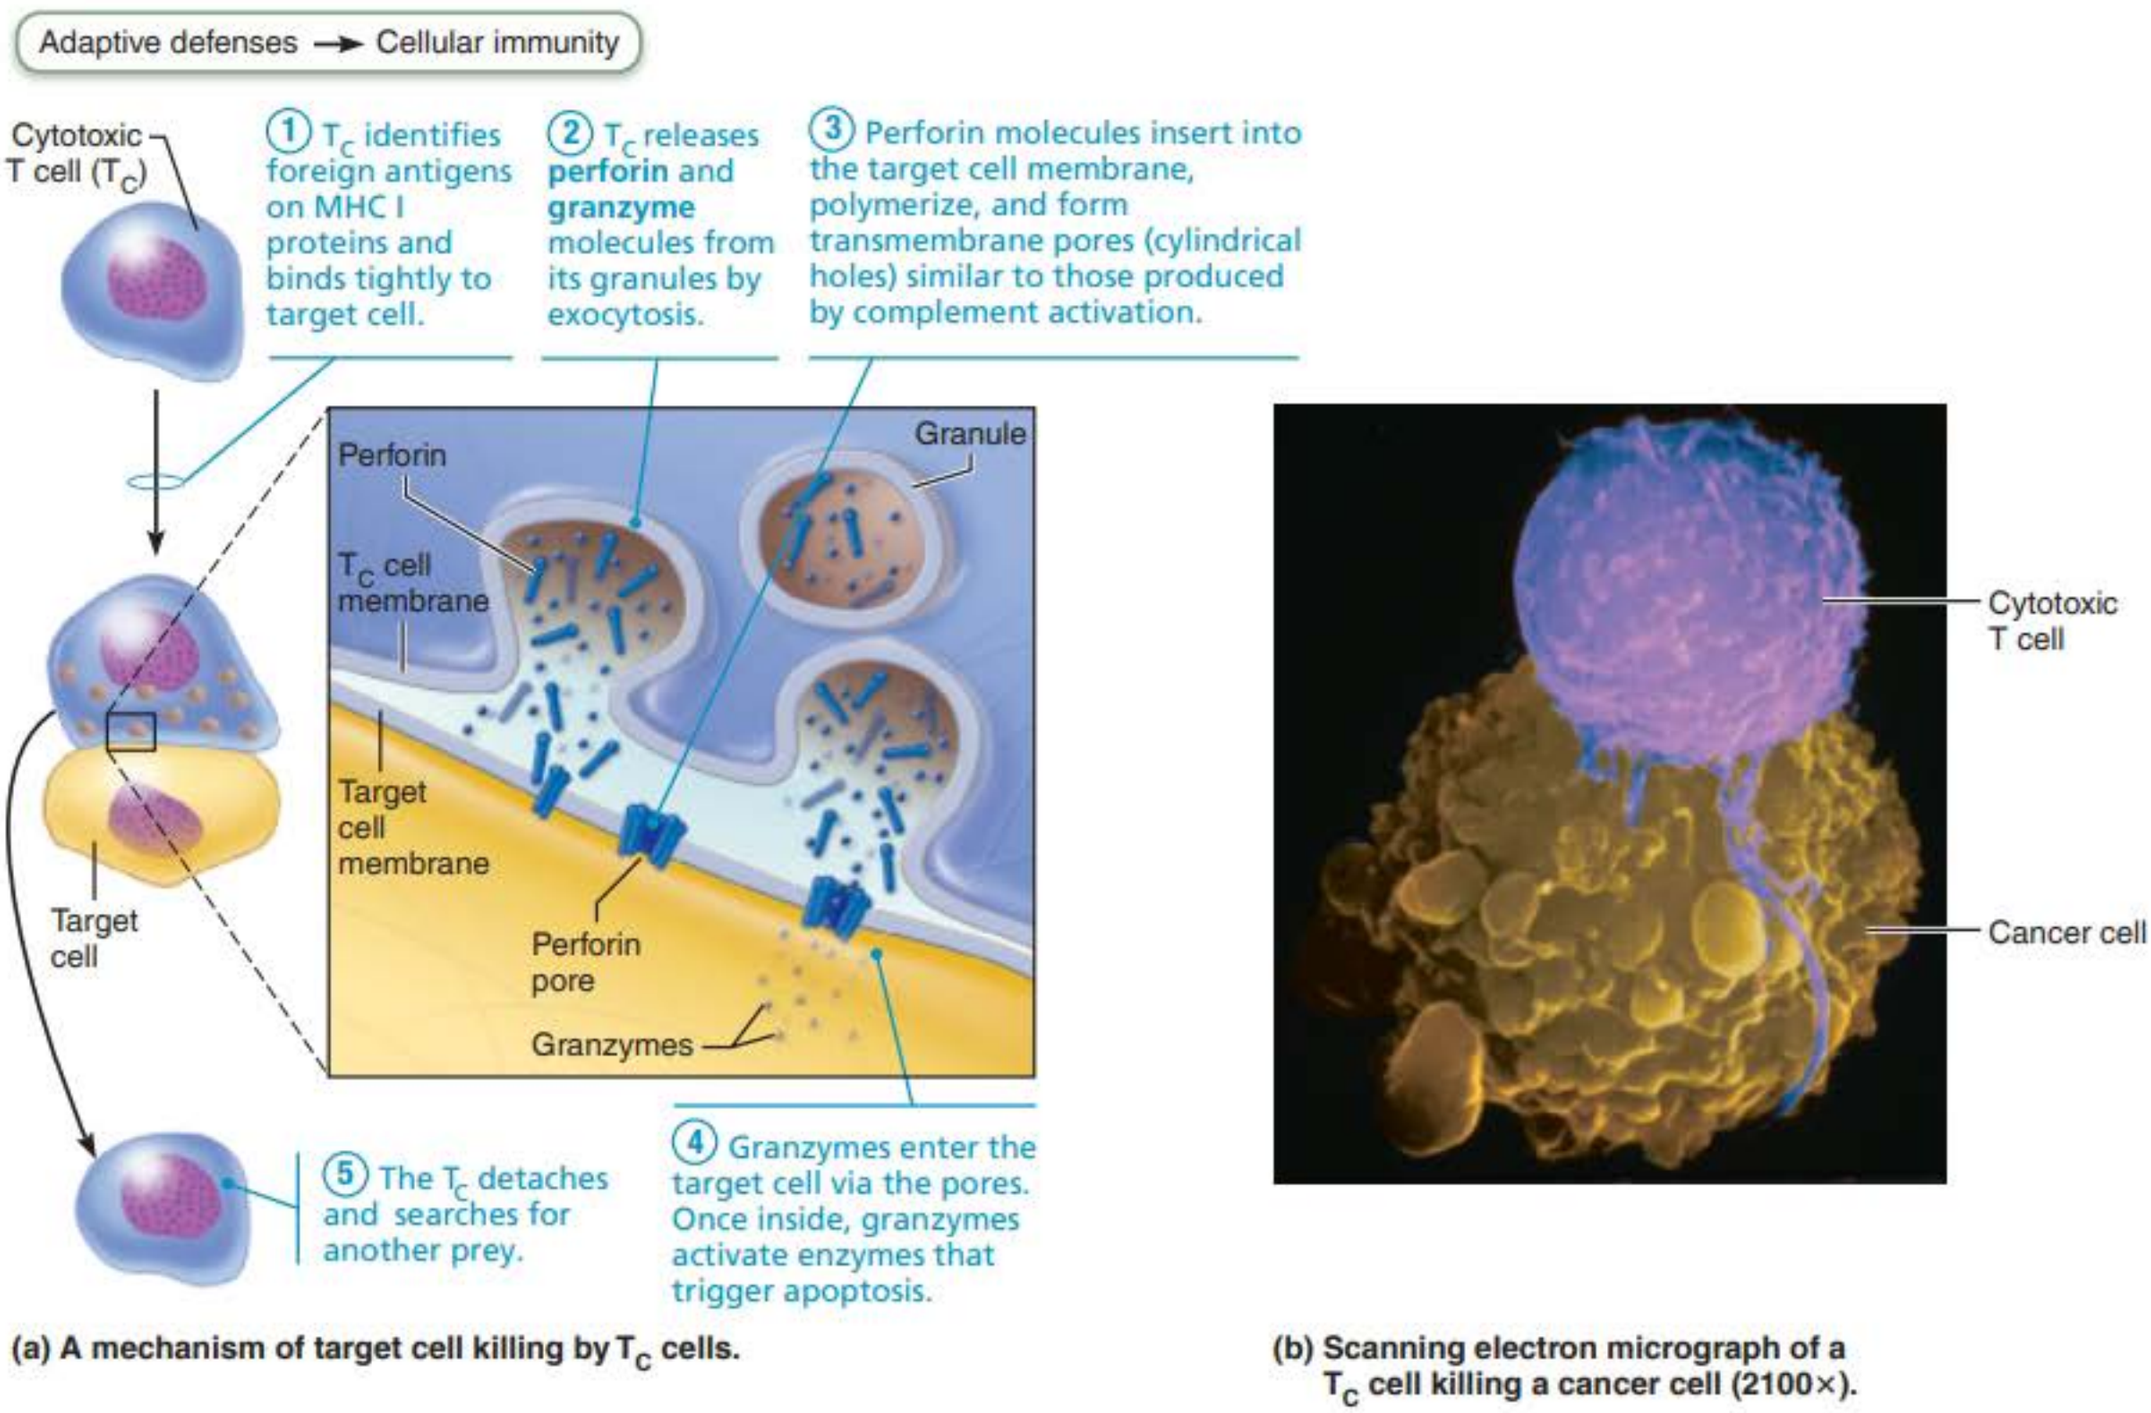
Some B cells may be activated solely by binding to certain antigens called **T cell–independent antigens**. However, T cell–independent antigen responses tend to be weak and short-lived. Most antigens are **T cell–dependent antigens** that require T cell help to activate the B cells to which they bind.

Activation of CD8 Cells Like B cells, CD8 cells usually require help from T_H cells to activate into destructive cytotoxic T cells. As shown in Figure 21.18b, T_H cells cause dendritic cells to express on their surfaces the co-stimulatory molecules required to activate CD8 cells.

Amplification of Innate Defenses T_H cells also amplify the responses of the innate immune system. For example, they activate macrophages to become more potent killers. The cytokines released by T_H cells not only mobilize lymphocytes and macrophages but also attract other types of white blood cells into the area. As the released chemicals summon more and more cells into the battle, the immune response gains momentum, and the sheer number of immune elements overwhelms the antigens.

Subsets of T_H Cells Various subsets of helper T cells exist. Which subset develops during T_H cell differentiation depends on the type of antigen and the site at which it is encountered as well as the cytokine exposure of the differentiating T_H cell.

- *T_H1 cells* stimulate inflammation, activate macrophages, and promote differentiation of cytotoxic T cells. They mediate most aspects of cellular immunity.
- *T_H2 cells* mainly defend against parasitic worms. They mobilize eosinophils and activate immune responses that depend on B cells and antibody formation. They are also the cells that promote allergies.
- *T_H17 cells* link together adaptive and innate immunity by releasing IL-17, which promotes inflammatory responses against extracellular microbes and may underlie most autoimmune diseases.



(a) A mechanism of target cell killing by T_C cells.

(b) Scanning electron micrograph of a T_C cell killing a cancer cell (2100×).

Figure 21.19 Cytotoxic T cells attack infected and cancerous cells. MHC proteins and T cell receptors not shown.

Cytotoxic T Cells

Cytotoxic T (T_C) cells (activated CD8 cells) are T cells that can directly attack and kill other cells. T_C cells roam the body, circulating in and out of the blood and lymph and through lymphoid organs in search of body cells displaying antigens that the T_C cells recognize. Their main targets are virus-infected cells, but they also attack tissue cells infected by certain intracellular bacteria or parasites, cancer cells, and foreign cells introduced into the body by blood transfusions or organ transplants.

Before the onslaught can begin, the cytotoxic T cell must "dock" on the target cell by binding to a self-nonself complex. Remember, all body cells display class I MHC antigens, so T_C cells can destroy all infected or abnormal body cells. The attack on foreign human cells, such as those of a graft, is more difficult to explain because here *all* of the antigens are nonself. However, apparently the T_C cells sometimes "see" the foreign class I MHC antigens as a combination of self class I MHC protein bound to foreign antigen.

Once cytotoxic T cells recognize their targets, how do they deliver a *lethal hit*? There are two major mechanisms. One involves **perforins** and **granzymes** (Figure 21.19). The other involves binding to a specific membrane receptor on the target cell that stimulates the target cell to undergo apoptosis.

NK cells, introduced earlier, use the same key mechanisms to kill their target cells. NK cells, however, do not look for foreign antigen displayed on class I MHC proteins. Instead they search for other signs of abnormality, including the *lack* of class I MHC or the presence of antibodies coating the target cell. Stressed cells also often express different surface markers, which can activate NK cells. In short, NK cells stalk abnormal or foreign cells in the body that T_C cells can't "see."

NK cells and T_C lymphocytes roam the body, adhering to and crawling over the surfaces of other cells, examining them for markers they might recognize, a process called **immune surveillance**. NK cells check to make sure each cell has "identity flags" (class I MHC proteins *inhibit* NK cell attack), whereas T_C cells check the "identity flags" to see if they look the way they are supposed to (foreign antigens *stimulate* T_C cell attack).

Regulatory T Cells

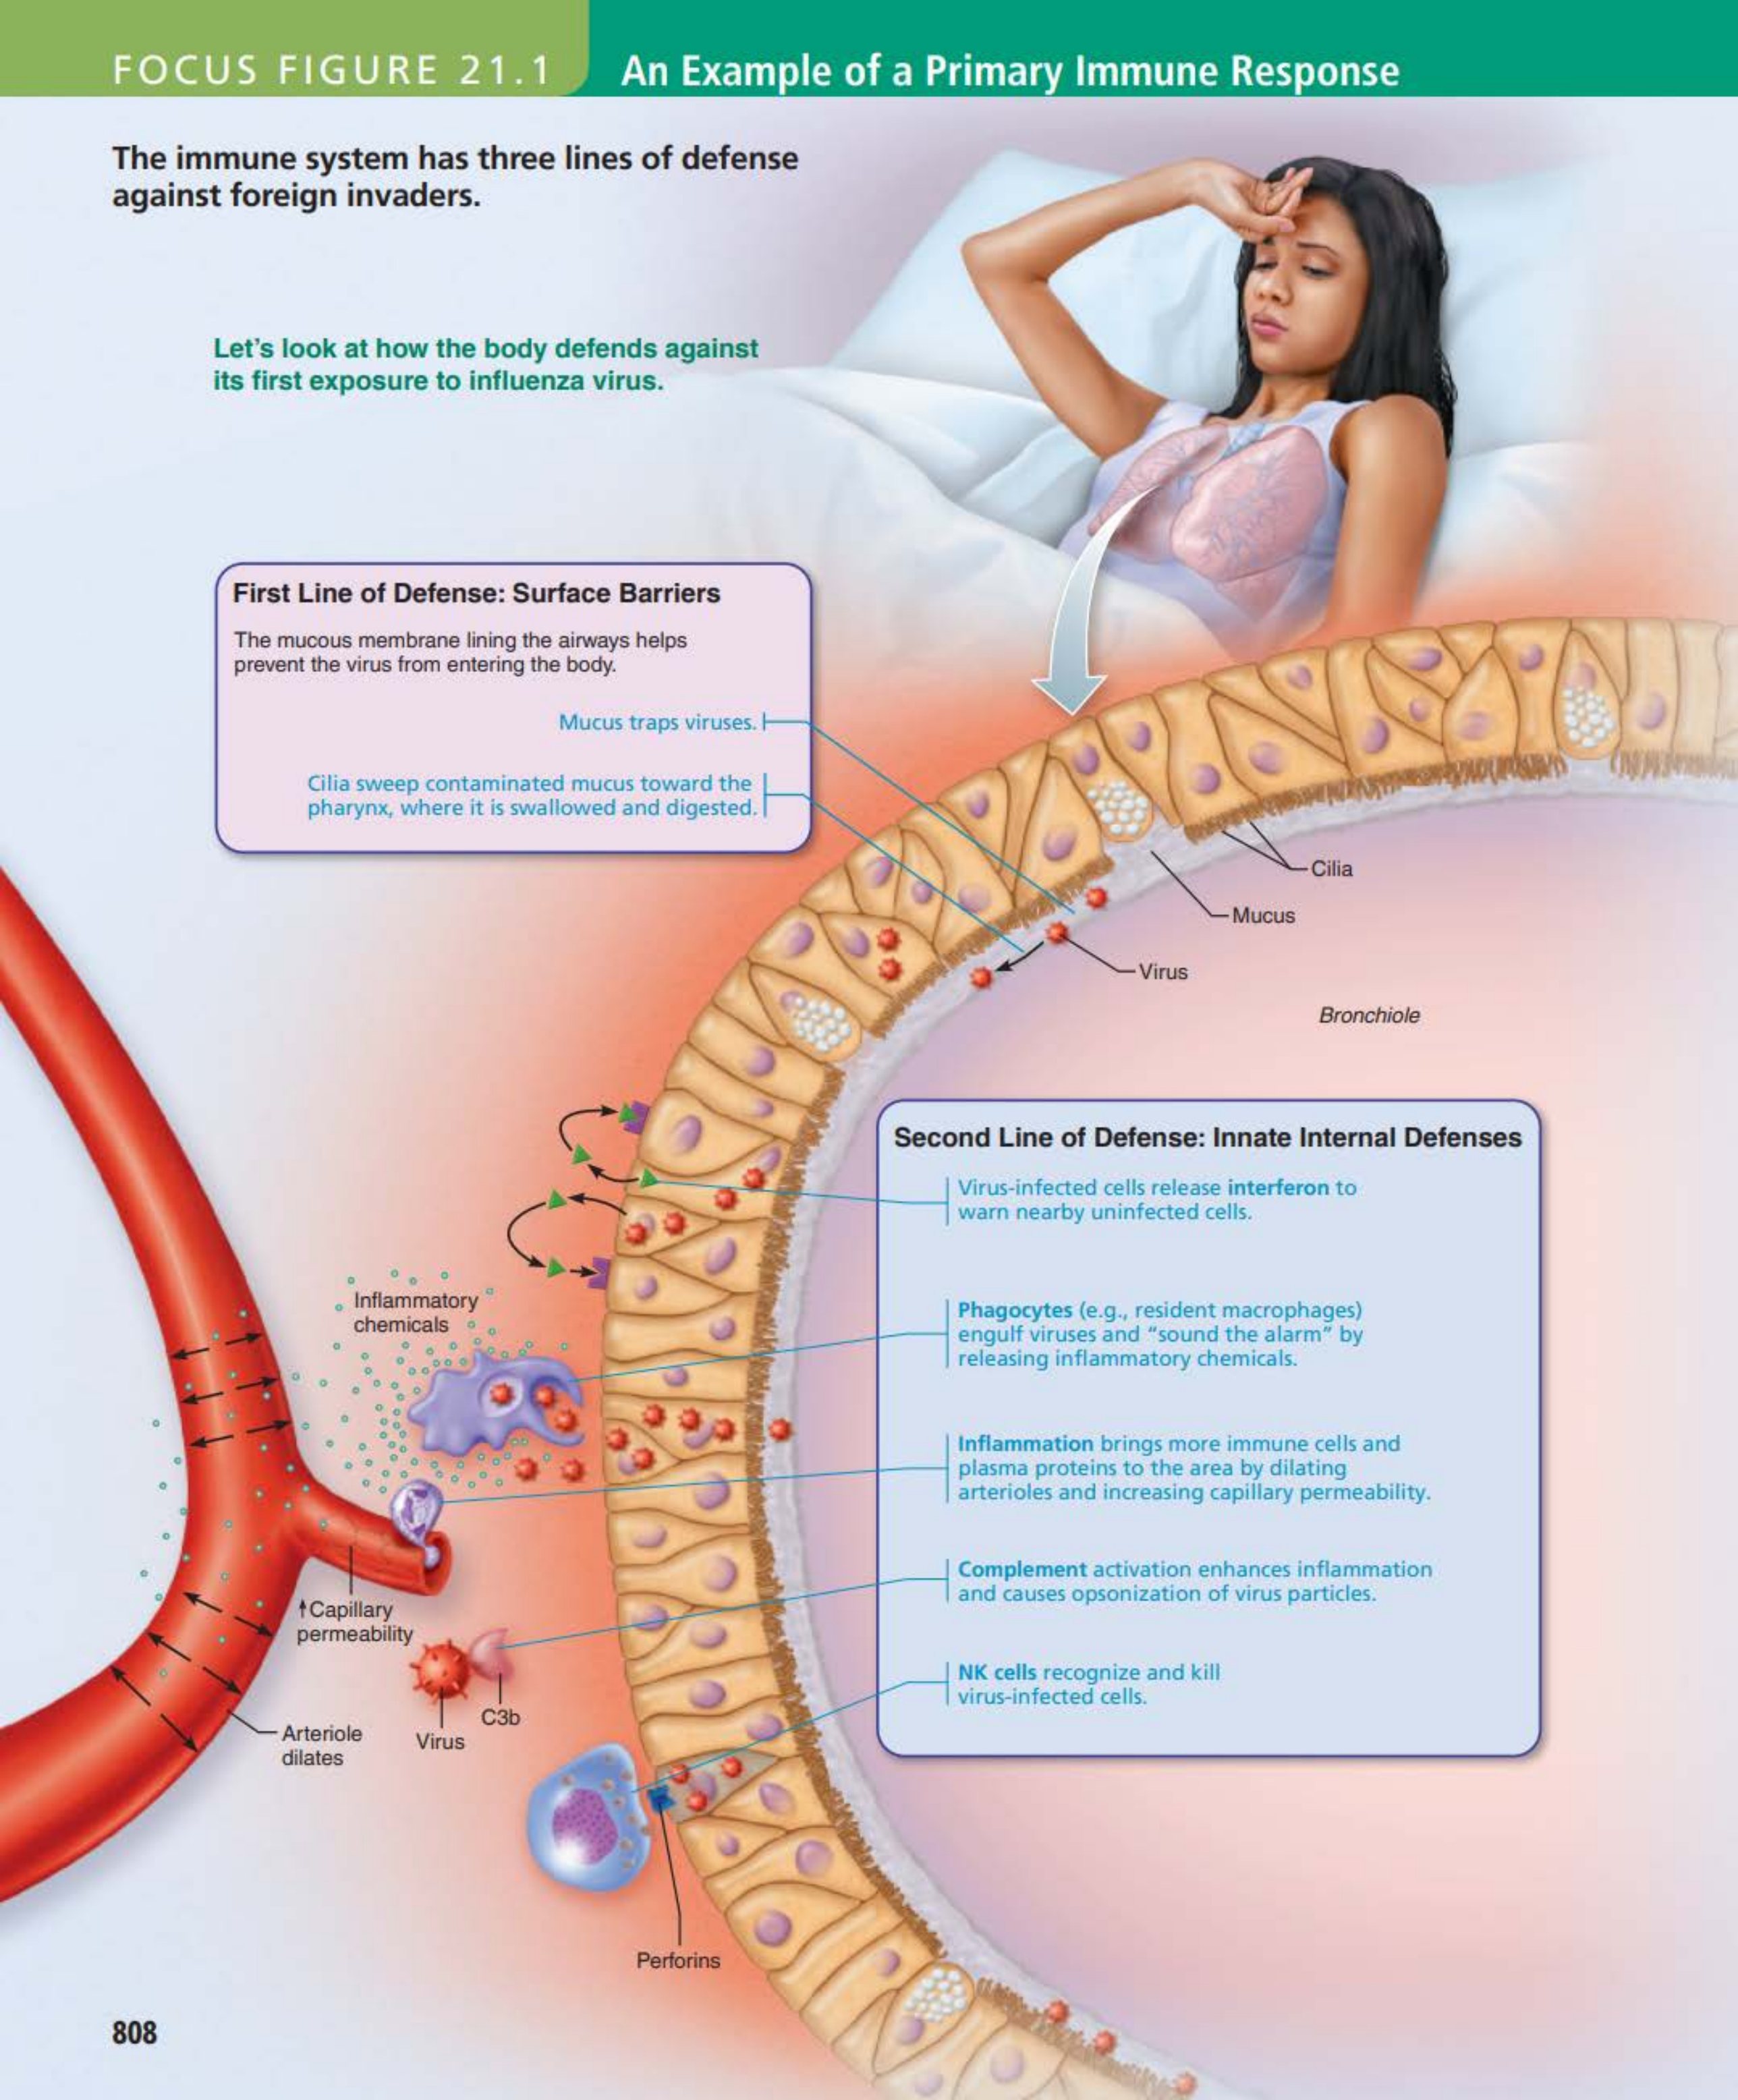
While T_H cells help activate adaptive immune responses, related T cells called **regulatory T (T_{Reg}) cells** dampen the immune response. They act either by direct contact or by releasing inhibitory cytokines.

T_{Reg} cells are important in preventing autoimmune reactions because they suppress self-reactive lymphocytes in the

FOCUS FIGURE 21.1 An Example of a Primary Immune Response

The immune system has three lines of defense against foreign invaders.

Let's look at how the body defends against its first exposure to influenza virus.



Third Line of Defense: Adaptive Defenses

1 Dendritic cells (APCs) engulf viruses and dead virus-infected cells.

2 Dendritic cells migrate to a lymph node where they activate T lymphocytes.

Lymph node

3 Dendritic cell activates CD4 cell, which forms a clone of helper T (T_H) cells and memory cells.

4b T_H cell activates a B cell, which forms a clone of plasma cells and memory B cells.

Memory CD8 T cell

Memory B cell

Cellular immunity (via T_C cells) targets intracellular viruses by killing infected cells.

T_C cells

Plasma cells

5a T_C cells migrate to site of infection. They attack and kill the infected cells.

Antibodies

Perforins

5b Plasma cells release antibodies, which travel (via blood) to site of infection.

Humoral immunity targets extracellular (free) viruses.

Antibodies **neutralize** viruses by covering the proteins that allow the virus to bind to and enter our cells. No entry = no infection.

Agglutination and **complement activation** enhance phagocytosis by neutrophils and macrophages.

Table 21.8 Cells and Molecules of the Adaptive Immune Response

ELEMENT		FUNCTION IN IMMUNE RESPONSE
Cells		
B cell		Lymphocyte that matures in bone marrow. Its progeny (clone members) form plasma cells and memory cells.
Plasma cell		Antibody-producing "machine"; produces huge numbers of antibodies. An effector B cell.
T cells		
• Helper T (T_H) cell		An effector CD4 T cell central to both humoral and cellular immunity. It stimulates production of cytotoxic T cells and plasma cells, activates macrophages, and acts both directly and indirectly by releasing cytokines.
• Cytotoxic T (T_C) cell		An effector CD8 T cell that kills invaded body cells and cancer cells.
• Regulatory T (T_{Reg}) cell		An effector CD4 T cell that slows or stops activity of immune system. Important in controlling autoimmune diseases; several different kinds.
Memory cell		Descendant of activated B cell or any class of activated T cell; generated during initial immune response. May exist in body for years, enabling it to respond quickly and efficiently to subsequent encounters with same antigen.
Antigen-presenting cell (APC)		Any of several cell types (dendritic cell, macrophage, B cell) that engulfs and digests antigens that it encounters, then presents parts of them on its plasma membrane (bound to an MHC protein) for recognition by T cells bearing receptors for the same antigen. This function, antigen presentation, is essential for activation of T cells.
Molecules		
Antigen		Substance capable of provoking an immune response. Typically a large, complex molecule (e.g., protein or modified protein) not normally present in the body.
Antibody (immunoglobulin or Ig)		Protein produced by B cell or by plasma cell. Antibodies produced by plasma cells are released into body fluids (blood, lymph, saliva, mucus, etc.), where they attach to antigens. This causes complement activation, neutralization, precipitation, or agglutination, which "marks" the antigens for destruction by phagocytes or complement.
Perforins, granzymes		Released by T_C cells. Perforins create large pores in the target cell's membrane, allowing entry of apoptosis-inducing granzymes.
Complement		Group of bloodborne proteins activated after binding to antibody-covered antigens or certain molecules on the surface of microorganisms; enhances inflammatory response and lyses some microorganisms.
Cytokines		Small proteins that act as chemical messengers between various parts of the immune system. See Table 21.7.

periphery—that is, outside the lymphoid organs. T_{Reg} cells and their subpopulations are currently hot research topics. For example, researchers hope to use them to induce tolerance to transplanted tissue and to lessen the severity of autoimmune diseases.

Table 21.8 summarizes the cells and molecules of the adaptive immune response. *Focus on An Example of a Primary Immune Response* (**Focus Figure 21.1** on pp. 808–809) gives an overview of the entire primary immune response, both innate and adaptive.

Organ Transplants and Prevention of Rejection

CLINICAL

The goal of organ transplantion is to provide patients with a functional organ from a living or deceased donor. This is often the only viable option left in end-stage cardiac or renal disease. Immune rejection presents a particular problem and so transplant success depends in part on the similarity of the donor and recipient tissues. NK cells, macrophages, antibodies, and

especially T cells act vigorously to destroy any tissue they recognize as foreign.

The most common type of transplant is the *allograft*. Allografts are grafts transplanted from different individuals of the same species.* Before an allograft is attempted, the ABO and other blood group antigens of donor and recipient must be determined because these antigens are also present on most body cells and mismatches lead to immediate rejection. Matching donor and recpient MHCs helps minimize long-term rejection.

Following surgery the patient is treated with *immunosuppressive therapy*. Many of the drugs used to suppress rejection kill rapidly dividing cells (such as activated lymphocytes), and all of them have severe side effects. The major problem with immunosuppressive therapy is that the patient's suppressed immune system cannot protect the body against other foreign agents. As a result, overwhelming bacterial and viral infection remains the most frequent cause of death in transplant patients. Even under the best conditions, by 10 years after receiving a transplant, roughly 50% of patients have rejected the donor organ.

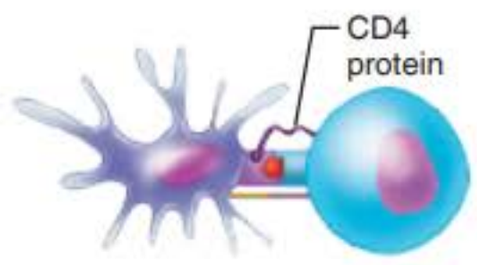
Check Your Understanding

20. Class II MHC proteins display what kind of antigens? What class of T cell recognizes antigens bound to class II MHC? What types of cells display these proteins?

21. Which type of T cell is the most important in both cellular and humoral immunity? Why?

22. Two killing mechanisms that we have seen in this chapter create pores in their target. Name the proteins that form this structure if they are (a) secreted by an immune cell that binds to the target cell or (b) derived from plasma proteins. Describe how these pores kill.

23. Once activated, the lymphocyte below will become one of two types of effector cells. Name them.



For answers, see Answers Appendix.

21.7 Insufficient or overactive immune responses create problems

CLINICAL

Learning Outcomes

- **Give examples of immunodeficiency diseases and of hypersensitivity states.**
- **Cite factors involved in autoimmune disease.**

Certain circumstances can cause the immune system to weaken, fail, or act in a way that damages the body. Most such problems can be classified as immunodeficiencies, autoimmune diseases, or hypersensitivities.

*Autografts, isografts, and xenografts are described in Related Clinical Terms on p. 814.

Immunodeficiencies

An **immunodeficiency** is a congenital or acquired condition that impairs the production or function of immune cells or certain molecules, such as complement or antibodies.

The most devastating *congenital immunodeficiencies* are a group of related disorders called **severe combined immunodeficiency (SCID) syndromes**, which result from various genetic defects that produce a marked deficit of B and T cells.

Children afflicted with SCID have little or no protection against disease-causing organisms. Interventions must begin in the first months of life because minor infections easily shrugged off by most children cause those children with SCID to become deathly ill. Untreated, this condition is fatal, but successful transplants of matched donor hematopoietic stem cells dramatically improve survival rates. Genetic engineering techniques using viruses to carry corrected genes into the patient's own hematopoietic stem cells can also help.

There are various *acquired immunodeficiencies*. For example, *Hodgkin's lymphoma*, a cancer of the B cells, can lead to immunodeficiency by depressing lymph node cells. Immunosuppressive drugs used in transplantation and certain drugs used to treat cancer also suppress the immune system.

The most devastating of the acquired immunodeficiencies is **acquired immune deficiency syndrome (AIDS)**, which cripples the immune system by interfering with the activity of helper T cells. AIDS is caused by the **human immunodeficiency virus (HIV)**, a virus transmitted in body secretions—especially blood, semen, and vaginal secretions. HIV commonly enters the body via blood-contaminated needles, or during sexual intercourse. An infected mother can also transmit the virus to her fetus.

HIV targets CD4 cells via their CD4 surface proteins. Once inside a CD4 cell, HIV "sets up housekeeping," using the viral enzyme *reverse transcriptase* to produce DNA from its (viral) RNA. This DNA copy, now called a *provirus*, inserts itself into the target cell's DNA and directs the cell to crank out new copies of viral RNA and proteins so that the virus can multiply and infect other cells. In the process, HIV destroys T_H cells, depressing both branches of adaptive immunity and turning the whole immune system topsy-turvy.

The HIV reverse transcriptase enzyme is not very accurate and produces errors rather frequently, causing HIV's relatively high mutation rate and its ability to develop drug resistance.

No cure for AIDS has yet been found. Fortunately, a number of classes of antiviral drugs are available, and these are often used in combination. Sadly, even combination drug therapies often fail as the virus becomes resistant.

Autoimmune Diseases

Occasionally the immune system loses its ability to distinguish friend (self) from foe (foreign antigens). When this happens, the artillery of the immune system, like friendly fire, turns against itself. The body produces antibodies (*autoantibodies*) and cytotoxic T cells that destroy its own tissues. This puzzling phenomenon is called **autoimmunity**. If a disease state results, it is referred to as **autoimmune disease**.

Some 5% of adults in North America—two-thirds of them women—are afflicted with an autoimmune disease. You have encountered examples of autoimmune diseases in earlier chapters, and you will encounter more later on. Some important autoimmune diseases are:

- *Rheumatoid arthritis*, which systematically destroys joints (◀ p. 275)
- *Myasthenia gravis*, which impairs communication between nerves and skeletal muscles (◀ p. 293)
- *Multiple sclerosis*, which destroys the myelin of the white matter of the brain and spinal cord (◀ p. 412)
- *Graves' disease*, which prompts the thyroid gland to produce excessive amounts of thyroxine (◀ pp. 620–621)
- *Type 1* (*insulin-dependent*) *diabetes mellitus*, which destroys pancreatic beta cells, resulting in a deficit of insulin and inability to use carbohydrates (◀ pp. 632–634)
- *Systemic lupus erythematosus* (*SLE*), a systemic disease that particularly affects the kidneys, heart, lungs, and skin (see Related Clinical Terms, p. 814)
- *Glomerulonephritis*, which damages the kidney's filtration membrane and severely impairs renal function (see p. 1008)

Treatment of Autoimmune Diseases

The most widely used treatments for autoimmune conditions suppress the entire immune system—for example, anti-inflammatory drugs such as corticosteroids. Newer treatments seek to target specific aspects of the immune response. Fortunately, the immune system offers many potential targets because it is so complex. Two widely used therapeutic approaches involve:

- Blocking the actions of various cytokines using antibodies against them or their receptors
- Blocking the co-stimulatory molecules required to activate effector cells

Approaches still being developed include reestablishing self-tolerance by:

- Activating regulatory T cells
- Inducing self-tolerance using vaccines
- Destroying self-reactive immune cells by directing antibodies against them

The biggest challenge is selectively blocking autoimmune responses without blocking responses necessary to combat infection.

Failure of Self-Tolerance

Every autoimmune disease represents a failure of self-tolerance. How does this happen? As you recall, maturing lymphocytes undergo an extensive education (negative selection) that weeds out self-reactive cells. This weeding is thorough, but not too thorough, since there are pathogens that look somewhat like self. Weakly self-reactive lymphocytes that can detect these pathogens are allowed to survive negative selection and so they may cause autoimmune disease if they become activated.

Recall that activation of a T cell requires a co-stimulatory signal on an APC (see p. 804), and these co-stimulatory signals are only present if the APC has received "danger" signals alerting it to damage or invasion. This important safety check and the presence of regulatory T cells generally keeps both humoral and cellular immunity under control.

Normally, these mechanisms are sufficient, but sometimes self-reactive lymphocytes slip out of control. One of the following conditions or events may trigger this:

- **Foreign antigens resemble self-antigens.** If the determinants of a foreign antigen resemble those on a self-antigen, antibodies made against the foreign antigen can cross-react with the self-antigen. In the disease *rheumatic fever*, for instance, antibodies produced during a streptococcal infection react with heart antigens, causing lasting damage to the heart muscle and valves, as well as to joints and kidneys.
- **New self-antigens appear.** Self-proteins not previously exposed to the immune system may appear in the circulation. They may be generated by (1) gene mutations that cause new proteins to appear at the external cell surface, (2) changes in the structure of self-antigens as a result of hapten attachment or infectious damage, or (3) novel self-antigens, normally hidden behind barriers such as the blood brain barrier, that are released by trauma. These newly generated proteins then become immune system targets.

Hypersensitivities

Hypersensitivities result when the immune system damages tissue as it fights off a perceived threat (such as pollen or animal dander) that would otherwise be harmless to the body. People rarely die of hypersensitivities. They just make you miserable.

The different types of hypersensitivity reactions are distinguished by (1) their time course, and (2) whether they involve antibodies or T cells. Antibody-associated reactions cause *immediate* and *subacute hypersensitivities*. T cells cause *delayed hypersensitivities*.

Immediate Hypersensitivities

Immediate hypersensitivities, also called **acute** or **type I hypersensitivities**, are simply what most of us would call **allergies** (*allo* = altered; *erg* = reaction). An **allergen** is an antigen that causes an allergic reaction. Allergic reactions begin within seconds after contact with the allergen and last about half an hour.

The initial meeting with an allergen produces no symptoms but it sensitizes a susceptible person, causing IgE antibodies to be secreted that attach to the surfaces of the body's *mast cells* and *basophils* (**Figure 21.20**). Later encounters with the same allergen trigger an allergic reaction, in which the allergen promptly binds and cross-links the IgE antibodies on the surfaces of the mast cells and basophils. This event causes mast cells and basophils to release a flood of *histamine* and other inflammatory chemicals that together induce the inflammatory response typical of allergy.

Allergic reactions may be local or systemic (bodywide). Mast cells are abundant in connective tissues of the skin and beneath

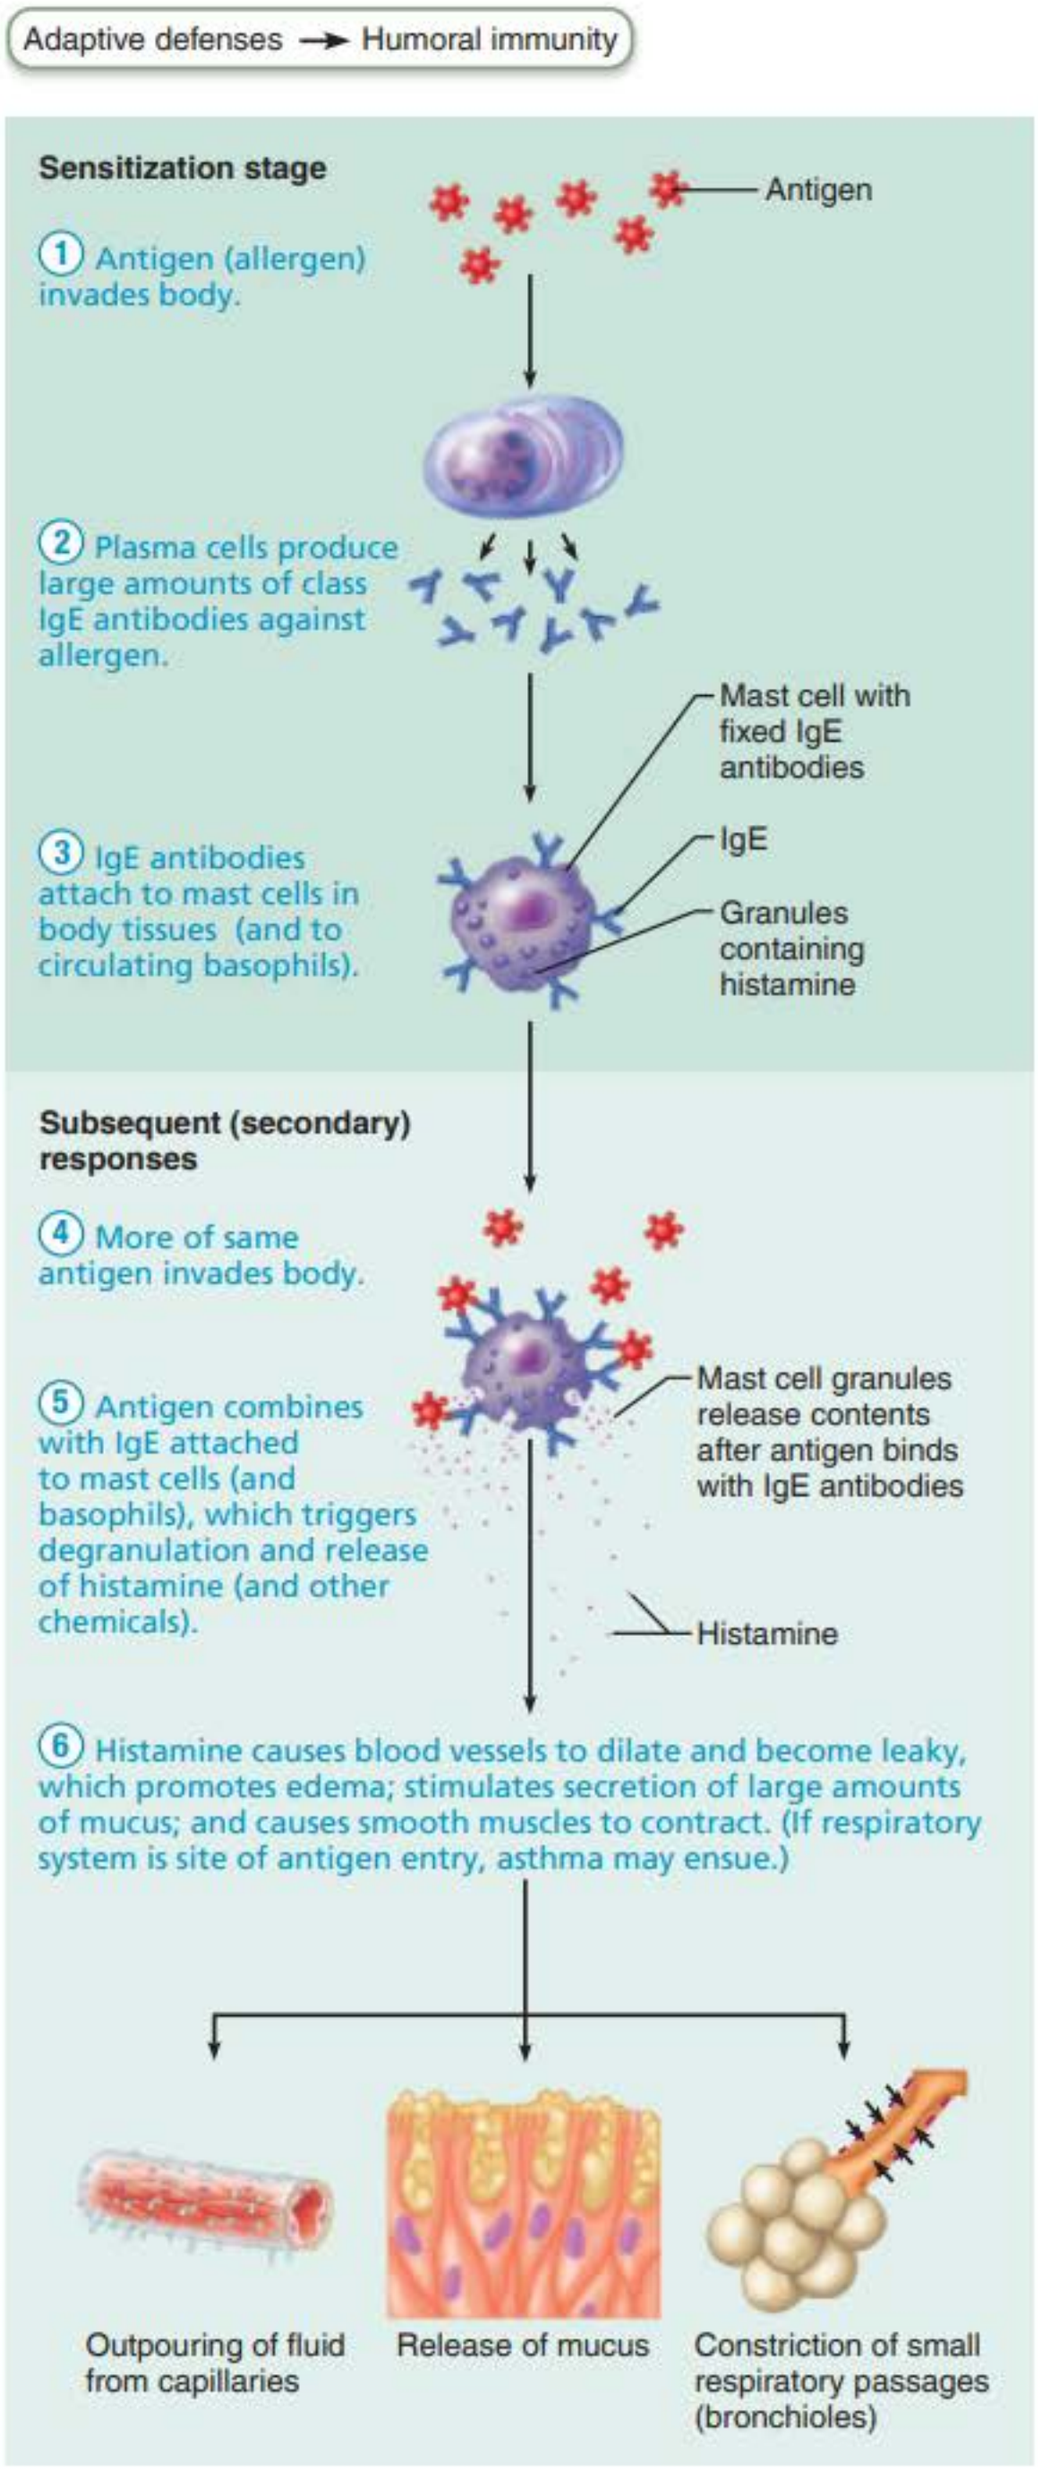


Figure 21.20 Mechanism of an acute allergic (immediate hypersensitivity) response.

the mucosa of respiratory passages and the gastrointestinal tract, and these areas are common sites of local allergic reactions.

Histamine causes blood vessels to dilate and become leaky, and is largely to blame for the best-recognized symptoms of allergy: runny nose, itching reddened skin (hives), and watery eyes. When the allergen is inhaled, symptoms of *asthma* appear because smooth muscle in the walls of bronchioles (small airways) contracts, constricting those small passages and restricting air flow. When the allergen is ingested in food or via drugs, gastrointestinal discomfort occurs. Over-the-counter antiallergy drugs contain antihistamines that counteract these effects.

The systemic response known as **anaphylactic shock** is fairly rare. It typically occurs when the allergen directly enters the blood and circulates rapidly through the body—for example, a bee sting, spider bite, or injection of a foreign substance (such as penicillin or other drugs that act as haptens).

The mechanism of anaphylactic shock is essentially the same as that of local responses, but when mast cells and basophils are enlisted throughout the body, the outcome is life threatening. The bronchioles constrict (and the tongue may swell), making it difficult to breathe, and the sudden vasodilation and fluid loss from the bloodstream may cause circulatory collapse (hypotensive shock) and death within minutes. Epinephrine is the drug of choice to reverse these histamine-mediated effects.

Subacute Hypersensitivities

Like the immediate types, **subacute hypersensitivities** are caused by antibodies (IgG and IgM rather than IgE). However, their onset is slower (1–3 hours after antigen exposure) and the reaction lasts longer (10–15 hours).

Cytotoxic (type II) reactions occur when antibodies bind to antigens on specific body cells and stimulate phagocytosis and complement-mediated lysis of the cellular antigens. Cytotoxic hypersensitivity may occur after a patient has received a transfusion of mismatched blood and complement lyses the foreign red blood cells.

Immune-complex (type III) hypersensitivities result when antigens are widely distributed through the body or blood and the huge number of insoluble antigen-antibody complexes formed cannot be cleared from a particular area. (This may reflect a persistent infection or an autoimmune disease.) An intense inflammatory reaction occurs, complete with complement-mediated cell lysis and cell killing by neutrophils that severely damages local tissues. An example of type III hypersensitivity is the glomerulonephritis of systemic lupus erythematosus (see Related Clinical Terms, p. 814).

Delayed Hypersensitivities

Delayed (type IV) hypersensitivity reactions are caused by T cells and take longer to appear (1–3 days) than antibody-mediated hypersensitivity reactions. Inflammation and tissue damage result from the action of cytokine-activated macrophages, and sometimes cytotoxic T cells.

The most familiar examples of delayed hypersensitivity reactions are those classified as **allergic contact dermatitis** which follow skin contact with poison ivy, some metals (nickel in jewelry),

and certain cosmetic and deodorant chemicals. These agents diffuse through the skin and attach to self-proteins as *haptens*.

Skin tests for tuberculosis depend on a delayed hypersensitivity reaction. When the tubercle antigens are introduced just under the skin, a small hard lesion forms that persists for days if the person has been sensitized to the antigen.

Check Your Understanding

24. What makes HIV particularly hard for the immune system to defeat?

25. What event triggers the release of histamine from mast cells in an allergic response?

For answers, see Answers Appendix.

Developmental Aspects of the Immune System

Stem cells of the immune system originate in the liver and spleen during weeks 1–9 of embryonic development. Later the red bone marrow becomes the predominant source of stem cells, and it persists in this role into adult life. The lymphocyte precursors become immunocompetent in the thymus and bone marrow, and then populate other lymphoid tissues.

The newborn's immune system depends primarily on antibodies and T_H2 lymphocytes. The T_H1 system is educated and gets stronger as a result of encounters with microbes—both harmful and harmless. If such exposure and education does not occur, immune balance is upset and the T_H2 system flourishes, causing the immune system to teeter toward allergies. Unhappily, the desire to keep our children squeaky clean with antibiotics that kill off both harmful and harmless bacteria may derail normal immune development.

A wide variety of factors outside the immune system influence immune function. For example:

- *Nervous system.* The study of psychoneuroimmunology—a brain-twisting term coined to describe links between the brain and the immune system—helps explain how various stressors such as depression, emotional stress, sleep deprivation, and grief can impair the immune response.
- *Diet.* Researchers have discovered that vitamin D is required for CD8 cells to become T_C cells. On the other hand, vitamin D deficiency has been linked with autoimmune diseases such as multiple sclerosis.

The immune system normally serves us well until late in life. Then its efficiency begins to wane, and its ability to fight infection declines. Old age is also accompanied by greater susceptibility to both immunodeficiency and autoimmune diseases. The greater incidence of cancer in the elderly may also reflect the progressive failure of the immune system. We do not know why the immune system begins to fail, but we do know that the thymus begins to atrophy after puberty. Memory cells accumulate, but the production of naive T and B cells declines with age, possibly because progenitor cells reach the limits of their ability to divide. This reduces the body's capacity to repond to new antigens.

In many elderly people, the immune system enters a state of sustained, low-grade inflammation due to the increased production of inflammatory chemicals. Such chronic inflammation is thought to cause or promote many diseases associated with aging, such as atherosclerosis and Alzheimer's disease.

RELATED CLINICAL TERMS

Autograft A tissue graft transplanted from one location to another in the same person.

Congenital thymic aplasia An immune deficiency disease in which the thymus fails to develop. Affected individuals have no T cells, and so have little or no immune protection; fetal thymic and bone marrow transplants have been helpful in some cases.

Eczema (ek′zĕ-mah) A clinical term for several conditions that cause "weeping" skin lesions and intense itching. One common cause, *atopic dermatitis*, has a strong familial predisposition, has features of immediate hypersensitivity, and usually begins in the first five years of life. Recent research suggests the underlying defect may be increased leakiness of the skin.

Hashimoto's thyroiditis An autoimmune disease in which both B and T lymphocytes attack the thyroid gland. It is the most common cause of hypothyroidism, affecting mostly middle-aged and elderly women. Genetic factors associated with this autoimmune disease (certain MHC variants) make individuals susceptible to environmental triggers (possibly iodine, irradiation, or trauma).

Immunization The process of rendering a subject immune (by vaccination or injecting antiserum).

Immunology The study of immunity.

Immunopathology Disease related to the immune system.

Isograft A graft transplated from a genetically identical individual. The only example is identical twins.

Septic shock (sepsis) A dangerous condition in which the inflammatory response goes out of control. It results from especially severe bacterial infections or more ordinary infections that grow rapidly worse in patients with weakened defenses, such as the hospitalized elderly recovering from surgery. In an inflammatory response, neutrophils and other white blood cells secrete cytokines that increase capillary permeability. In sepsis, continued cytokine release makes capillaries so leaky that the bloodstream is depleted of fluid. Blood pressure falls and the body organs shut down, causing death in 50% of cases. Sepsis has proven difficult to control and its incidence remains high.

Systemic lupus erythematosus (SLE) (er″ĭ-the″mah-to′sus) A systemic autoimmune disorder that occurs mainly in young females. Diagnosis is helped by finding antinuclear (anti-DNA) antibodies in the patient's blood. DNA–anti-DNA complexes (typical of type III hypersensitivity) localize in the kidneys, blood vessels, brain, and synovial membranes. This results in glomerulonephritis (see Related Clinical Terms, p. 1008), vascular problems, loss of memory and mental sharpness, and painful arthritis. Reddened skin lesions, particularly a "butterfly rash" (the sign of the wolf, or lupus) on the face, are common.

Xenograft A tissue or organ graft taken from a different species. Generally not viable except for acellular grafts such as heart valves.

CHAPTER SUMMARY

PART 1
INNATE DEFENSES

21.1 Surface barriers act as the first line of defense to keep invaders out of the body (pp. 782–783)

1. Skin and mucous membranes constitute the first line of defense. Protective membranes line all body cavities and organs exposed to the exterior.
2. Surface membranes provide mechanical barriers to pathogens. Some have structural modifications and produce secretions that enhance their defensive effects: The skin's acidity, lysozyme, mucus, keratin, and ciliated cells are examples.

21.2 Innate internal defenses are cells and chemicals that act as the second line of defense (pp. 783–790)

Phagocytes (pp. 784–785)

1. Phagocytes (macrophages and neutrophils) engulf and destroy pathogens that breach epithelial barriers. This process is facilitated when opsonins (antibodies or complement to which the phagocyte's receptors can bind) attach to the pathogen's surface. The respiratory burst enhances cell killing.

Natural Killer (NK) Cells (p. 785)

2. Natural killer (NK) cells are large granular lymphocytes that act nonspecifically to kill virus-infected and cancerous cells.

Inflammation: Tissue Response to Injury (pp. 785–787)

3. The inflammatory response prevents the spread of harmful agents, disposes of pathogens and dead tissue cells, and promotes healing. Exudate forms; protective leukocytes enter the area; fibrin walls off the area; and tissue repair occurs.
4. The cardinal signs of inflammation are swelling, redness, heat, and pain. These result from inflammatory chemicals that induce vasodilation and make capillaries and venules more permeable. Impaired function may be a fifth cardinal sign.

Antimicrobial Proteins (pp. 788–789)

5. Interferons are a group of related proteins synthesized by virus-infected cells and certain immune cells that prevent viruses from multiplying in other body cells.
6. Activation of complement (a group of plasma proteins) on the membrane of a foreign cell promotes phagocytosis of that cell, enhances inflammation, and sometimes causes lysis of the target cell.

Fever (p. 789)

7. Fever enhances the body's fight against pathogens.

PART 2
ADAPTIVE DEFENSES

1. The adaptive immune system recognizes something as foreign and acts to immobilize, neutralize, or remove it. The adaptive immune response involves B and T lymphocytes, is antigen-specific, systemic, and has memory. It provides the body's third line of defense.

21.3 Antigens are substances that trigger the body's adaptive defenses (pp. 791–792)

1. Complete antigens have both immunogenicity and reactivity. Incomplete antigens, or haptens, must combine with a body protein before becoming immunogenic.
2. Antigenic determinants are the portions of antigen molecules that are recognized as foreign. Most antigens have many such sites.
3. Major histocompatibility complex (MHC) proteins are membrane-bound glycoproteins that mark our cells as "self."

21.4 B and T lymphocytes and antigen-presenting cells are cells of the adaptive immune response (pp. 792–795)

Lymphocytes (pp. 792–794)

1. Lymphocytes arise from hematopoietic stem cells of the bone marrow and are educated to develop immunocompetence and self-tolerance. T cells are educated in the thymus and provide cellular immunity. B cells are educated in the bone marrow and provide humoral immunity. Immunocompetence is signaled by the appearance of antigen-specific receptors on the surface of the lymphocyte. Immunocompetent lymphocytes seed the secondary lymphoid organs, where the antigen encounter occurs, and circulate between the blood, lymph, and lymphoid organs. When naive lymphocytes encounter their antigen, clonal selection, proliferation, and differentiation occur. Most of the clone members become effector cells, but some become memory cells.
2. In both B and T lymphocytes, antigen receptor diversity is generated by shuffling gene fragments.

Antigen-Presenting Cells (APCs) (pp. 794–795)

3. Antigen-presenting cells (APCs) include dendritic cells, macrophages, and B lymphocytes. They internalize antigens and present antigenic determinants on their surfaces for recognition by T cells.

21.5 In humoral immunity, antibodies are produced that target extracellular antigens (pp. 796–801)

Activation and Differentiation of B Cells (pp. 796–797)

1. When B cells are activated, most of the clone members become effector cells called plasma cells, which secrete antibodies. This is the primary adaptive immune response.

Immunological Memory (p. 797)

2. Other clone members become memory B cells, capable of mounting a rapid attack against the same antigen in subsequent encounters (secondary immune responses). The memory B cells provide humoral immunological memory.

Active and Passive Humoral Immunity (pp. 797–798)

3. Active humoral immunity is acquired during an infection or via vaccination and provides immunological memory. Passive immunity is conferred when a donor's antibodies are injected into the bloodstream, or when the mother's antibodies cross the placenta. Its protection is short-lived; immunological memory is not established.

Antibodies (pp. 798–801)

4. The antibody monomer consists of four polypeptide chains, two heavy and two light. Each chain has both a constant and a

variable region. Constant regions determine antibody function and class. Variable regions enable the antibody to recognize its specific antigen.

5. Five classes of antibodies exist: IgM, IgA, IgD, IgG, and IgE. They differ structurally and functionally.
6. Antibody functions include complement activation and antigen neutralization, precipitation, and agglutination.
7. Monoclonal antibodies are pure preparations of a single antibody type useful in diagnostic tests and treating some types of cancer.

21.6 Cellular immunity consists of T lymphocytes that direct adaptive immunity or attack cellular targets (pp. 801–811)

MHC Proteins and Antigen Presentation (pp. 802–804)

1. MHC proteins present antigens to T cells. Class I MHC proteins are found on all nucleated cells, but class II MHC proteins are found only on APCs.

Activation and Differentiation of T Cells (pp. 804–805)

2. Immunocompetent CD4 and CD8 T cells are activated by binding to an antigen-MHC complex on the surface of an APC. A co-stimulatory signal is also essential. The resulting clone members differentiate into either the appropriate effector T cells that mount the primary immune response (e.g., helper or cytotoxic T cells) or memory T cells.
3. The immune response is enhanced by cytokines such as interleukin 1 released by macrophages, and interleukin 2, gamma interferon, and others released by activated T cells.

Roles of Specific Effector T Cells (pp. 805–810)

4. Helper T cells are required for full activation of most B and T cells, activate macrophages, and release essential cytokines. Cytotoxic T cells directly attack and kill infected cells and cancer cells. Together with NK cells, they conduct immune surveillance. Regulatory T (T_{Reg}) cells help to maintain tolerance.

Organ Transplants and Prevention of Rejection (p. 810–811)

5. Cell-mediated responses reject grafts and foreign organ transplants unless the recipient is immunosuppressed. Infections are major complications in such patients.

21.7 Insufficient or overactive immune responses create problems (pp. 811–814)

1. Immunodeficiency diseases include acquired immune deficiency syndrome (AIDS), caused by HIV, and severe combined immunodeficiency (SCID) syndromes. Minor infections become fatally overwhelming because the immune system is unable to combat them.
2. Autoimmune disease occurs when the body regards its own tissues as foreign and mounts an immune attack against them. Examples include rheumatoid arthritis and multiple sclerosis.
3. Hypersensitivity is an abnormally intense reaction to an otherwise harmless antigen. Immediate hypersensitivities (allergies) are mounted by IgE antibodies. Subacute hypersensitivities, involving both antibodies and complement, include antibody-mediated cytotoxic and immune-complex hypersensitivities. Cell-mediated hypersensitivity is called delayed hypersensitivity.

Developmental Aspects of the Immune System (p. 814)

1. The liver and spleen are the initial sources of immune stem cells before the red bone marrow takes over.
2. The nervous system plays an important role in regulating immune responses. Various stressors can impair immune function.
3. With aging, the immune system becomes less responsive. The elderly more often suffer from immunodeficiency, autoimmune diseases, and cancer.

REVIEW QUESTIONS

To access additional practice questions using your smartphone, tablet, or computer: MasteringA&P® > Study Area > Practice Tests & Quizzes

Level 1 Remember/Understand

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. All of the following are considered innate body defenses *except* **(a)** complement, **(b)** phagocytosis, **(c)** antibodies, **(d)** lysozyme, **(e)** inflammation.
2. The process by which neutrophils squeeze through capillary walls in response to inflammatory signals is called **(a)** diapedesis, **(b)** chemotaxis, **(c)** margination, **(d)** opsonization.
3. Antibodies released by plasma cells are involved in **(a)** humoral immunity, **(b)** immediate hypersensitivity reactions, **(c)** autoimmune disorders, **(d)** all of the above.
4. Which antibody class is abundant in body secretions? **(a)** IgA, **(b)** IgD, **(c)** IgE, **(d)** IgG, **(e)** IgM.
5. Small molecules that must combine with large proteins to become immunogenic are called **(a)** complete antigens, **(b)** kinins, **(c)** antigenic determinants, **(d)** haptens.
6. Lymphocytes that develop immunocompetence in the bone marrow are **(a)** T lymphocytes, **(b)** B lymphocytes, **(c)** NK cells, **(d)** B and T lymphocytes.
7. Cells that can directly attack target cells include all of the following *except* **(a)** macrophages, **(b)** cytotoxic T cells, **(c)** helper T cells, **(d)** natural killer cells.
8. Which of the following is not involved in the activation of a B cell? **(a)** antigen, **(b)** helper T cell, **(c)** cytokine, **(d)** cytotoxic T cell.
9. Complement activation promotes all of the following except **(a)** cell lysis, **(b)** inflammation, **(c)** opsonization, **(d)** interferon release, **(e)** chemotaxis of neutrophils and other cells.
10. Using the letters from column B, match the cell description in column A. (Note that all require more than a single choice.)

Column A	Column B
____ **(1)** phagocytic "cleanup crew"	**(a)** natural killer cell
____ **(2)** releases histamine	**(b)** neutrophil
____ **(3)** releases perforins	**(c)** dendritic cell
____ **(4)** lymphocyte	**(d)** mast cell
____ **(5)** effector cells of adaptive immunity	**(e)** cytotoxic T cell
____ **(6)** antigen-presenting cell	**(f)** B cell
	(g) macrophage
	(h) helper T cell
	(i) basophil

11. The cell type most often invaded by HIV is a(n) **(a)** eosinophil, **(b)** cytotoxic T cell, **(c)** natural killer cell, **(d)** helper T cell, **(e)** B cell.
12. Name the five antibody classes and describe where each is most likely to be found in the body.

Level 2 Apply/Analyze

13. Besides acting as mechanical barriers, the skin epidermis and mucosae of the body have other attributes that contribute to their protective roles. Cite the common body locations and the importance of mucus, lysozyme, keratin, acid pH, and cilia.
14. What is complement? How does it cause bacterial lysis? What are some of the other roles of complement?
15. Interferons are referred to as antiviral proteins. What stimulates their production, and how do they protect uninfected cells? Which cells of the body secrete interferons?
16. Define immunocompetence and self-tolerance. How is self-tolerance achieved?
17. Differentiate between a primary and a secondary immune response. Which is more rapid and why?
18. Define antibody. Using an appropriately labeled diagram, describe the structure of an antibody monomer. Indicate and label variable and constant regions, heavy and light chains.
19. How do antibodies help defend the body?
20. Describe the specific roles of helper, regulatory, and cytotoxic T cells in normal cellular immunity.
21. Name several cytokines and describe their role in the immune response.
22. Define hypersensitivity. List three types of hypersensitivity reactions. For each, note whether antibodies or T cells are involved and provide examples.
23. What accounts for the declining efficiency of the immune system with age?

Level 3 Evaluate/Synthesize

24. Differentiate between humoral and cellular adaptive immunity.
25. Although the adaptive immune system has two arms, it has been said, "no T cells, no immunity." Explain.
26. Isabella, a 6-year-old child who has been raised in a germ-free environment from birth, has one of the most severe examples of an abnormal immune system. Isabella also suffers from cancer caused by the Epstein-Barr virus. Relative to this case: **(a)** Why is Isabella's brother chosen as the hematopoietic stem cell donor? **(b)** Why is her physician planning to use umbilical cord blood as a source of stem cells for transplant if her brother's stem cells fail (what are the hoped-for results)? **(c)** Attempt to explain Isabella's cancer. **(d)** What similarities and dissimilarities exist between Isabella's illness and AIDS?
27. Capillary permeability increases and plasma proteins leak into the interstitial fluid as part of the inflammatory process. Why is this desirable?
28. Caroline, a pregnant 29-year-old, has been HIV-positive for at least 10 years, dating back to when she was homeless and injecting heroin. While she currently has no symptoms of AIDS, she is taking several medications and is worried about the possibility that her baby might be infected. How do you think the HIV virus might be transferred from a mother to her offspring? Which of Caroline's cells are infected by the virus and why is the viral attack on these cells so devastating? Why is Caroline taking medication even though she has no symptoms?

CLINICAL CASE STUDY

52-Year-Old Male with Multiple Sclerosis

Mr. Ayers was diagnosed with an aggressive form of multiple sclerosis 18 years ago. His illness has not responded to conventional treatments so he's been referred to your clinic for a clinical trial. The doctor explains that his treatment will involve giving Mr. Ayers a drug that will release stem cells from his bone marrow so they can be collected from his blood. Then Mr. Ayers will be given (1) drugs that will destroy the blood-forming cells in his bone marrow, and (2), antibodies against his T lymphocytes. Finally, the stem cells that were collected from him will be used to repopulate his bone marrow.

The doctor says, "This treatment avoids problems, such as transplant rejection, that are associated with other kinds of transplants."

1. In organ transplantation, the transplanted organ is called a graft. What type of graft would it be if Mr. Ayers received someone else's bone marrow? What type would it be if he receives his own bone marrow?
2. One reason for using Mr. Ayers's own tissue is that it can be very difficult to find a donor whose bone marrow cells match the patient's class I and II MHC proteins. What is an MHC protein? What is the difference between class I and class II MHC proteins?
3. ✚ NCLEX-STYLE The nurse explains to Mr. Ayers that a bone marrow transplant from another donor could result in the transplanted immune cells attacking his own cells. The best explanation for this is:
   - **a.** Transplants from another person are never perfect matches. Any organ transplant could cause this problem.
   - **b.** A donor transplant would be a problem because Mr. Ayers's own immune system will be destroyed, so he wouldn't be able to fight off mismatched cells from a donor transplant.
   - **c.** Bone marrow is where immune cells are made. If Mr. Ayers received mismatched immune cells, these cells could attack his body.
   - **d.** Because Mr. Ayers has an autoimmune disorder, his body will attack anything transplanted into it.
4. ✚ NCLEX-STYLE You're talking with Mr. Ayers about his course of treatment. Which of his statements indicates a need for further instruction?
   - **a.** "It's ironic that they're giving me antibodies against my T cells, when I already attack my own tissues."
   - **b.** "I'm gonna ask the doc to not give me the stem cells after they destroy my bone marrow. After all, the immune cells are what's hurting me!"
   - **c.** "My T cells are just brutal. Gotta get those bad boys under control!"
   - **d.** "I'm guessing the real trouble was something that happened to my T cells."

22 The Respiratory System

In this chapter, you will learn that

The respiratory system supplies cells with oxygen and eliminates carbon dioxide

by first examining

Part 1 Functional Anatomy

looking closer at

- **22.1 The upper respiratory system**
- **22.2 The lower respiratory system**
  - includes
  - **22.3 The lungs and pleurae**

then exploring

Part 2 Respiratory Physiology

by asking

- **22.4 What causes air to move in and out of the lungs?**
  - and
- **22.5 How do we assess ventilation?**
- **22.6 How do gases move between the lungs, blood, and tissues?**
  - and
- **22.7 How does blood carry oxygen and carbon dioxide?**
  - transported through
  - **The cardiovascular system** Ch. 17–19

and then exploring

- **22.8 Control of respiration**
- **22.9 Exercise and high altitude**
- **22.10 What happens when things go wrong?**

and finally, exploring

Developmental Aspects of the Respiratory System

CAREER CONNECTION

Far from self-sustaining, our bodies depend on the external environment, both as a source of substances we need to survive and as a catch basin for wastes. We require a continuous supply of oxygen so that our trillions of cells can carry out their vital functions. We can live without food or water for days, but we cannot do without oxygen for even a little while.

As cells use oxygen, they give off carbon dioxide, a waste product the body must get rid of. They also generate dangerous free radicals, the inescapable by-products of living in a world full of oxygen.

The major function of the **respiratory system** is to supply the body with oxygen and dispose of carbon dioxide. To accomplish this function, at least four processes, collectively called **respiration**, must happen. These processes are shown in **Figure 22.1**.

The respiratory system is responsible for only the first two processes, but it cannot accomplish its primary goal of obtaining oxygen and eliminating carbon dioxide unless the third and fourth processes also occur. As you can see, the respiratory and circulatory systems are closely coupled, and if either system fails, the body's cells begin to die from oxygen starvation.

The actual use of oxygen and production of carbon dioxide by tissue cells, known as *cellular respiration*, is the cornerstone of all energy-producing chemical reactions in the body. We discuss cellular respiration, which is not a function of the respiratory system, in the metabolism section of Chapter 24.

Because it moves air, the respiratory system is also involved with the sense of smell and with speech.

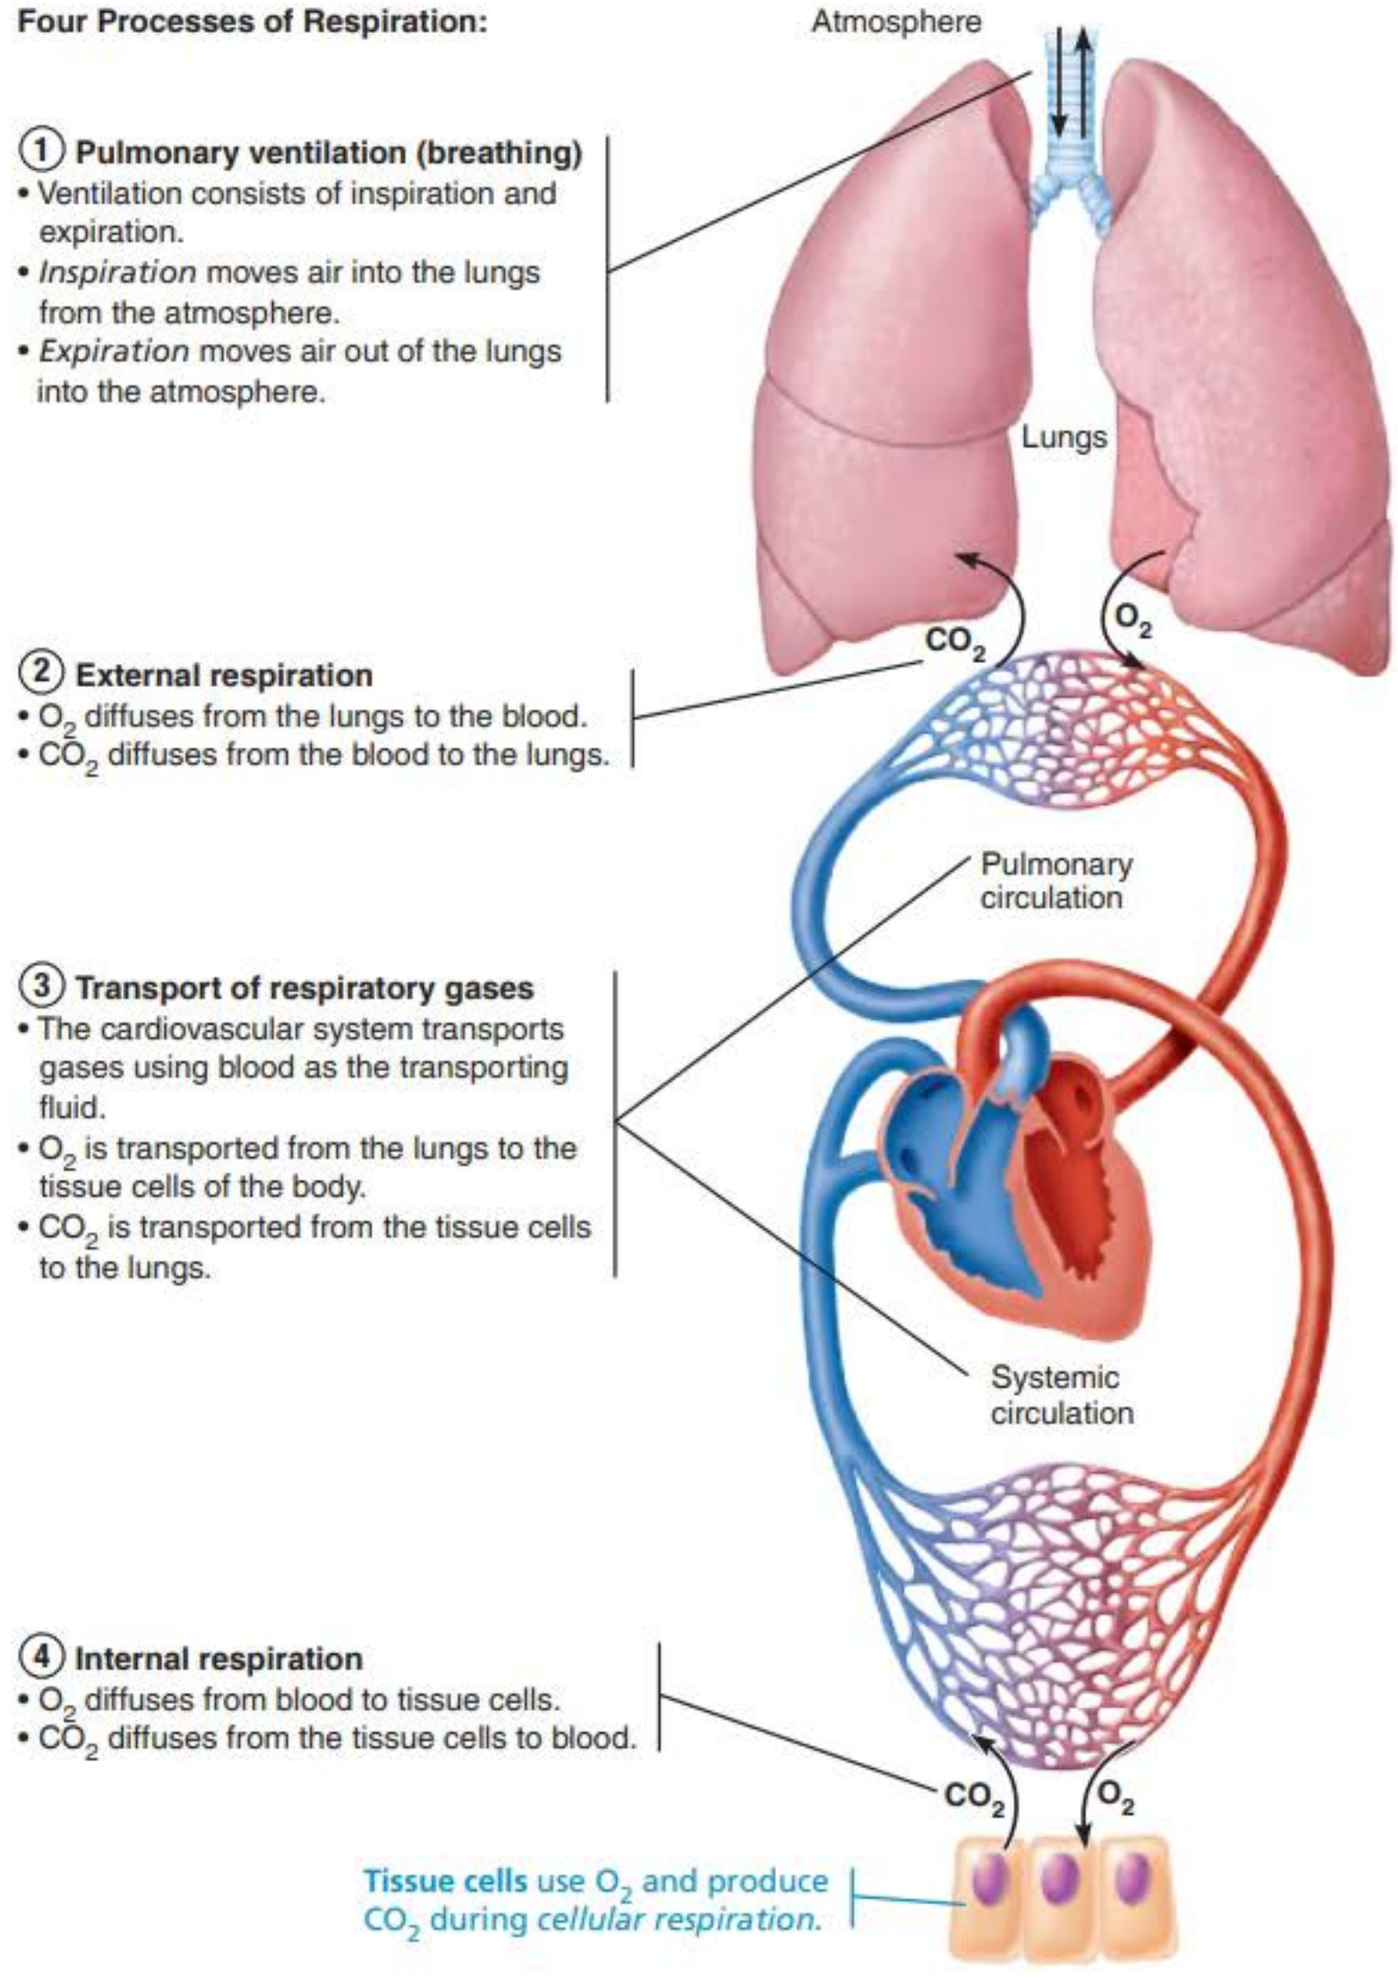

Figure 22.1 **Respiration consists of four processes.**

PART 1

FUNCTIONAL ANATOMY

The respiratory system (**Figure 22.2**) includes the *nose* and *paranasal sinuses*; the *pharynx*; the *larynx*; the *trachea*; the *bronchi* and their smaller branches; and the *lungs*, which contain tiny air sacs called *alveoli*. The *upper respiratory system* (summarized in **Table 22.1**, p. 824) consists of all the structures from the nose to the larynx. The *lower respiratory system* (**Table 22.2**, p. 831) consists of the larynx and all the structures below it.

Some authorities also include the respiratory muscles (diaphragm, etc.) as part of the respiratory system. Although we will consider how these skeletal muscles bring about the volume changes that promote ventilation, we continue to classify them as part of the *muscular system*.

22.1 The upper respiratory system warms, humidifies, and filters air

Learning Outcomes

- **Describe the location, structure, and function of each of the following: nose, paranasal sinuses, and pharynx.**
- **List and describe several protective mechanisms of the respiratory system.**

The Nose and Paranasal Sinuses

The nose is the only externally visible part of the respiratory system. Unlike the eyes and lips, facial features often referred to poetically, the nose is usually an irreverent target. We are urged to keep our nose to the grindstone and keep it out of other people's business. Considering its important functions, however, it deserves more esteem. The nose (1) provides an airway for respiration, (2) moistens and warms entering air, (3) filters and cleans inspired air, (4) serves as a resonating chamber for speech, and (5) houses the olfactory (smell) receptors.

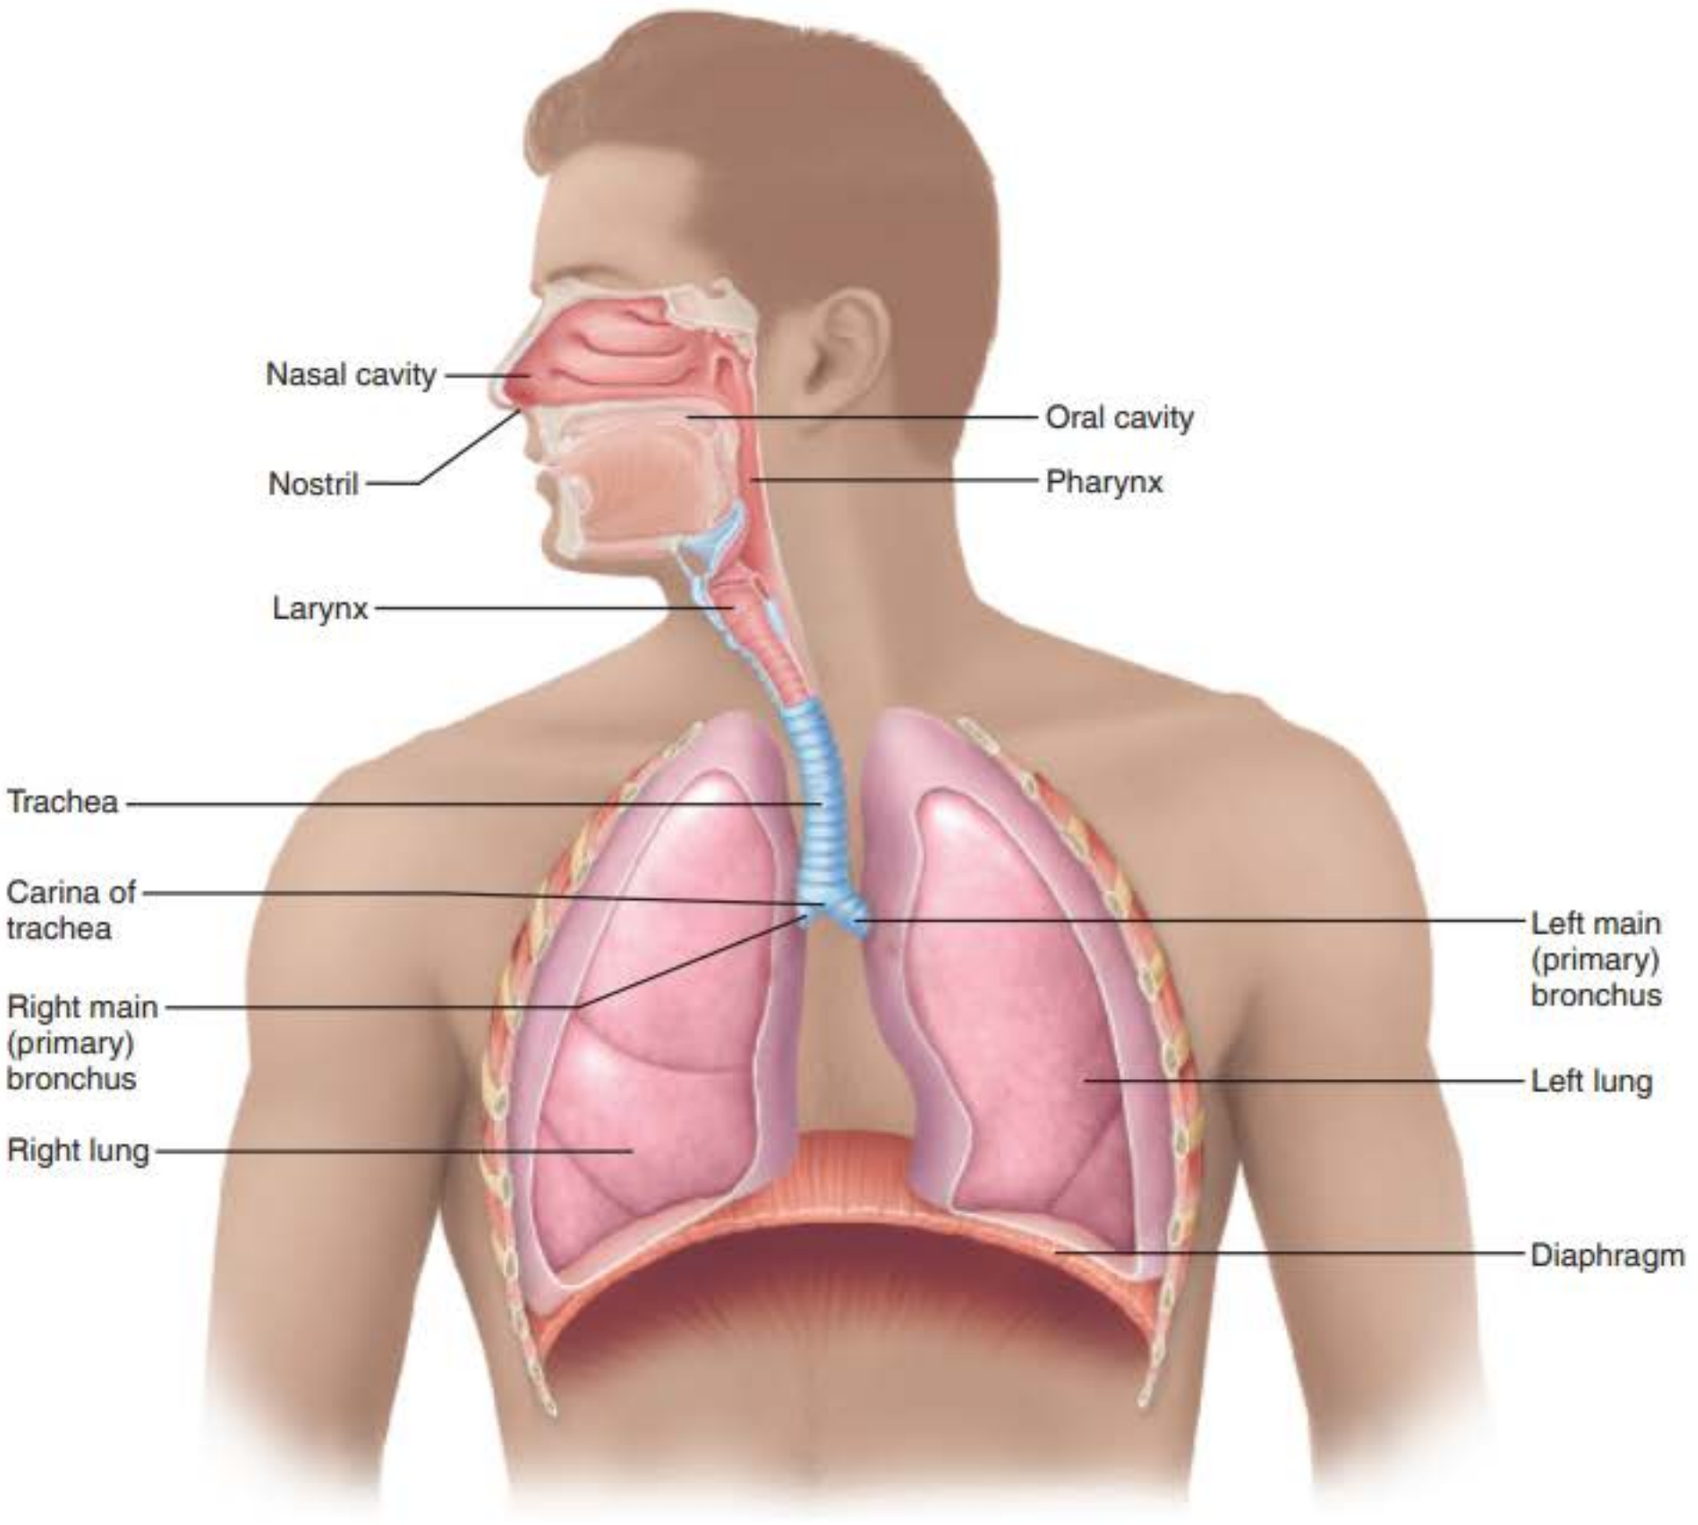

Figure 22.2 **The major respiratory organs in relation to surrounding structures.**

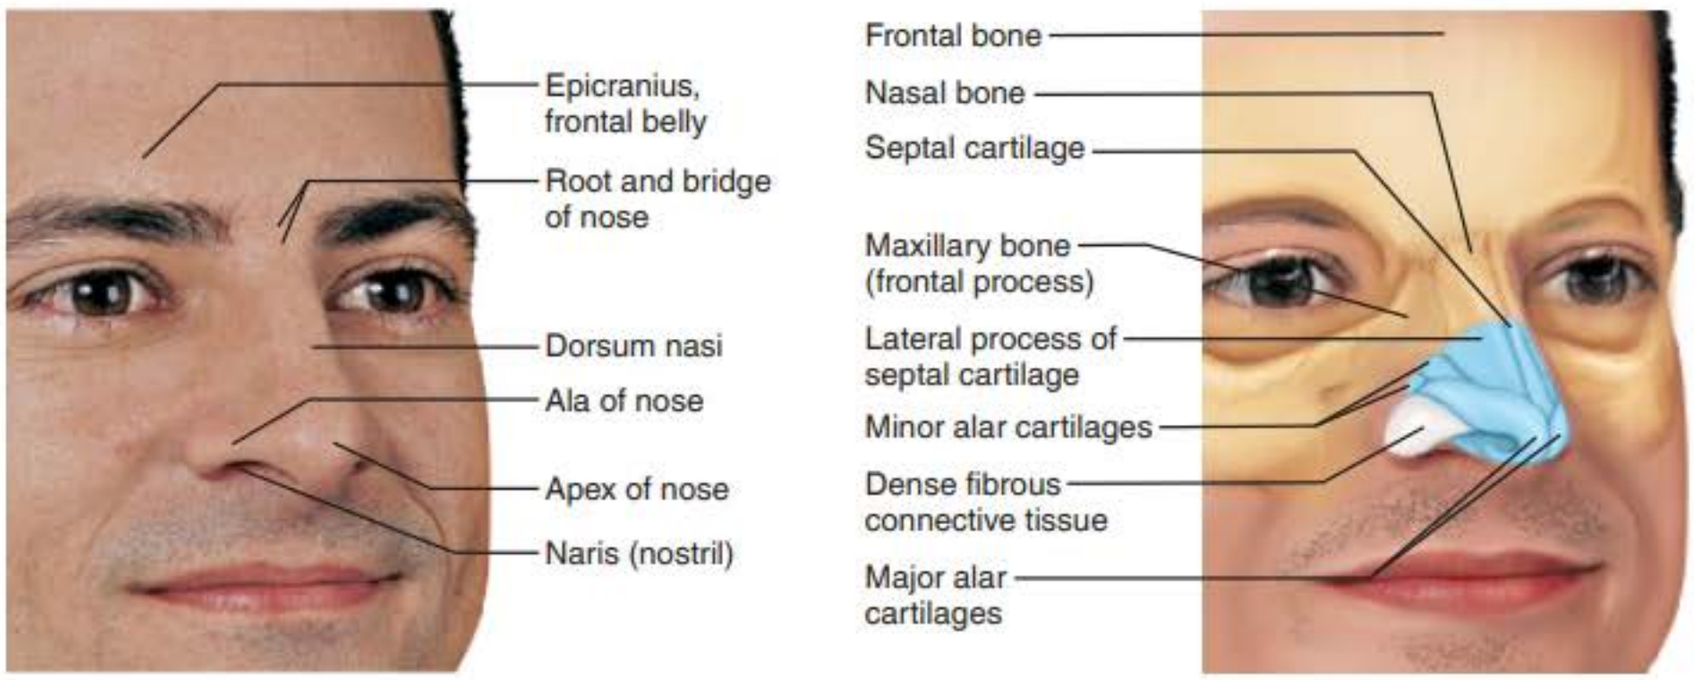

(a) Surface anatomy (b) External skeletal framework

Figure 22.3 The external nose.

The structures of the nose are divided into the *external nose* and the internal *nasal cavity* for ease of consideration.

External Nose

The surface features of the external nose include the *root* (area between the eyebrows), *bridge*, and *dorsum nasi* (anterior margin), the latter terminating in the *apex* (tip of the nose) (**Figure 22.3a**). The external openings of the nose, the **nostrils** or **nares** (na′rēz), are bounded laterally by the flared *alae*.

The skeletal framework of the external nose is fashioned by the nasal and frontal bones superiorly (forming the bridge and root, respectively), the maxillary bones laterally, and flexible plates of hyaline cartilage (the alar and septal cartilages, and the lateral processes of the septal cartilage) inferiorly (Figure 22.3b). Noses vary a great deal in size and shape, largely because of differences in nasal cartilages. The skin covering the nose's anterior and lateral aspects is thin and contains many sebaceous glands.

Nasal Cavity

The internal **nasal cavity** lies in and posterior to the external nose. During breathing, air enters the cavity by passing through the *nostrils* or *nares* (Figure 22.3a and **Figure 22.4**). The nasal cavity is divided by a midline **nasal septum**, formed anteriorly by the septal cartilage and posteriorly by the vomer bone and perpendicular plate of the ethmoid bone (◀ Figure 7.14b, p. 214). The nasal cavity is continuous posteriorly with the nasal

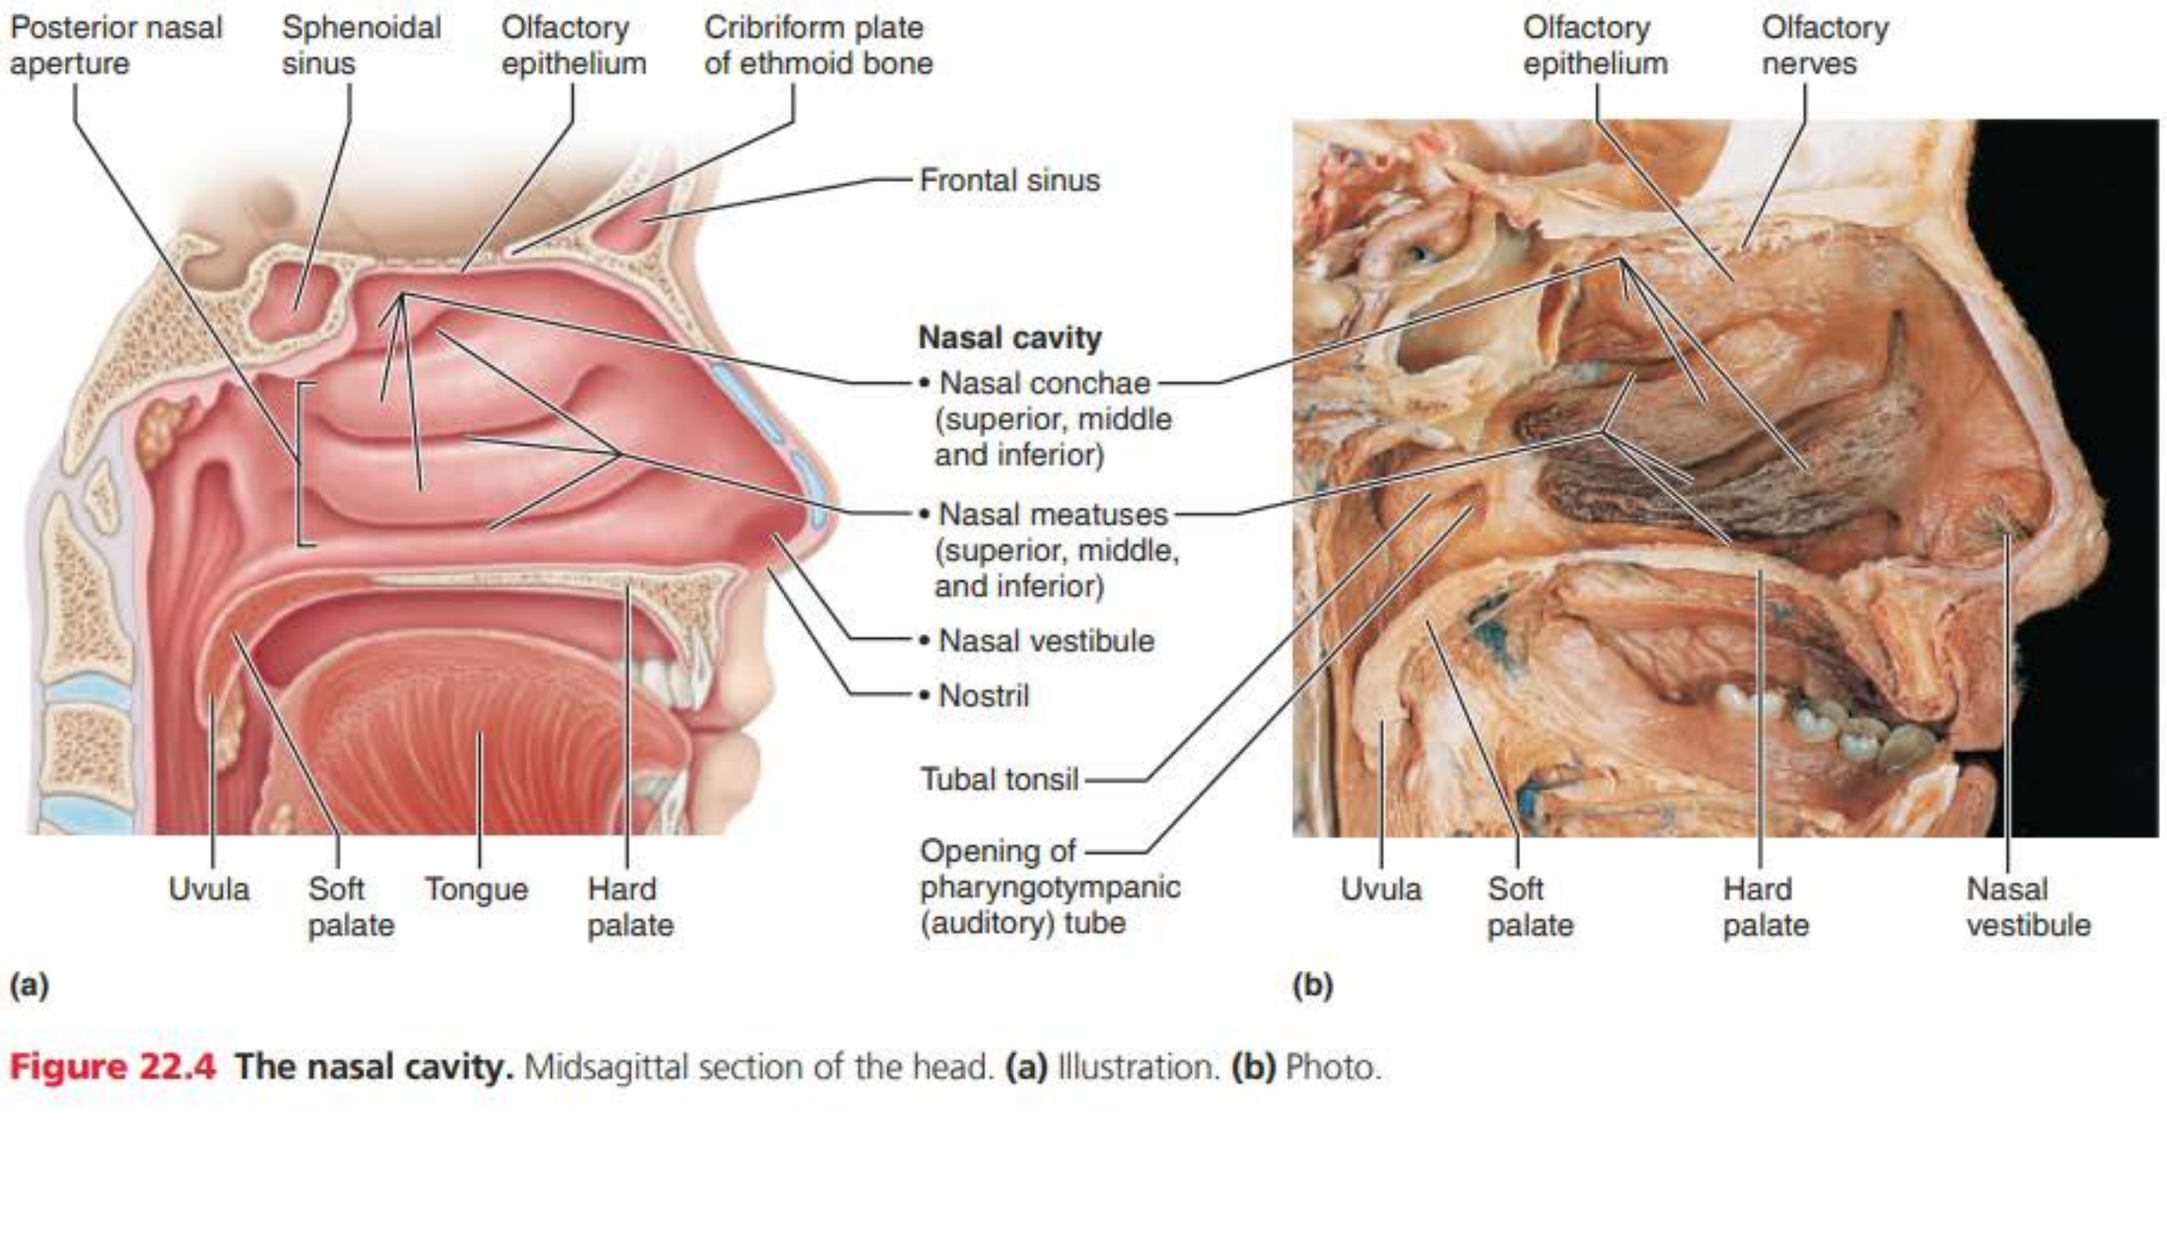

Figure 22.4 The nasal cavity. Midsagittal section of the head. **(a)** Illustration. **(b)** Photo.

portion of the pharynx through the **posterior nasal apertures**, also called the *choanae* (ko-a′ne; "funnels").

The roof of the nasal cavity is formed by the ethmoid and sphenoid bones of the skull. The floor is formed by the *palate*, which separates the nasal cavity from the oral cavity below. Anteriorly, where the palate is supported by the palatine bones and processes of the maxillary bones, it is called the **hard palate**. The unsupported posterior portion is the muscular **soft palate**.

The part of the nasal cavity just superior to each nostril, called the **nasal vestibule**, is lined with skin containing sebaceous and sweat glands and numerous hair follicles. The hairs, or **vibrissae** (vi-bris′e; *vibro* = to quiver), filter coarse particles (dust, pollen) from inspired air. The rest of the nasal cavity is lined with two types of mucous membrane.

- The small patch of **olfactory mucosa** lines the slitlike superior region of the nasal cavity and contains smell receptors in its **olfactory epithelium** (◀ p. 576).
- The **respiratory mucosa** lines most of the nasal cavity. The respiratory mucosa is a pseudostratified ciliated columnar epithelium, containing scattered *goblet cells*, that rests on a lamina propria richly supplied with seromucous *nasal glands*.

Seromucous nasal glands contain mucus-secreting mucous cells and serous cells that secrete a watery fluid containing enzymes. Each day, these glands secrete about a quart (a liter) of mucus containing *lysozyme*, an antibacterial enzyme. The sticky mucus traps inspired dust, bacteria, and other debris, while lysozyme attacks and chemically destroys bacteria. The epithelial cells of the respiratory mucosa also secrete *defensins*, natural antibiotics that help kill invading microbes. Additionally, the high water content of the mucus film humidifies incoming air.

The ciliated cells of the respiratory mucosa create a gentle current that moves the sheet of contaminated mucus posteriorly toward the throat, where it is swallowed and digested. We are usually unaware of this important action of our nasal cilia, but when exposed to cold air they become sluggish, allowing mucus to accumulate in the nasal cavity and dribble out the nostrils. This, along with the fact that water vapor in expired air tends to condense at lower temperatures, explains why you have a runny nose on a crisp wintry day.

The nasal mucosa is richly supplied with sensory nerve endings, and contact with irritating particles (dust, pollen, and the like) triggers a sneeze reflex. The sneeze forces air outward in a violent burst—a crude but effective way to expel irritants.

Rich plexuses of capillaries and thin-walled veins underlie the nasal epithelium and warm incoming air as it flows across the mucosal surface. When the inspired air is cold, the vascular plexus becomes engorged with blood, intensifying the air-heating process. Because these blood vessels are abundant and located superficially, nosebleeds are common and often profuse.

Nasal Conchae Protruding medially from each lateral wall of the nasal cavity are three scroll-like mucosa-covered projections, the *superior*, *middle*, and *inferior nasal conchae* (kong′ke) (Figure 22.4). The groove inferior to each concha is a *nasal meatus* (me-a′tus).

The curved conchae greatly increase the mucosal surface area exposed to air and enhance air turbulence in the cavity. The gases in inhaled air swirl through the twists and turns, deflecting heavier, nongaseous particles onto the mucus-coated surfaces, where they become trapped. As a result, few particles larger than 6 μm make it past the nasal cavity.

The conchae and nasal mucosa not only function during inhalation to filter, heat, and moisten the air, but also act during exhalation to reclaim this heat and moisture. In other words, inspired air cools the conchae, then during exhalation these cooled conchae precipitate moisture and extract heat from the humid air flowing over them. This reclamation process minimizes the amount of moisture and heat lost from the body through breathing, helping us to survive in dry and cold climates.

Paranasal Sinuses

The nasal cavity is surrounded by a ring of **paranasal sinuses** (Figure 22.4a). They are located in the frontal, sphenoid, ethmoid, and maxillary bones (◀ Figure 7.15, p. 215). The sinuses lighten the skull, and they may help warm and moisten the air. The mucus they produce ultimately flows into the nasal cavity, and the suctioning effect created by nose blowing helps drain the sinuses.

HOMEOSTATIC IMBALANCE 22.1 CLINICAL

Cold viruses, streptococcal bacteria, and various allergens can cause *rhinitis* (ri-ni′tis), inflammation of the nasal mucosa accompanied by excessive mucus production, nasal congestion, and postnasal drip. The nasal mucosa is continuous with the mucosa of the other respiratory passageways, explaining the typical nose to throat to chest progression of colds. Because the mucosa extends tentacle-like into the nasolacrimal (tear) ducts and paranasal sinuses, nasal cavity infections often spread to those regions, causing **sinusitis** (inflamed sinuses).

When mucus or infectious materials block the passageways connecting the sinuses to the nasal cavity, the pressure within the sinuses may no longer be the same as atmospheric pressure. A change in pressure can result in a *sinus headache*.

The Pharynx

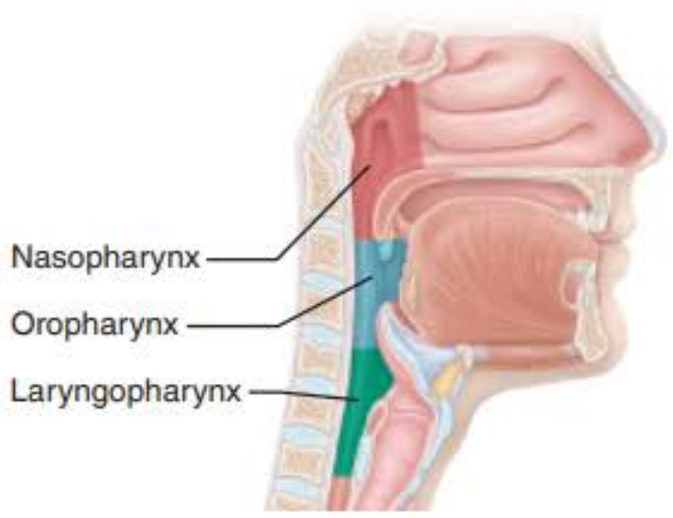
The funnel-shaped **pharynx** (far′ingks) connects the nasal cavity and mouth superiorly to the larynx and esophagus inferiorly. Commonly called the *throat*, the pharynx vaguely resembles a short length of garden hose as it extends for about 13 cm (5 inches) from the base of the skull to the level of the sixth cervical vertebra (Figure 22.2).

From superior to inferior, the pharynx is divided into three regions—the *nasopharynx*, *oropharynx*, and *laryngopharynx* (**Figure 22.5a**). The muscular pharynx wall is composed of skeletal muscle throughout its length (◀ Table 10.3, pp. 338–339). However, the cellular composition of its mucosa varies from one pharyngeal region to another.

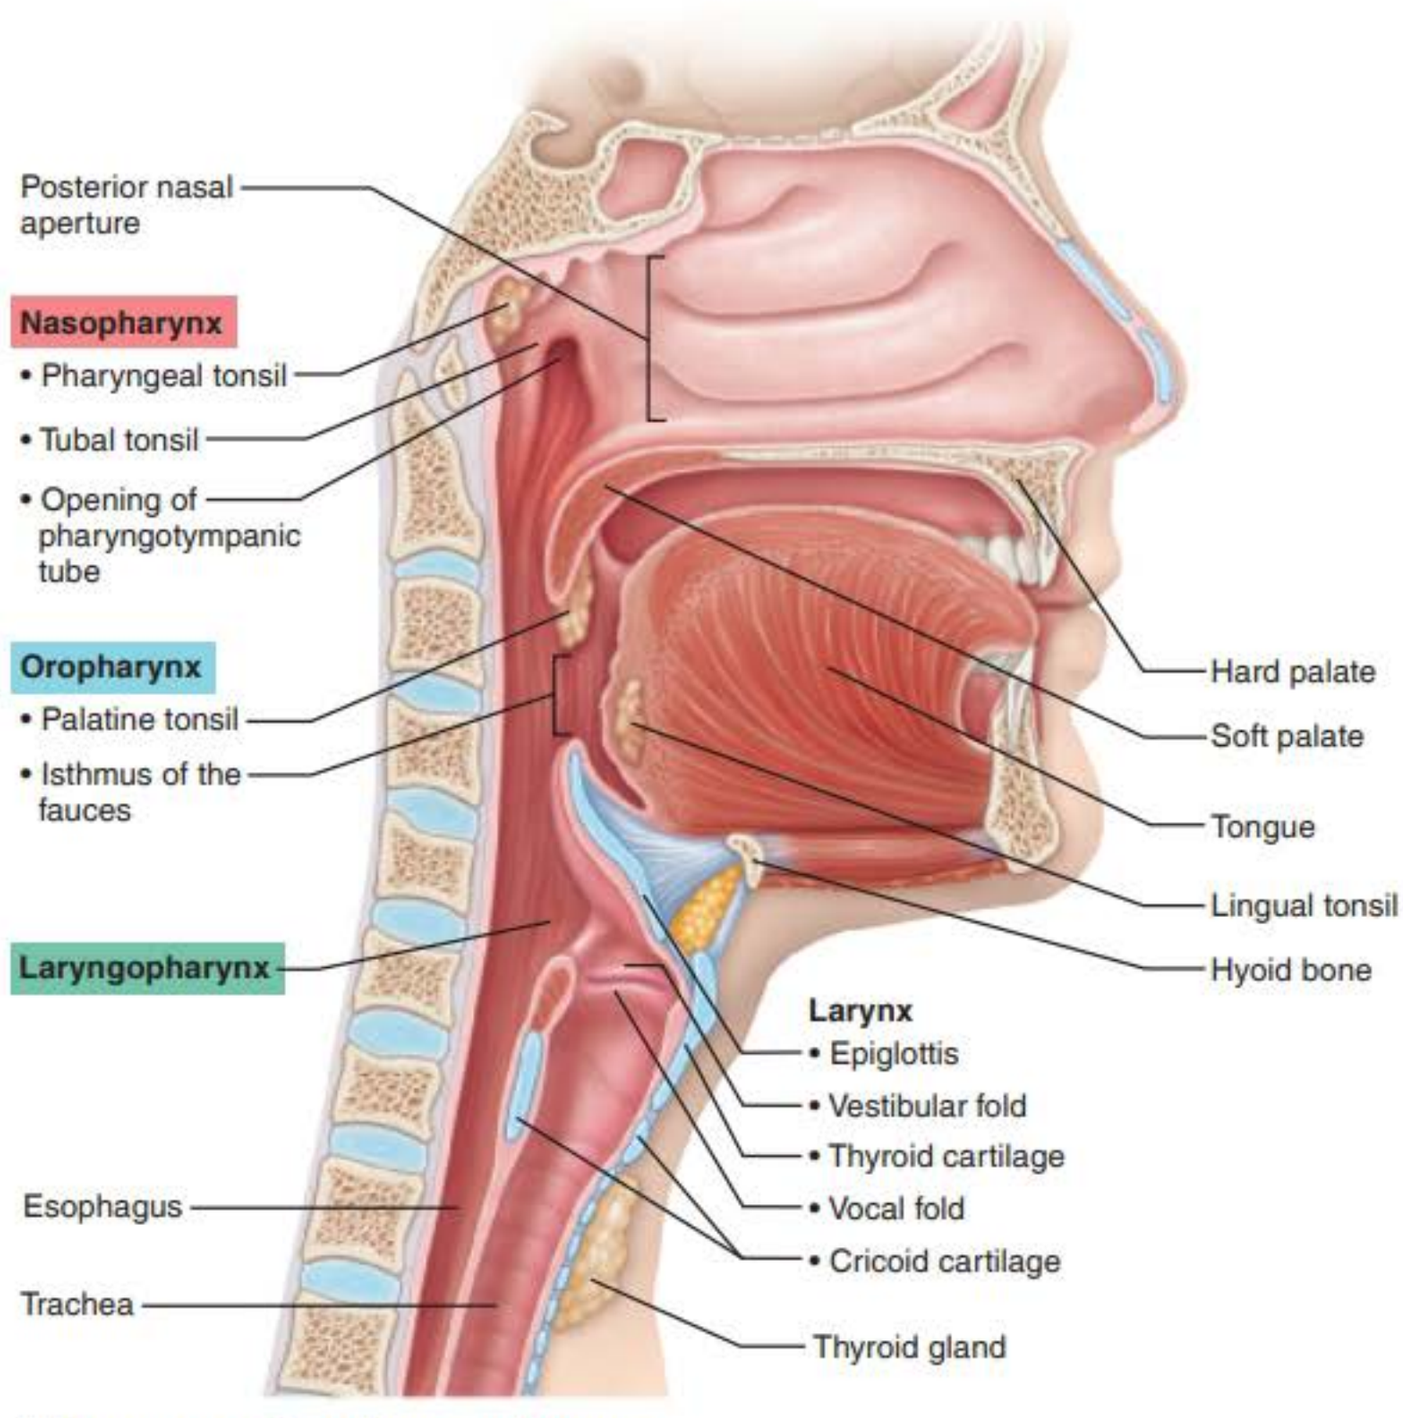
The Nasopharynx

The **nasopharynx** is posterior to the nasal cavity, inferior to the sphenoid bone, and superior to the level of the soft palate. Because it lies above the point where food enters the body, it serves *only* as an air passageway. During swallowing, the soft palate and its pendulous *uvula* (u′vu-lah; "little grape") move superiorly, an action that closes off the nasopharynx and prevents food from entering the nasal cavity. (When we giggle, this sealing action fails and fluids being swallowed can end up spraying out the nose.)

The nasopharynx is continuous with the nasal cavity through the posterior nasal apertures (Figure 22.5b). Its pseudostratified ciliated epithelium takes over the job of propelling mucus where the nasal mucosa leaves off. High on its posterior wall is the **pharyngeal tonsil** (far-rin′je-al) (or *adenoids*), which traps and destroys pathogens entering the nasopharynx in air.



(a) Regions of the pharynx



(b) Structures of the pharynx and larynx

Figure 22.5 The pharynx, larynx, and upper trachea. Midsagittal section of the head and neck.

HOMEOSTATIC IMBALANCE 22.2 — CLINICAL

Infected and swollen adenoids block air passage in the nasopharynx, making it necessary to breathe through the mouth. As a result, the air is not properly moistened, warmed, or filtered before reaching the lungs. When the adenoids are chronically enlarged, both speech and sleep may be disturbed.

The *pharyngotympanic* (*auditory*) *tubes*, which drain the middle ear cavities and allow middle ear pressure to equalize with atmospheric pressure, open into the lateral walls of the nasopharynx (Figures 22.4b and 22.5b). A ridge of pharyngeal mucosa posterior to each of these openings marks the site of the *tubal tonsil* (Figure 22.5b). Its strategic location helps protect the middle ear against infections likely to spread from the nasopharynx.

The Oropharynx

The **oropharynx** lies posterior to the oral cavity and is continuous with it through an archway called the **isthmus of the fauces** (faw′sēz; "throat") (Figure 22.5b). Because the oropharynx extends inferiorly from the level of the soft palate to the epiglottis, both swallowed food and inhaled air pass through it.

As the nasopharynx blends into the oropharynx, the epithelium changes from pseudostratified columnar to a more protective stratified squamous epithelium. This structural adaptation accommodates the increased friction and chemical trauma (characteristic of hot and spicy foods) accompanying food passage.

The paired **palatine tonsils** lie embedded in the lateral walls of the oropharyngeal mucosa just posterior to the oral cavity. The **lingual tonsil** covers the posterior surface of the tongue.

The Laryngopharynx

Like the oropharynx above it, the **laryngopharynx** (lah-ring″go-far′ingks) serves as a passageway for food and air and is lined with a stratified squamous epithelium. It lies

Table 22.1 The Upper Respiratory System

STRUCTURE	DESCRIPTION, GENERAL AND DISTINCTIVE FEATURES	FUNCTION
Nose (external nose and nasal cavity)	Jutting external portion is supported by bone and cartilage. Internal nasal cavity is divided by midline nasal septum and lined with mucosa.	Produces mucus; filters, warms, and moistens incoming air; resonance chamber for speech
	Roof of nasal cavity contains olfactory epithelium.	Receptors for sense of smell
Paranasal sinuses	Mucosa-lined, air-filled cavities in cranial bones surrounding nasal cavity (◀ p. 215).	Lighten skull; may also warm, moisten, and filter incoming air
Pharynx	Passageway connecting nasal cavity to larynx and oral cavity to esophagus. Three subdivisions: nasopharynx, oropharynx, and laryngopharynx.	Passageway for air and food
	Houses tonsils (lymphoid tissue masses involved in protection against pathogens).	Facilitates exposure of immune system to inhaled antigens

directly posterior to the larynx, where the respiratory and digestive pathways diverge, and extends to the inferior edge of the cricoid cartilage. The laryngopharynx is continuous with the esophagus posteriorly.

The esophagus conducts food and fluids to the stomach; air enters the larynx anteriorly. During swallowing, food has the "right of way," and air passage temporarily stops.

Check Your Understanding

1. Air moving from the nose to the larynx passes by a number of structures. List (in order) as many of these structures as you can.
2. Name the two types of mucous membrane found in the nasal cavity.
3. DRAW Create a summary table to help you study the pharynx by comparing and contrasting its three parts. For each part, identify what it conducts (air, food, or both), the type of epithelium found there, and the associated tonsils.

For answers, see Answers Appendix.

22.2 The lower respiratory system consists of conducting and respiratory zone structures

Learning Outcomes

- **Distinguish between conducting and respiratory zone structures.**
- **Describe the structure, function, and location of the larynx, trachea, and bronchi.**
- **Describe the makeup of the respiratory membrane, and relate structure to function.**
- **Identify the organs forming the respiratory passageway(s) in descending order until you reach the alveoli.**

Anatomically, the lower respiratory system consists of the *larynx*, *trachea*, *bronchi*, and *lungs*. Functionally, the respiratory system as a whole consists of two zones:

- The **respiratory zone**, the actual site of gas exchange, is composed of the respiratory bronchioles, alveolar ducts, and alveoli, all microscopic structures.
- The **conducting zone** consists of all of the respiratory passageways from the nose to the respiratory bronchioles. These provide fairly rigid conduits for air to reach the gas exchange sites. The conducting zone organs also cleanse, humidify, and warm incoming air. As a result, air reaching the lungs has fewer irritants (dust, bacteria, etc.) than when it entered the body, and it is warm and damp, like the air of the tropics.

The Larynx

Basic Anatomy

The **larynx** (lar′ingks), or voice box, extends for about 5 cm (2 inches) from the level of the third to the sixth cervical vertebra. Superiorly it attaches to the hyoid bone and opens into the laryngopharynx. Inferiorly it is continuous with the trachea (Figure 22.5b).

The larynx has three functions:

- Provide a *patent* (open) airway
- Act as a switching mechanism to route air and food into the proper channels
- Voice production [because it houses the vocal folds (vocal cords)]

The framework of the larynx is an intricate arrangement of nine cartilages connected by membranes and ligaments (**Figure 22.6**). Except for the epiglottis, all laryngeal cartilages are hyaline cartilages.

The large, shield-shaped **thyroid cartilage** is formed by the fusion of two cartilage plates at the midline. It resembles an upright open book, with the book's "spine" lying in the anterior midline of the neck. This "book spine" is the **laryngeal prominence** (lah-rin′je-al), which can be seen externally as the *Adam's apple* (Figure 22.6a). The thyroid cartilage is typically larger in males than in females because male sex hormones stimulate its growth during puberty. Inferior to the thyroid cartilage is the ring-shaped **cricoid cartilage** (kri′koid), perched atop and anchored to the trachea inferiorly.

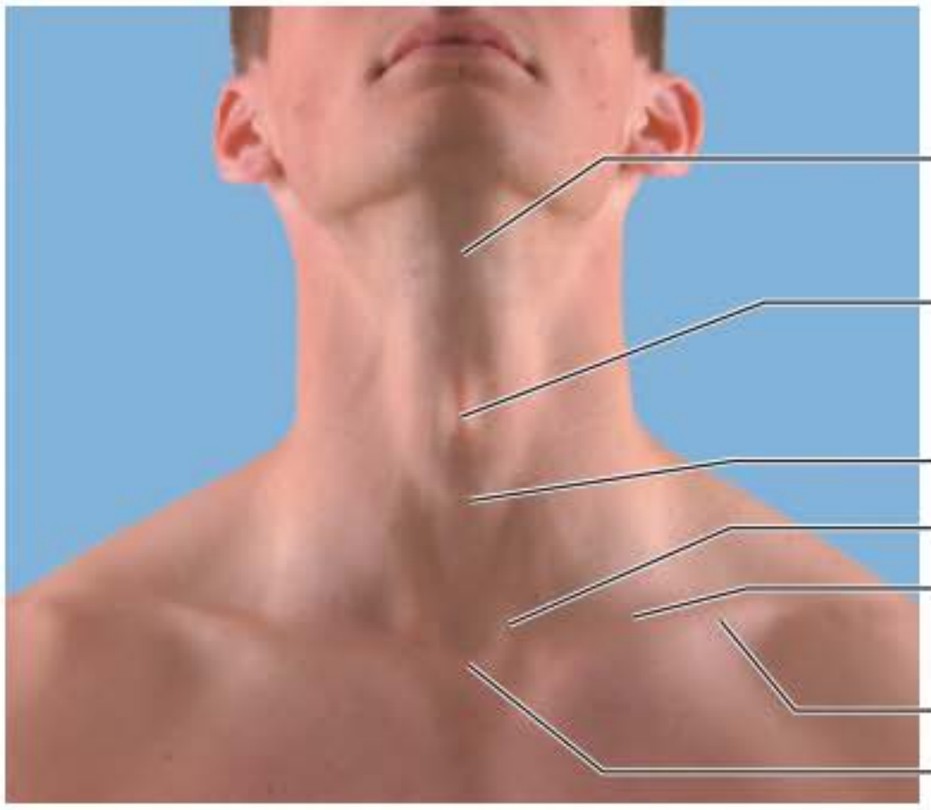
Three pairs of small cartilages—**arytenoid** (ar″ĭ-te′noid), **cuneiform** (ku-ne′ĭ-form), and **corniculate cartilages**—form part of the lateral and posterior walls of the larynx. The most

important of these are the pyramid-shaped arytenoid cartilages, which anchor the vocal folds.

Epiglottis The ninth cartilage, the flexible, spoon-shaped **epiglottis** (ep″ĭ-glot′is; "above the glottis"), is composed of elastic cartilage and is almost entirely covered by a taste bud–containing mucosa. The epiglottis extends from the posterior aspect of the tongue to its anchoring point on the anterior rim of the thyroid cartilage (Figure 22.6c and d).

When only air is flowing into the larynx, the inlet to the larynx is wide open and the free edge of the epiglottis projects upward. During swallowing, the larynx is pulled superiorly and the epiglottis tips to cover the laryngeal inlet. Because this action keeps food out of the lower respiratory passages, the epiglottis has been called the guardian of the airways. Anything other than air entering the larynx initiates the cough reflex to expel the substance. This protective reflex does not work when we are unconscious, so it is never a good idea to administer liquids when attempting to revive an unconscious person.

Vocal Folds Lying under the laryngeal mucosa on each side are the **vocal ligaments**, which attach the arytenoid cartilages to the thyroid cartilage. These ligaments, composed largely of elastic fibers, form the core of mucosal folds called the



(a) Surface view

(d) Sagittal section (anterior on the right)

Figure 22.6 The larynx.

vocal folds, or **true vocal cords**, which appear pearly white because they lack blood vessels (**Figure 22.7**).

The vocal folds vibrate, producing sounds as air rushes up from the lungs. The vocal folds and the medial opening between them through which air passes are called the **glottis**. Superior to the vocal folds is a similar pair of mucosal folds called the **vestibular folds**, or **false vocal cords**. These play no direct part in sound production but help to close the glottis when we swallow.

Epithelium of Larynx Stratified squamous epithelium lines the superior portion of the larynx, an area subject to food contact. Below the vocal folds the epithelium is a pseudostratified ciliated columnar type that filters dust. The power stroke of its cilia is directed upward toward the pharynx to continually move mucus *away* from the lungs. We help move mucus up and out of the larynx when we "clear our throat."

Voice Production

Speech involves the intermittent release of expired air as the glottis opens and closes. The length of the vocal folds and the size of the glottis change with the action of the intrinsic laryngeal muscles that clothe the cartilages. Most of these muscles move the arytenoid cartilages. As the length and tension of the vocal folds change, the pitch of the sound varies. Generally, the tenser the vocal folds, the faster they vibrate and the higher the pitch.

As a boy's larynx enlarges during puberty, his vocal folds become longer and thicker. Because this causes them to vibrate more slowly, his voice becomes deeper. Until the young man learns to control his newly enlarged vocal folds, his voice "cracks."

Loudness of the voice depends on the force with which the airstream rushes across the vocal folds. The greater the force, the stronger the vibration and the louder the sound. The vocal folds do not move at all when we whisper, but they vibrate vigorously when we yell. The muscles of the chest, abdomen, and back provide the power for the airstream.

The vocal folds actually produce buzzing sounds. The perceived quality of the voice depends on the coordinated activity of many structures above the glottis. For example, the entire length of the pharynx acts as a resonating chamber, to amplify and enhance the sound quality. The oral, nasal, and sinus cavities also contribute to vocal resonance. In addition, good enunciation depends on muscles in the pharynx, tongue, soft palate, and lips that "shape" sound into recognizable consonants and vowels.

HOMEOSTATIC IMBALANCE 22.3 CLINICAL

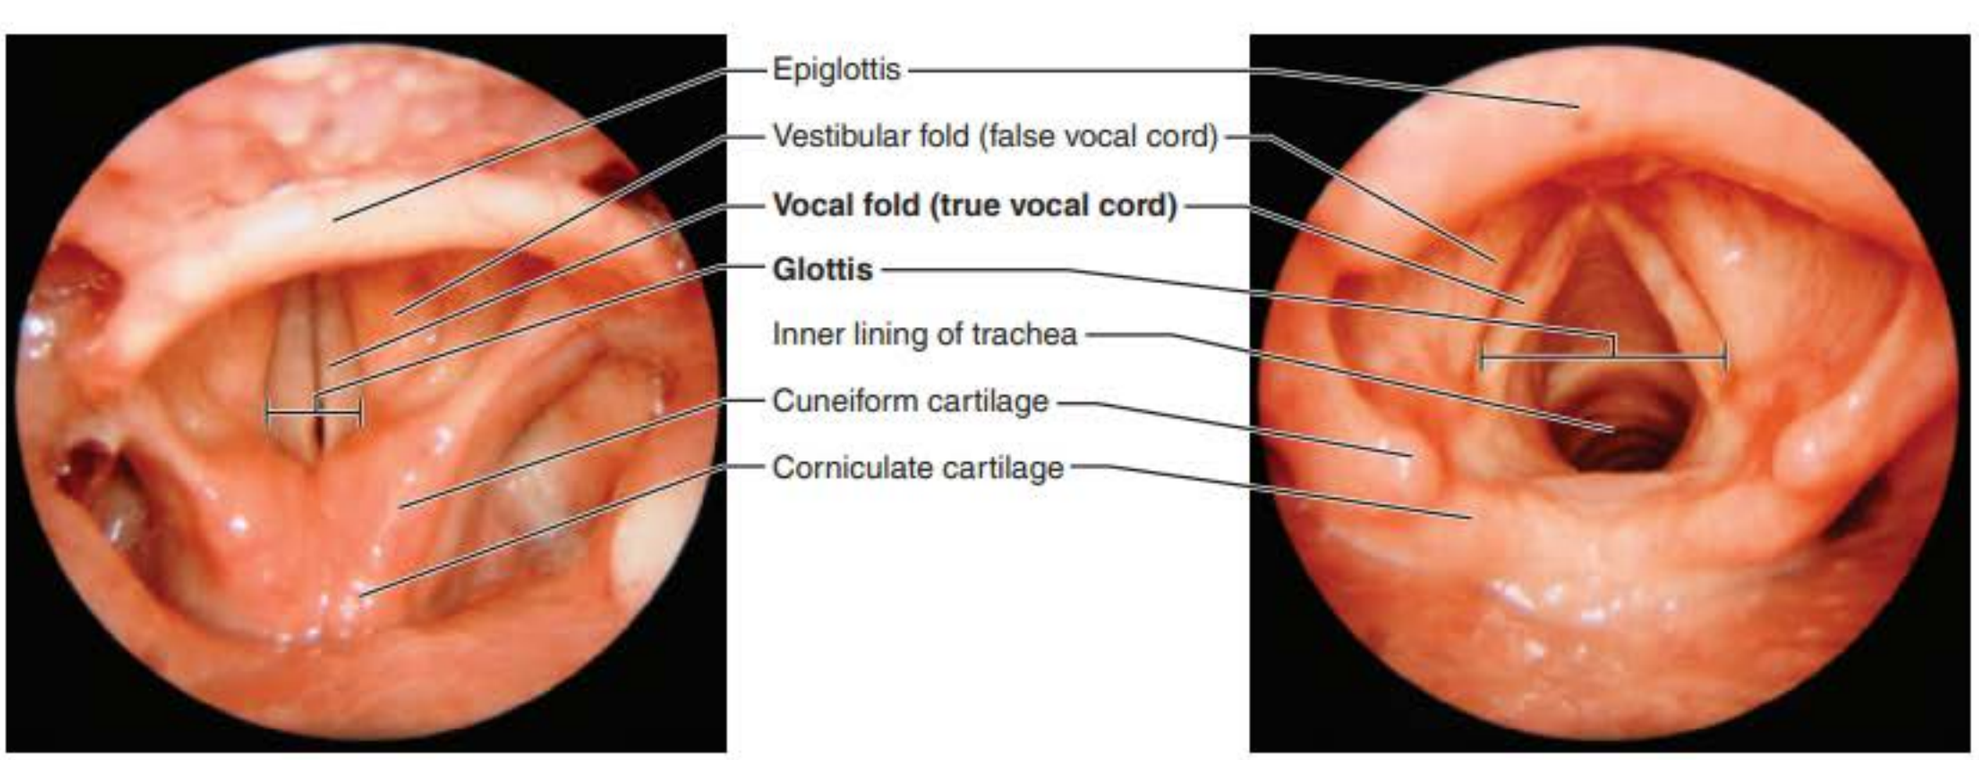
Inflammation of the vocal folds, or **laryngitis**, causes the vocal folds to swell, interfering with their vibration. This changes the vocal tone, causing hoarseness, or in severe cases limiting us to a whisper. Laryngitis is most often caused by viral infections, but may also be due to overusing the voice, very dry air, bacterial infections, tumors on the vocal folds, or inhalation of irritating chemicals.

Sphincter Functions of the Larynx

Under certain conditions, the vocal folds act as a sphincter that prevents air passage. During abdominal straining associated with defecation, the glottis closes to prevent exhalation and the abdominal muscles contract, causing the intra-abdominal pressure to rise. These events, collectively known as the **Valsalva maneuver**, help empty the rectum and can also splint (stabilize) the body trunk when lifting a heavy load.

The Trachea

The **trachea** (tra′ke-ah), or *windpipe*, descends from the larynx through the neck and into the mediastinum. It ends by dividing into the two main bronchi at midthorax (see Figure 22.2 on



(a) Vocal folds in closed position; closed glottis

(b) Vocal folds in open position; open glottis

Practice Histology questions:
MasteringA&P® > Study Area > Lab Tools > PAL

(c) Scanning electron micrograph of cilia in the trachea (2500×)

p. 820). In humans, it is 10–12 cm (about 4 inches) long and 2 cm (3/4 inch) in diameter, and very flexible and mobile.

The tracheal wall consists of several layers that are common to many tubular body organs—the *mucosa, submucosa*, and *adventitia*—plus a layer of hyaline cartilage (**Figure 22.8**). The **mucosa** has the same goblet cell–containing pseudostratified epithelium that occurs throughout most of the respiratory tract. Its cilia continually propel debris-laden mucus toward the pharynx. This epithelium rests on a fairly thick lamina propria that has a rich supply of elastic fibers.

HOMEOSTATIC IMBALANCE 22.4 CLINICAL

Smoking inhibits and ultimately destroys cilia. Without ciliary activity, coughing is the only way to prevent mucus from accumulating in the lungs. When someone stops smoking, ciliary function usually recovers within a few weeks, and the morning "smoker's cough" subsides.

The **submucosa**, a connective tissue layer deep to the mucosa, contains seromucous glands that help produce the mucus "sheets" within the trachea. The submucosa is supported by 16 to 20 C-shaped rings of hyaline cartilage encased by the **adventitia**, the outermost layer of connective tissue (Figure 22.8).

The trachea's elastic elements make it flexible enough to stretch and move inferiorly during inspiration and recoil during expiration, but the cartilage rings prevent it from collapsing and keep the airway patent despite the pressure changes that occur during breathing. The open posterior parts of the cartilage rings, which lie next to the esophagus (Figure 22.8a), are connected by smooth muscle fibers of the **trachealis** and by soft connective tissue. Because this portion of the tracheal wall is flexible, the esophagus can expand anteriorly as swallowed food passes through it.

Contraction of the trachealis decreases the trachea's diameter, causing expired air to rush upward from the lungs with greater force. This action helps expel mucus from the trachea when we cough by accelerating the exhaled air to speeds of 100 mph!

The last tracheal cartilage is expanded, and a spar of cartilage, called the **carina** (kar-ri′nah; "keel"), projects posteriorly from its inner face, marking the point where the trachea branches into the two *main bronchi* (Figure 22.2). The mucosa

of the carina is highly sensitive, and violent coughing is triggered when a foreign object makes contact with it.

By the time incoming air reaches the end of the trachea, it is warm, cleansed of most impurities, and saturated with water vapor.

HOMEOSTATIC IMBALANCE 22.5 CLINICAL

Tracheal obstruction is life threatening. Many people have suffocated after choking on a piece of food that suddenly closed off their trachea. The **Heimlich maneuver**, a procedure in which air in the victim's lungs is used to "pop out," or expel, an obstructing piece of food, has saved many people from becoming victims of "café coronaries." The maneuver is simple to learn and easy to do. However, it is best learned by demonstration because cracked ribs are a distinct possibility when it is done incorrectly.

The Bronchi and Subdivisions

The air passageways in the lungs branch and branch again, about 23 times overall, in a pattern often called the **bronchial tree** (**Figure 22.9**). At the tips of the bronchial tree, conducting zone structures give way to respiratory zone structures.

Conducting Zone Structures

The trachea divides to form the **right** and **left main (primary) bronchi** (brong′ki) approximately at the level of T_7 in an erect (standing) person. Each bronchus runs obliquely in the mediastinum before plunging into the medial depression (hilum) of its lung. The right main bronchus is wider, shorter, and more vertical than the left. Consequently, it is more common for an inhaled foreign object to get stuck there.

Once inside the lungs, each main bronchus subdivides into **lobar (secondary) bronchi**—three on the right and two on the left—each supplying one lung lobe (Figure 22.9). The lobar bronchi branch into third-order **segmental (tertiary) bronchi**, which divide repeatedly into smaller and smaller bronchi (fourth-order, fifth-order, etc.). Passages smaller than 1 mm in diameter are called **bronchioles** ("little bronchi"), and the tiniest of these, the **terminal bronchioles**, are less than 0.5 mm in diameter.

The tissue composition of the walls of the main bronchi mimics that of the trachea. However, as the conducting tubes become smaller, the following structural changes occur:

- **Support structures change.** Irregular patches, or *plates*, of cartilage replace the cartilage rings, and by the time the bronchioles are reached, the tube walls no longer contain supportive cartilage. However, the tube walls throughout the bronchial tree contain elastic fibers.
- **Epithelium type changes.** The mucosal epithelium thins as it changes from pseudostratified columnar to simple columnar and then to simple cuboidal in the terminal bronchioles. Mucus-producing cells and cilia are sparse in the bronchioles. For this reason, most airborne debris found at or below the level of the bronchioles must be removed by macrophages in the alveoli.
- **Amount of smooth muscle increases.** The relative amount of smooth muscle in the tube walls increases as the passageways become smaller. A complete layer of circular smooth muscle in the bronchioles and the lack of supporting cartilage (which would hinder constriction) allows the bronchioles to

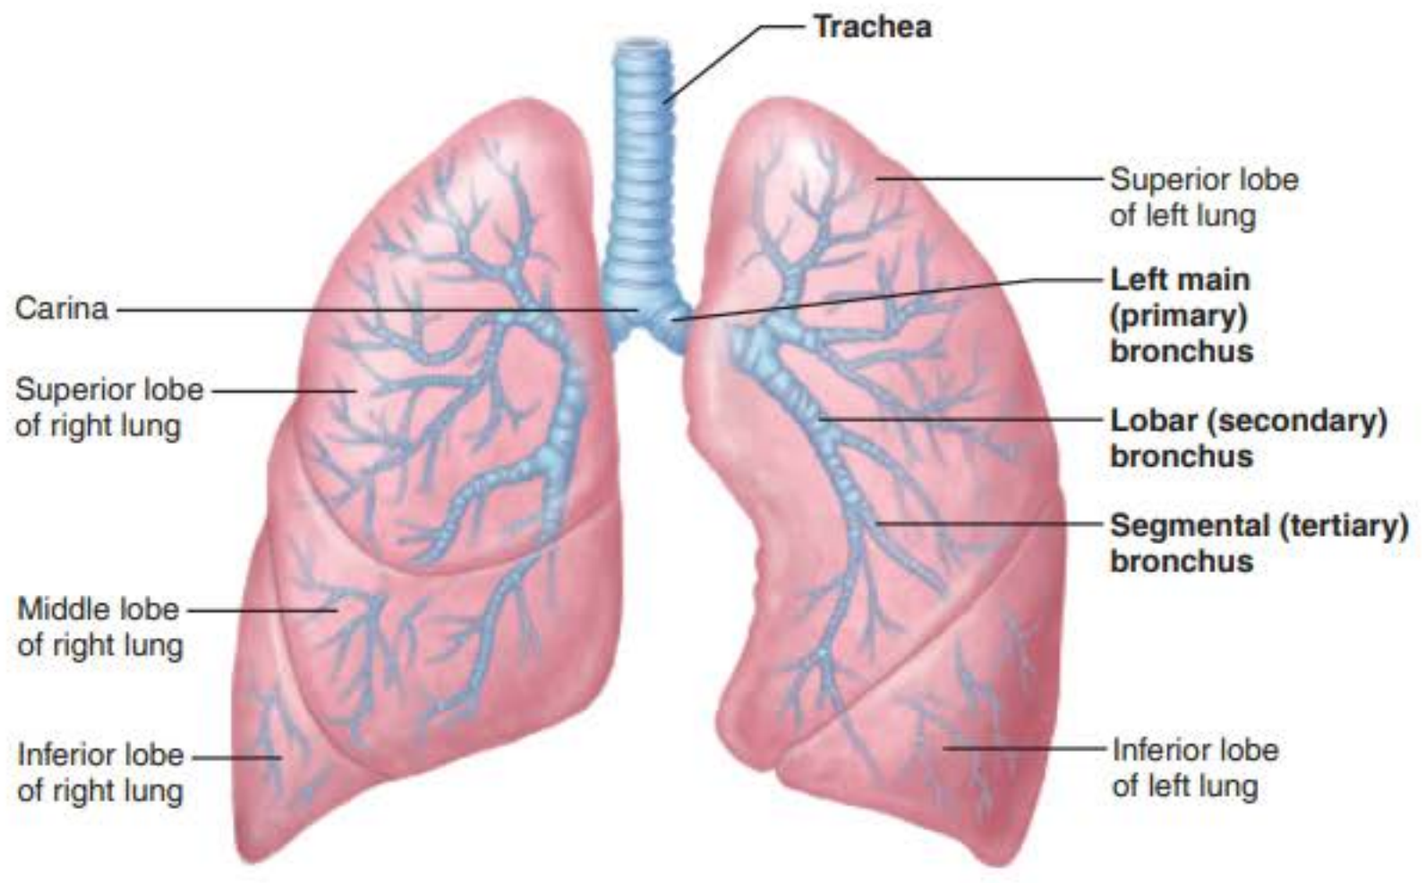

Figure 22.9 Conducting zone passages. The air pathway inferior to the larynx consists of the trachea and the main, lobar, and segmental bronchi, which branch into the smaller bronchi and bronchioles until reaching the terminal bronchioles of the lungs.

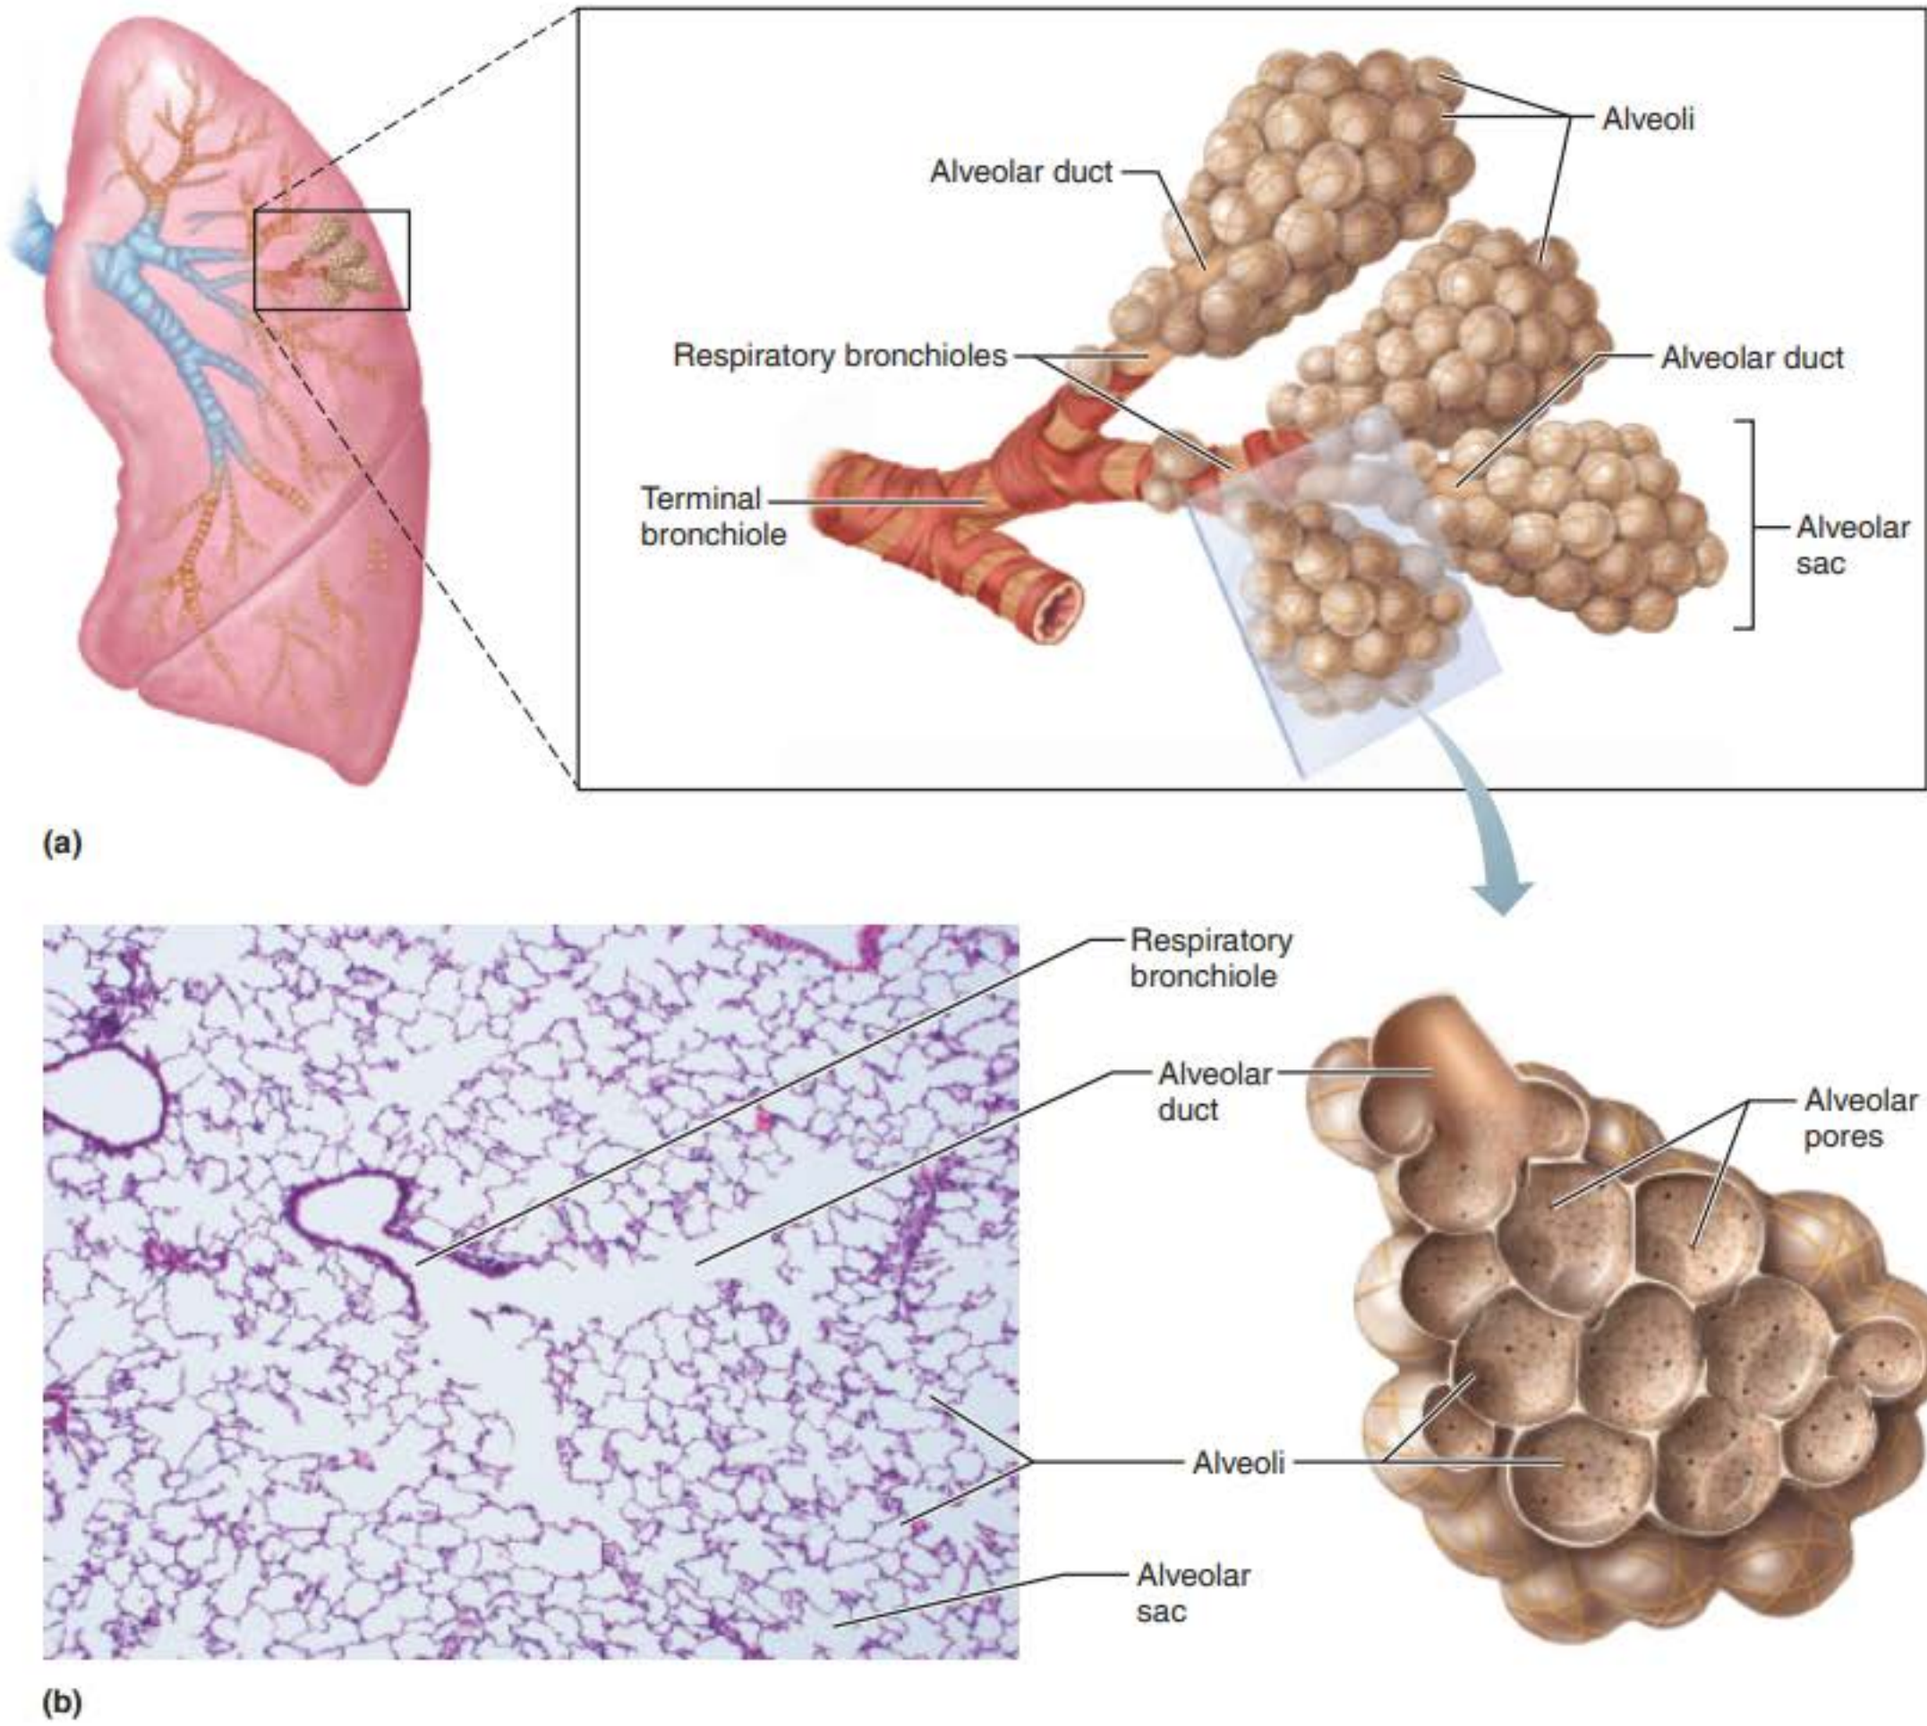

Figure 22.10 Respiratory zone structures. (a) Diagram of respiratory bronchioles, alveolar ducts, alveolar sacs, and alveoli. **(b)** Photomicrograph of a section of the lung (80×). Notice the thinness of the alveolar walls.

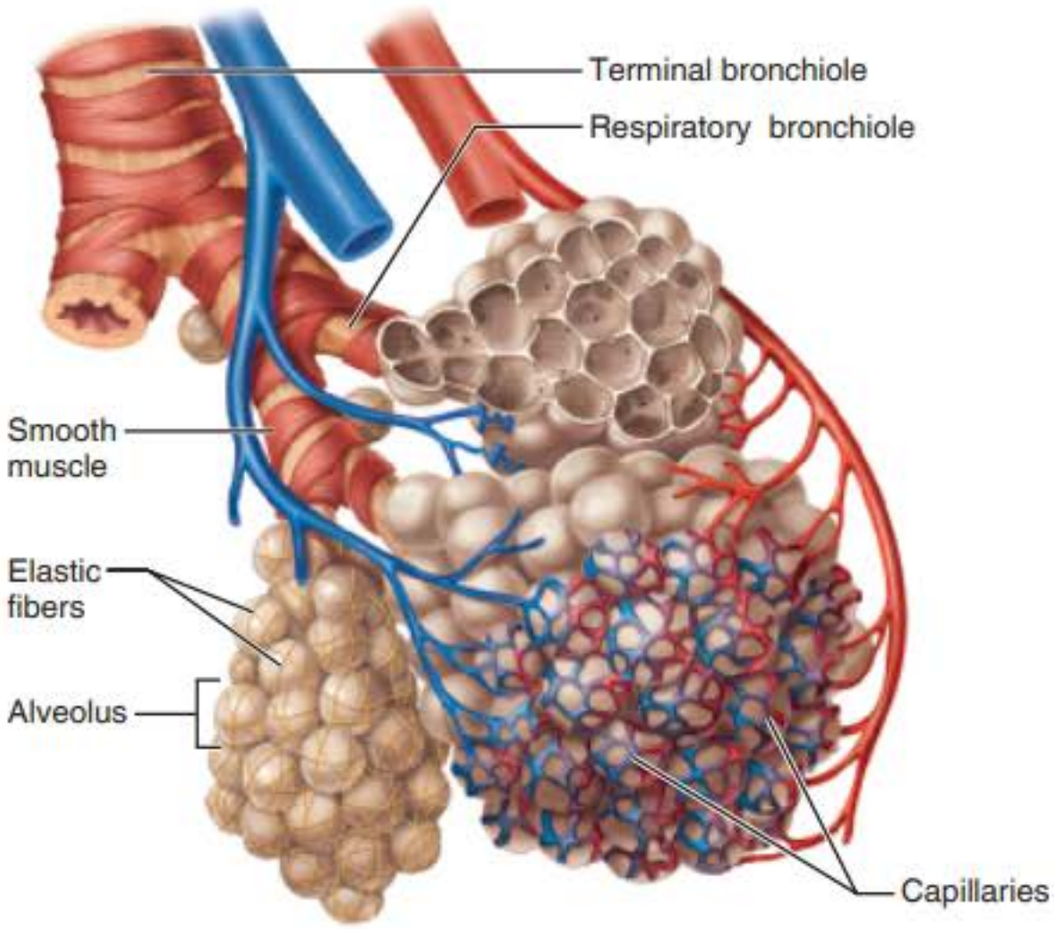
provide substantial resistance to air passage under certain conditions (as we will describe later).

Respiratory Zone Structures

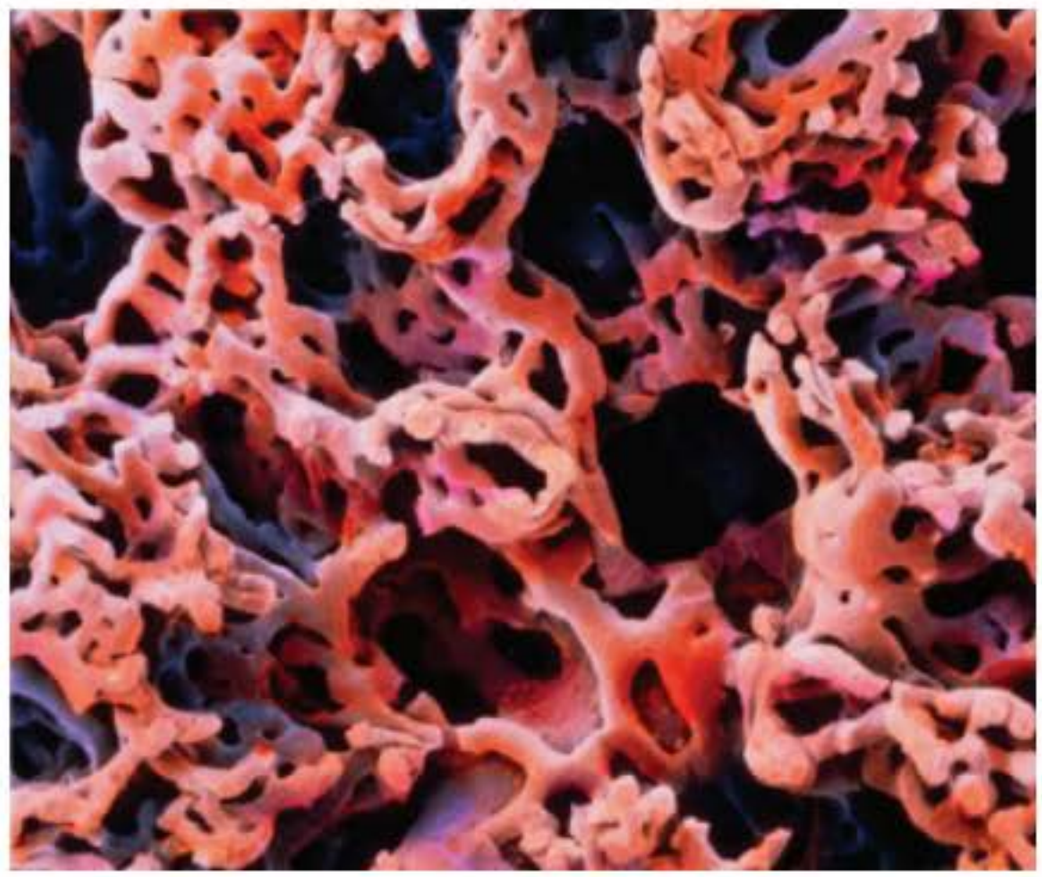
Defined by the presence of thin-walled air sacs called **alveoli** (al-ve′o-li; *alveol* = small cavity), the respiratory zone begins as the terminal bronchioles feed into **respiratory bronchioles** within the lung (**Figure 22.10**). Protruding from these smallest bronchioles are scattered alveoli. The respiratory bronchioles lead into winding **alveolar ducts**, whose walls consist of diffusely arranged rings of smooth muscle cells, connective tissue fibers, and outpocketing alveoli. The alveolar ducts lead into terminal clusters of alveoli called **alveolar sacs** or **alveolar saccules**.

Many people mistakenly equate alveoli, the site of gas exchange, with alveolar sacs, but they are not the same thing. The alveolar sac is analogous to a bunch of grapes, and the alveoli are the individual grapes. The 300 million or so gas-filled alveoli in the lungs account for most of our lung volume and provide a tremendous surface area for gas exchange.

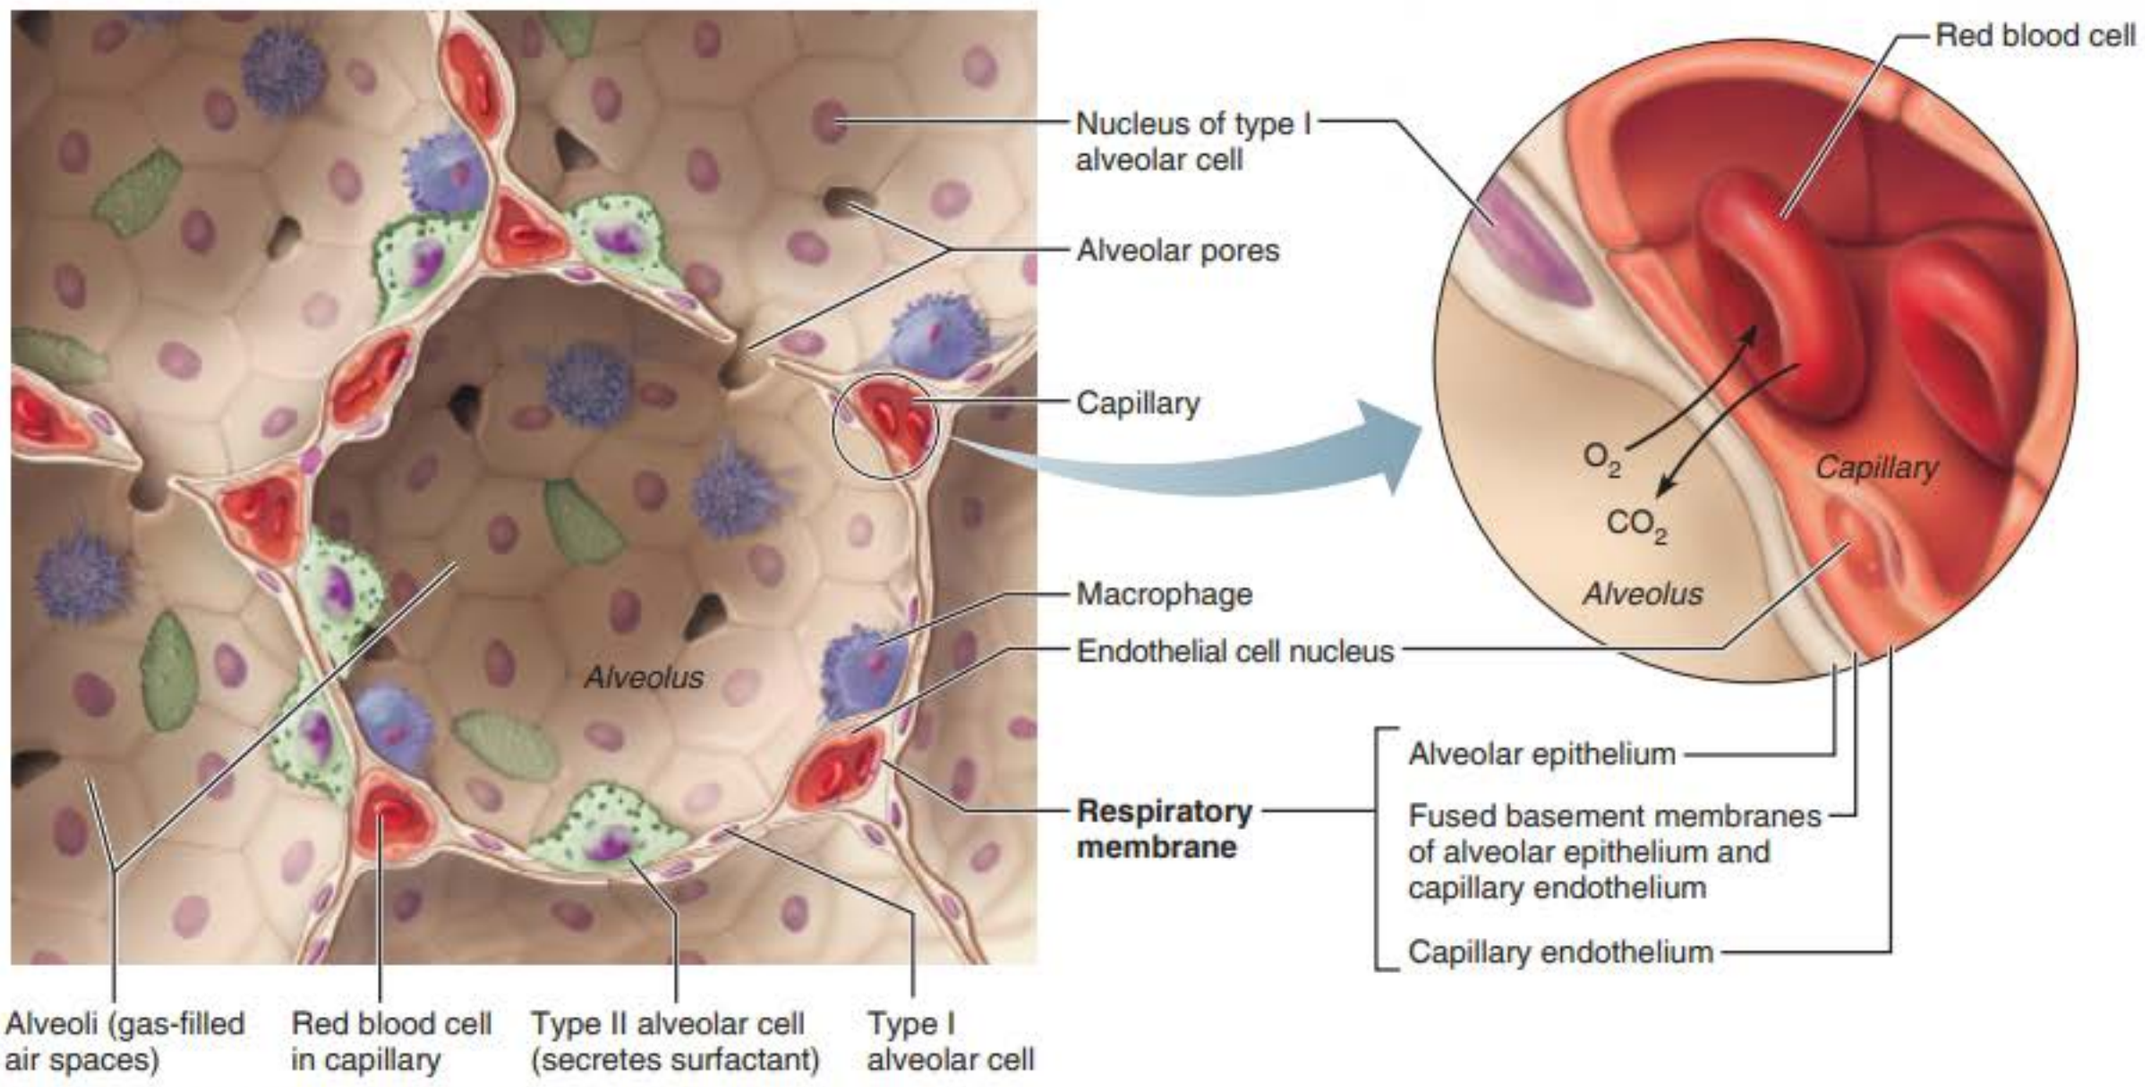
The Respiratory Membrane The walls of the alveoli are composed primarily of a single layer of squamous epithelial cells, called **type I alveolar cells**, surrounded by a flimsy basement membrane. The thinness of their walls is hard to imagine, but a sheet of tissue paper is 15 times thicker!



(a) Diagrammatic view of capillary-alveoli relationships



(b) Scanning electron micrograph of pulmonary capillary casts (300×)



(c) Detailed anatomy of the respiratory membrane

Figure 22.11 Alveoli and the respiratory membrane. Elastic fibers and capillaries surround all alveoli, but for clarity they are shown only on some alveoli in (a). In (b), the tissue forming the alveoli has been removed. Only the capillary network remains.

The external surfaces of the alveoli are densely covered with a "cobweb" of pulmonary capillaries (**Figure 22.11**). Together, the capillary and alveolar walls and their fused basement membranes form the **respiratory membrane**, a 0.5-μm-thick *blood air barrier* that has blood flowing past on one side and gas on the other (Figure 22.11c). Gas exchanges occur readily by simple diffusion across the respiratory membrane—O_2 passes from the alveolus into the blood, and CO_2 leaves the blood to enter the gas-filled alveolus.

Table 22.2 The Lower Respiratory System

STRUCTURE	DESCRIPTION, GENERAL AND DISTINCTIVE FEATURES	FUNCTION
Larynx	Connects pharynx to trachea. Has framework of cartilage and dense connective tissue. Opening (glottis) can be closed by epiglottis or vocal folds.	Air passageway; prevents food from entering lower respiratory tract
	Houses vocal folds (true vocal cords).	Voice production
Trachea	Flexible tube running from larynx and dividing inferiorly into two main bronchi. Walls contain C-shaped cartilages that are incomplete posteriorly where connected by trachealis.	Air passageway; cleans, warms, and moistens incoming air
Bronchial tree	Consists of right and left main bronchi, which subdivide within the lungs to form lobar and segmental bronchi and bronchioles. Bronchiolar walls lack cartilage but contain complete layer of smooth muscle. Constriction of this muscle impedes expiration.	Air passageways connecting trachea with alveoli; cleans, warms, and moistens incoming air
Alveoli	Microscopic chambers at termini of bronchial tree. Walls of simple squamous epithelium overlie thin basement membrane. External surfaces are intimately associated with pulmonary capillaries.	Main sites of gas exchange
	Special alveolar cells produce surfactant.	Surfactant reduces surface tension; helps prevent lung collapse
Lungs	Paired composite organs that flank mediastinum in thorax. Composed primarily of alveoli and respiratory passageways. Stroma is elastic connective tissue, allowing lungs to recoil passively during expiration.	House respiratory passages smaller than the main bronchi
Pleurae	Serous membranes. Parietal pleura lines thoracic cavity; visceral pleura covers external lung surfaces.	Produce lubricating fluid and compartmentalize lungs

Alveoli Three major types of cells are found in alveoli:

- **Type I alveolar cells** (described above) are squamous epithelial cells that form the major part of the alveolar walls.
- **Type II alveolar cells** are cuboidal epithelial cells that are scattered among the type I cells (Figure 22.11c). They secrete a fluid containing a detergent-like substance called *surfactant* that coats the gas-exposed alveolar surfaces. (We describe surfactant's role in reducing the surface tension of the alveolar fluid later in this chapter.) Type II alveolar cells also secrete a number of antimicrobial proteins that are important elements of innate immunity.
- **Alveolar macrophages** crawl freely along the internal alveolar surfaces consuming bacteria, dust, and other debris (Figure 22.11c).

The alveoli have two other significant features: (1) They are surrounded by fine elastic fibers of the same type that surround the entire bronchial tree. (2) Open **alveolar pores** connecting adjacent alveoli allow air pressure throughout the lung to be equalized and provide alternate air routes to any alveoli whose bronchi have collapsed due to disease.

Although huge numbers of infectious microorganisms are continuously carried into the alveoli, alveolar surfaces are usually sterile. Because the alveoli are "dead ends," aged and dead macrophages must be prevented from accumulating in them. Most macrophages simply get swept up by the ciliary current of superior regions and carried to the pharynx. In this manner, we clear and swallow over 2 million alveolar macrophages per hour!

Check Your Understanding

4. Which structure seals the larynx when we swallow?
5. Which structural features of the trachea allow it to expand and contract, yet keep it from collapsing?
6. What features of the alveoli and their respiratory membranes suit them to their function of exchanging gases by diffusion?
7. APPLY A 3-year-old boy is brought to the emergency department after aspirating (inhaling) a peanut. Bronchoscopy confirms the suspicion that the peanut is lodged in a bronchus and then it is successfully extracted. Which main bronchus was the peanut most likely to be in? Why?

For answers, see Answers Appendix.

22.3 Each multilobed lung occupies its own pleural cavity

Learning Outcome

▶ **Describe the gross structure of the lungs and pleurae.**

The paired **lungs** occupy all of the thoracic cavity except the mediastinum, which houses the heart, great blood vessels, bronchi, esophagus, and other organs (**Figure 22.12**).

Gross Anatomy of the Lungs

Each cone-shaped lung is surrounded by pleurae and connected to the mediastinum by vascular and bronchial attachments, collectively called the lung **root**. The anterior, lateral, and posterior lung surfaces lie in close contact with the ribs and form the continuously curving **costal surface**. Just deep to the clavicle is the **apex**, the narrow superior tip of the lung. The concave, inferior surface that rests on the diaphragm is the **base**.

On the mediastinal surface of each lung is an indentation, the **hilum**, through which pulmonary and systemic blood vessels, bronchi, lymphatic vessels, and nerves enter and leave the lungs. Each main bronchus plunges into the hilum on its own side and begins to branch almost immediately. All conducting and respiratory passageways distal to the main bronchi are found in the lungs.

The two lungs differ slightly in shape and size because the apex of the heart is slightly to the left of the median plane. The left lung is smaller than the right, and the **cardiac notch**—a concavity in its medial aspect—is molded to and accommodates the heart (Figure 22.12a). The left lung is subdivided into superior and inferior **lobes** by the *oblique fissure*, whereas the right lung is partitioned into superior, middle, and inferior lobes by the *oblique* and *horizontal fissures*.

Each lobe contains a number of pyramid-shaped **bronchopulmonary segments** separated from one another by connective tissue septa. The right lung has 10 bronchopulmonary segments, but the left lung is more variable and consists of 8 to 10 segments (**Figure 22.13**). Each segment is served by its own artery and vein and receives air from an individual segmental (tertiary) bronchus.

The bronchopulmonary segments are clinically important because pulmonary disease is often confined to one or a few segments. Their connective tissue partitions allow diseased segments to be surgically removed without damaging neighboring segments or impairing their blood supply.

The smallest subdivisions of the lung visible with the naked eye are the **lobules**, which appear at the lung surface as hexagons ranging from the size of a pencil eraser to the size of a penny (Figure 22.12b). A large bronchiole and its branches serve each lobule. In most city dwellers and in smokers, the connective tissue that separates the individual lobules is blackened with carbon.

As we mentioned earlier, the lungs consist largely of air spaces. The balance of lung tissue, or its **stroma** ("mattress" or "bed"), is mostly elastic connective tissue. As a result, the lungs are soft, spongy, elastic organs that together weigh just over 1 kg (2.2 lb). The elasticity of healthy lungs reduces the work of breathing, as we will describe shortly.

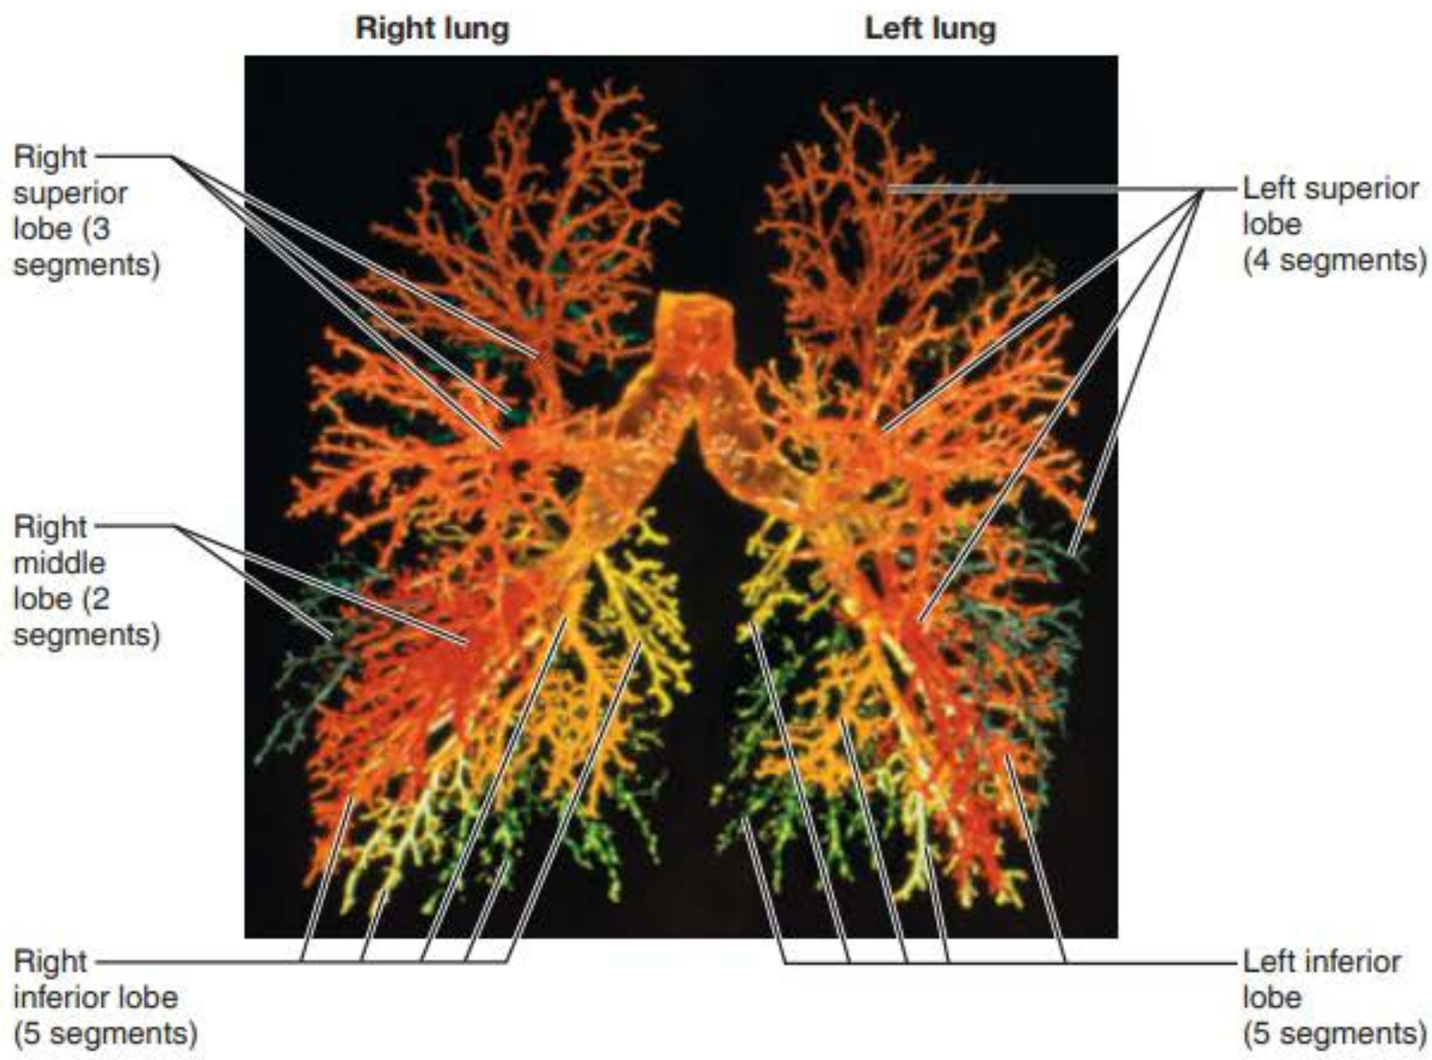

Figure 22.13 A cast of the bronchial tree. The individual bronchopulmonary segments have been painted different colors.

Blood Supply and Innervation of the Lungs

The lungs are perfused by two circulations, the pulmonary and the bronchial, which differ in size, origin, and function.

Pulmonary Circulation of the Lungs

Systemic venous blood that is to be oxygenated in the lungs is delivered by the **pulmonary arteries**, which lie anterior to the main bronchi (Figure 22.12c). In the lungs, the pulmonary arteries branch profusely along with the bronchi and finally feed into the **pulmonary capillary networks** surrounding the alveoli (see Figure 22.11a).

The **pulmonary veins** convey the freshly oxygenated blood from the respiratory zone of the lungs to the heart. Their tributaries course back to the hilum both with the corresponding bronchi and in the connective tissue septa separating the bronchopulmonary segments.

The pulmonary circuit is a low-pressure, high-volume circulation. Because *all* of the body's blood passes through the lungs about once each minute, the lung capillary endothelium is an ideal location for enzymes that act on materials in the blood. Examples include *angiotensin converting enzyme*, which activates an important blood pressure hormone, and enzymes that inactivate certain prostaglandins.

Bronchial Circulation of the Lungs

In contrast to the pulmonary circulation, the **bronchial arteries** provide oxygenated systemic blood to lung tissue. The bronchial arteries arise from the aorta, enter the lungs at the hilum, and then run along the branching bronchi. They provide a high-pressure, low-volume supply of oxygenated blood to all lung tissues except the alveoli. The tiny bronchial veins drain some systemic venous blood from the lungs, but there are multiple anastomoses between the two circulations, and most venous blood returns to the heart via the pulmonary veins.

Innervation of the Lungs

The lungs are innervated by parasympathetic and sympathetic motor fibers, and visceral sensory fibers. These nerve fibers enter each lung through the **pulmonary plexus** on the lung root and run along the bronchial tubes and blood vessels in the lungs. Parasympathetic fibers cause the air tubes to constrict, whereas sympathetic fibers dilate them.

The Pleurae

The **pleurae** (ploo′re; "sides") form a thin, double-layered serosa (◀ pp. 18–19). The layer called the **parietal pleura** covers the thoracic wall and superior face of the diaphragm (Figure 22.12a, c). It continues around the heart and between the lungs, forming the lateral walls of the mediastinal enclosure and snugly enclosing the lung root. From here, the pleura extends as the layer called the **visceral pleura** to cover the external lung surface, dipping into and lining its fissures.

The pleurae produce **pleural fluid**, which fills the slitlike **pleural cavity** between them. This lubricating secretion allows the lungs to glide easily over the thorax wall during our breathing movements. Although the pleurae slide easily across each other, the surface tension of the pleural fluid strongly resists their separation. Consequently, the lungs cling tightly to the thorax wall and expand and recoil passively as the volume of the thoracic cavity alternately increases and decreases during breathing.

The pleurae also help divide the thoracic cavity into three chambers—the central mediastinum and the two lateral pleural compartments, each containing a lung. This compartmentalization helps prevent one mobile organ (for example, the lung or heart) from interfering with another. It also limits the spread of local infections.

HOMEOSTATIC IMBALANCE 22.6 CLINICAL

Pleurisy (ploo′rĭ-se), inflammation of the pleurae, often results from pneumonia. Inflamed pleurae become rough, resulting in friction and stabbing pain with each breath. As the disease progresses, the pleurae may produce excessive amounts of fluid. This increased fluid relieves the pain caused by pleural surfaces rubbing together, but may exert pressure on the lungs and hinder breathing movements.

Other fluids that may accumulate in the pleural cavity include blood (leaked from damaged blood vessels) and blood filtrate (the watery fluid that oozes from the lung capillaries when left-sided heart failure occurs). The term for fluid accumulation in the pleural cavity is *pleural effusion*.

8. The lungs are perfused by two different circulations. Name these circulations and indicate their roles in the lungs.
9. MAKE CONNECTIONS Where is angiotensin converting enzyme found and why is this a good location for this enzyme? Name the blood pressure–increasing hormone cascade (described in Chapter 19) to which this enzyme belongs.

For answers, see Answers Appendix.

PART 2

RESPIRATORY PHYSIOLOGY

22.4 Volume changes cause pressure changes, which cause air to move

Learning Outcomes

- **Explain the functional importance of the partial vacuum that exists in the intrapleural space.**
- **Relate Boyle's law to events of inspiration and expiration.**
- **Explain the relative roles of the respiratory muscles and lung elasticity in producing the volume changes that cause air to flow into and out of the lungs.**
- **List several physical factors that influence pulmonary ventilation.**

Breathing, or **pulmonary ventilation**, consists of two phases: **inspiration**, the period when air flows into the lungs, and **expiration**, the period when gases exit the lungs.

Pressure Relationships in the Thoracic Cavity

Before we discuss the breathing process, it is important to understand that *respiratory pressures are always described relative to* **atmospheric pressure (P_{atm})**, which is the pressure exerted by the air (gases) surrounding the body. At sea level, atmospheric pressure is 760 mm Hg (the pressure exerted by a column of mercury 760 mm high). This pressure can also be expressed in atmosphere units: atmospheric pressure = 760 mm Hg = 1 atm.

- A negative respiratory pressure in any respiratory area indicates that the pressure in that region is lower than atmospheric pressure. For instance, a respiratory pressure of –4 mm Hg indicates a pressure that is lower than atmospheric pressure by 4 mm Hg (760 – 4 = 756 mm Hg). In this case, 756 mm Hg is the absolute pressure in that region.
- A positive respiratory pressure is higher than atmospheric pressure.
- A zero respiratory pressure is equal to atmospheric pressure.

Now we are ready to examine the pressure relationships that normally exist in the thoracic cavity.

Intrapulmonary Pressure (P_{pul})

The **intrapulmonary** (intra-alveolar) **pressure (P_{pul})** is the pressure in the alveoli. Intrapulmonary pressure rises and falls with the phases of breathing, but it *always* equalizes with the atmospheric pressure eventually (**Figure 22.14**).

Intrapleural Pressure (P_{ip})

The pressure in the pleural cavity, the **intrapleural pressure (P_{ip})**, also fluctuates with breathing phases, but is always about 4 mm Hg less than P_{pul}. That is, P_{ip} is *always* negative relative to P_{pul}.

What causes this negative intrapleural pressure? To answer this question, let's examine the forces that exist in the thorax. First of all, we know there are opposing forces. Two forces act to pull the lungs (visceral pleura) away from the thorax wall (parietal pleura) and cause the lungs to collapse:

- **The lungs' natural tendency to recoil.** Because of their elasticity, lungs always assume the smallest size possible.
- **The surface tension of the alveolar fluid.** The molecules of the fluid lining the alveoli attract each other. This produces *surface tension* (◀ p. 35) that constantly acts to draw the alveoli to their smallest possible dimension.

However, these lung-collapsing forces are opposed by the natural elasticity of the chest wall, a force that tends to pull the thorax outward and enlarge the lungs. So which force wins? In a healthy person, the answer is neither, because of the strong

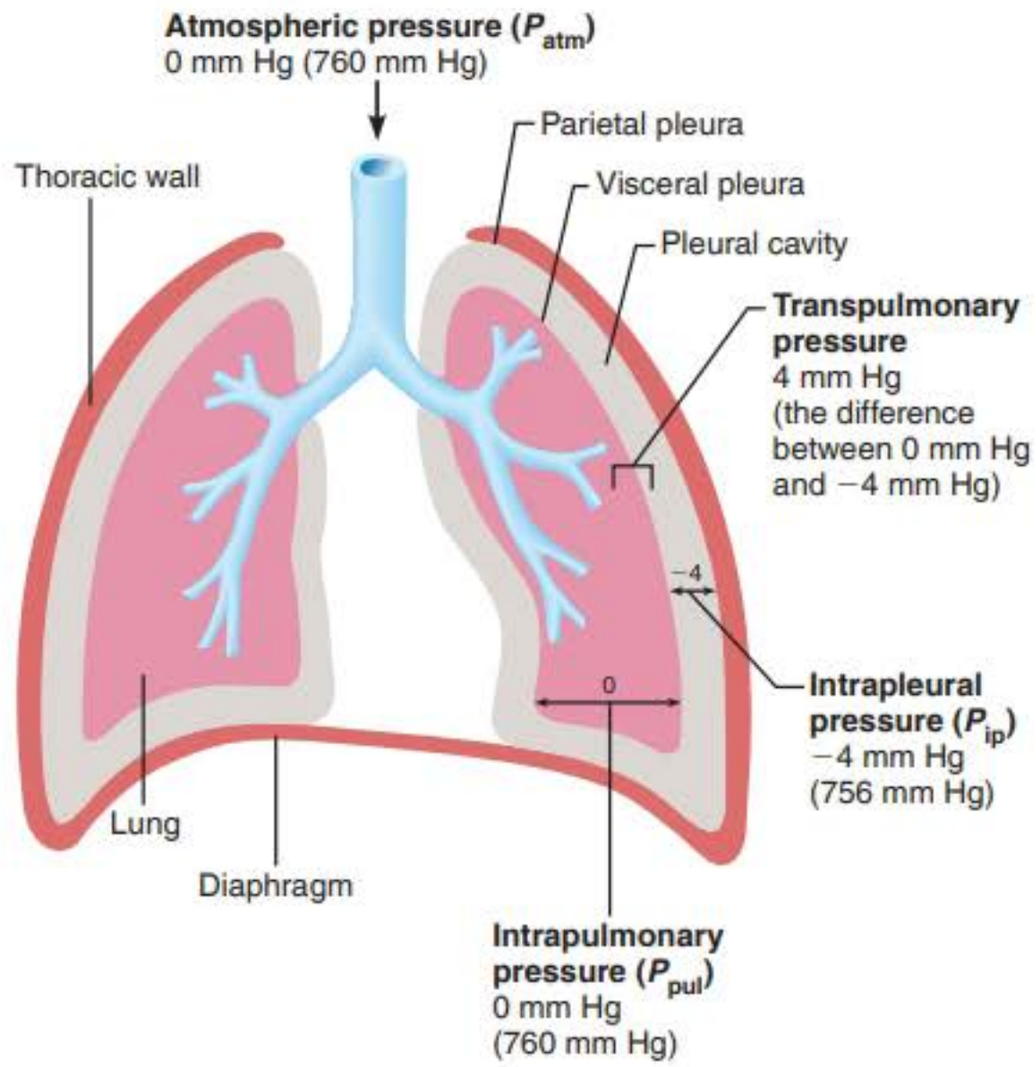

Figure 22.14 Intrapulmonary and intrapleural pressure relationships. Values shown are pressures relative to atmospheric pressure (760 mm Hg at sea level). Absolute pressures are given in parentheses. These pressures are at the end of a normal expiration. For illustration, the size of the pleural cavity has been greatly exaggerated.

adhesive force between the parietal and visceral pleurae. Pleural fluid secures the pleurae together in the same way a drop of water holds two glass slides together. The pleurae slide from side to side easily, but they remain stuck together, and separating them requires extreme force. The net result of the dynamic interplay between these forces is a negative P_{ip}.

The amount of pleural fluid in the pleural cavity must remain minimal to maintain a negative P_{ip}. The pleural fluid is actively pumped out of the pleural cavity into the lymphatics continuously. If it wasn't, fluid would accumulate in the intrapleural space (remember, fluids move from high to low pressure), producing a positive pressure in the pleural cavity.

Transpulmonary Pressure

The **transpulmonary pressure** is the difference between the intrapulmonary and intrapleural pressures ($P_{pul} - P_{ip}$). It is this pressure that keeps the air spaces of the lungs open or, phrased another way, keeps the lungs from collapsing. Moreover, *the size of the transpulmonary pressure determines the size of the lungs* at any time—the greater the transpulmonary pressure, the larger the lungs. We cannot overemphasize the importance of negative pressure in the intrapleural space and the tight coupling of the lungs to the thorax wall. Any condition that equalizes P_{ip} with

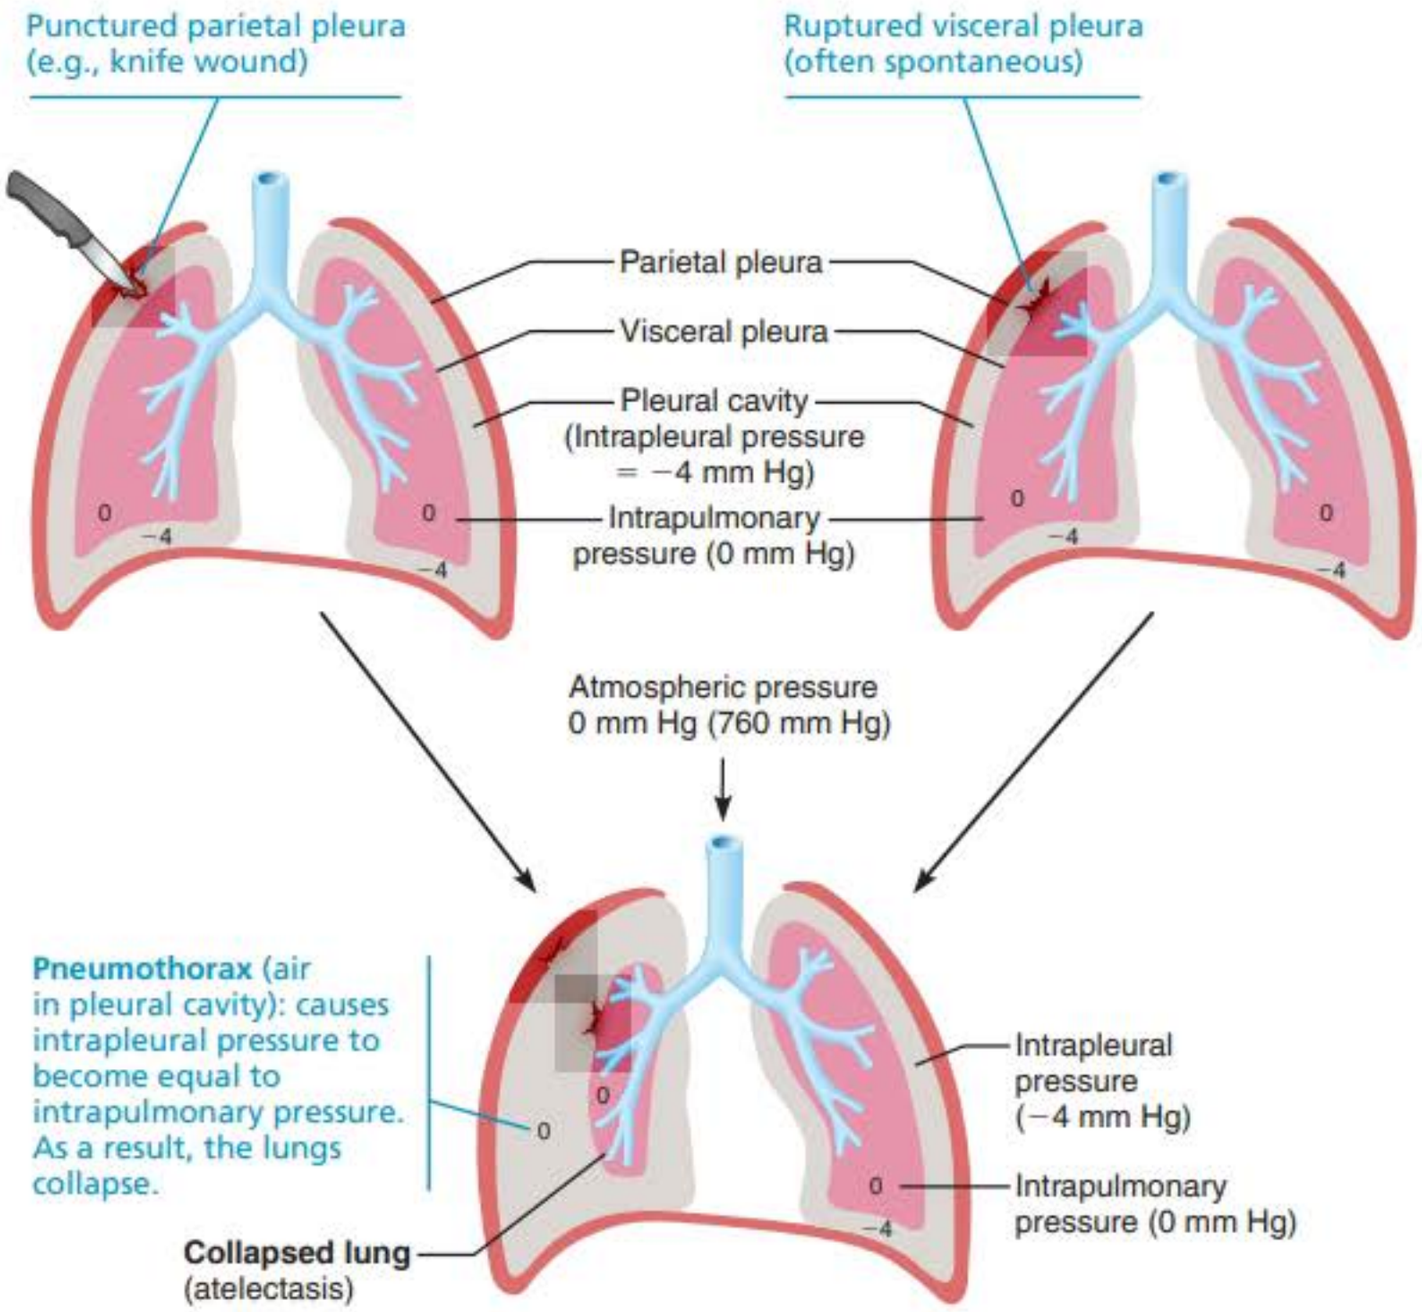

Figure 22.15 Pneumothorax. One lung can collapse without affecting the other because the lungs are in separate cavities.

the intrapulmonary (or atmospheric) pressure causes immediate *lung collapse* (**Figure 22.15**).

HOMEOSTATIC IMBALANCE 22.7 CLINICAL

Atelectasis (at″ĕ-lek′tah-sis), or lung collapse, occurs when a bronchiole becomes plugged (as may follow pneumonia). Its associated alveoli then absorb all of their air and collapse. Atelectasis can also occur when air enters the pleural cavity either through a chest wound or a rupture of the visceral pleura, which allows air from the respiratory tract to enter the pleural cavity.

The presence of air in the pleural cavity is referred to as a **pneumothorax** (nu″mo-tho′raks; "air thorax"), and is reversed by drawing air out of the intrapleural space with chest tubes. This procedure allows the pleurae to heal and the lung to reinflate and resume normal function.

Pulmonary Ventilation

Pulmonary ventilation, consisting of inspiration and expiration, is a mechanical process that depends on volume changes in the thoracic cavity. A rule to keep in mind is that *volume changes* lead to *pressure changes*, and pressure changes lead to the *flow of gases* to equalize the pressure.

Boyle's law gives the relationship between the pressure and volume of a gas: At constant temperature, the pressure of a gas varies inversely with its volume. That is,

$$P_1V_1 = P_2V_2$$

where P is the pressure of the gas, V is its volume, and subscripts 1 and 2 represent the initial and resulting conditions respectively.

Gases always *fill* their container. Consequently, in a large container, the molecules in a given amount of gas will be far apart and the pressure will be low. But if the volume of the container is reduced, the gas molecules will be forced closer together and the pressure will rise.

A good example is an inflated automobile tire. The tire is hard and strong enough to bear the weight of a car because air is compressed to about one-third of its atmospheric volume inside the tire, providing high pressure.

Now let's see how this relates to inspiration and expiration.

Inspiration

Visualize the thoracic cavity as a gas-filled box with a single entrance at the top, the tubelike trachea. The volume of this box can be increased by enlarging all of its dimensions, thereby decreasing the gas pressure inside it. This drop in pressure causes air to rush into the box from the atmosphere, because gases always flow down their pressure gradients.

The same thing happens during normal quiet (resting) inspiration, when the **inspiratory muscles**—the diaphragm and external intercostal muscles—are activated. Here's how quiet inspiration works:

- **Action of the diaphragm.** When the dome-shaped diaphragm contracts, it moves inferiorly and flattens out (**Figure 22.16**, top). As a result, the superior-inferior dimension (height) of the thoracic cavity increases.
- **Action of the intercostal muscles.** When the external intercostal muscles contract, they lift the rib cage and pull the sternum superiorly (Figure 22.16, top). Because the ribs curve downward as well as forward around the chest wall, the broadest lateral and anteroposterior dimensions of the rib cage are normally directed obliquely downward. But when the ribs are raised and drawn together, they swing outward, expanding the diameter of the thorax both laterally and in the anteroposterior plane. This is much like the

	Sequence of events	Changes in anterior-posterior and superior-inferior dimensions	Changes in lateral dimensions (superior view)
Inspiration	① Inspiratory muscles contract (diaphragm descends; rib cage rises). ↓ ② Thoracic cavity volume increases. ↓ ③ Lungs are stretched; intrapulmonary volume increases. ↓ ④ Intrapulmonary pressure drops (to −1 mm Hg). ↓ ⑤ Air (gases) flows into lungs down its pressure gradient until intrapulmonary pressure is 0 (equal to atmospheric pressure).		Expiration	① Inspiratory muscles relax (diaphragm rises; rib cage descends due to recoil of costal cartilages). ↓ ② Thoracic cavity volume decreases. ↓ ③ Elastic lungs recoil passively; intrapulmonary volume decreases. ↓ ④ Intrapulmonary pressure rises (to +1 mm Hg). ↓ ⑤ Air (gases) flows out of lungs down its pressure gradient until intrapulmonary pressure is 0.		
Figure 22.16 Changes in thoracic volume and sequence of events during inspiration and expiration. The sequence of events in the left column includes volume changes during inspiration (top) and expiration (bottom). The lateral views in the middle column show changes in the superior-inferior dimension (as the diaphragm alternately contracts and relaxes, see black arrows) and in the anterior-posterior dimension (as the external intercostal muscles alternately contract and relax). The superior views of transverse thoracic sections in the right column show lateral dimension changes resulting from alternate contraction and relaxation of the external intercostal muscles.

action that occurs when a curved bucket handle is raised—it moves outward as it moves upward, as shown at right.

Although these actions expand the thoracic dimensions by only a few millimeters along each plane, this is enough to increase thoracic volume by almost 500 ml—the usual volume of air that enters the lungs during a normal quiet inspiration. Of the two types of inspiratory muscles, the diaphragm is far more important in producing these volume changes that lead to normal quiet inspiration.

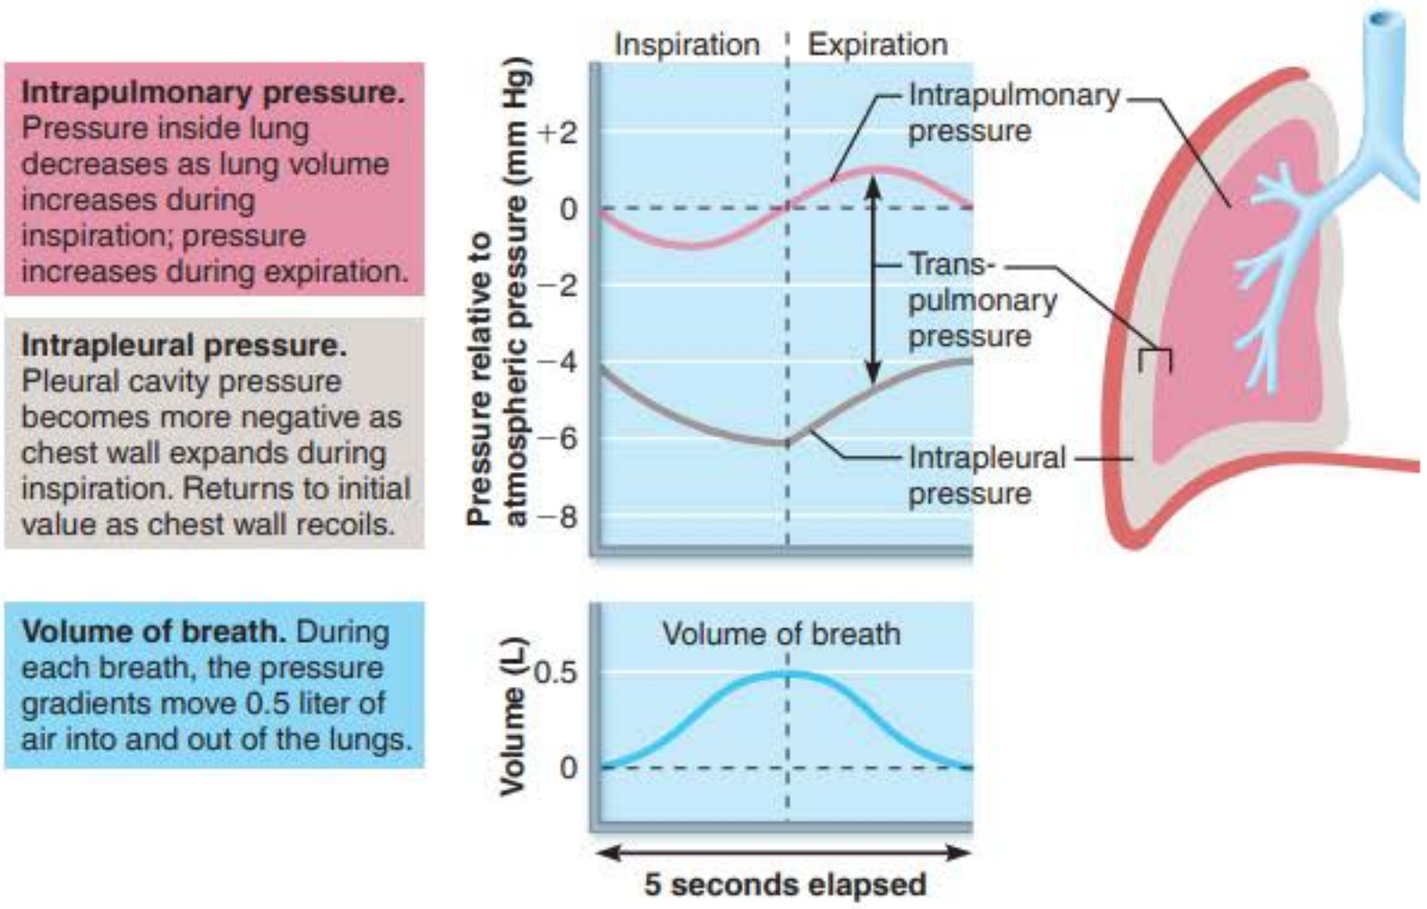

Figure 22.17 Changes in intrapulmonary and intrapleural pressures during inspiration and expiration. Notice that normal atmospheric pressure (760 mm Hg) is given a value of 0 on the scale.

As the thoracic dimensions increase during inspiration, the lungs are stretched and the intrapulmonary volume increases. As a result, P_{pul} drops about 1 mm Hg relative to P_{atm}. Anytime the intrapulmonary pressure is less than the atmospheric pressure ($P_{pul} < P_{atm}$), air rushes into the lungs along the pressure gradient. Inspiration ends when $P_{pul} = P_{atm}$. During the same period, P_{ip} declines to about –6 mm Hg relative to P_{atm} (**Figure 22.17**).

During the *deep* or *forced inspirations* that occur during vigorous exercise and in some chronic obstructive pulmonary diseases, accessory muscles further increase thoracic volume. Several muscles, including the scalenes and sternocleidomastoid muscles of the neck and the pectoralis minor of the chest, raise the ribs even more than during quiet inspiration. Additionally, the back extends as the erector spinae muscles straighten the thoracic curvature.

Expiration

In healthy individuals, quiet expiration is a passive process that depends more on lung elasticity than on muscle contraction. As the inspiratory muscles relax and resume their resting length, the rib cage descends and the lungs recoil (Figure 22.16, bottom). As a result, both the thoracic and intrapulmonary volumes decrease. This volume decrease compresses the alveoli, and P_{pul} rises to about 1 mm Hg above atmospheric pressure (Figure 22.17). When $P_{pul} > P_{atm}$, the pressure gradient forces gases to flow out of the lungs.

Forced expiration is an active process produced by contracting abdominal wall muscles, primarily the oblique and transversus muscles. These contractions (1) increase the intra-abdominal pressure, which forces the abdominal organs superiorly against the diaphragm, and (2) depress the rib cage. The internal intercostal muscles also help depress the rib cage and decrease thoracic volume.

To precisely regulate air flow from the lungs, it is necessary to control the accessory muscles of expiration. For instance, the ability of a trained vocalist to hold a musical note depends on the coordinated activity of several muscles normally used in forced expiration.

Nonrespiratory Air Movements

Many processes other than breathing move air into or out of the lungs, altering the normal respiratory rhythm. These **nonrespiratory air movements** occur whenever you cough, sneeze, cry, laugh, hiccup, or yawn. Some can be produced voluntarily, but some (such as sneezing and hiccups) are reflexive.

Physical Factors Influencing Pulmonary Ventilation

As we have seen, the lungs are stretched during inspiration and recoil passively during expiration. The inspiratory muscles consume energy to enlarge the thorax. Energy is also used to overcome various factors that hinder air passage and pulmonary ventilation. We examine these factors next.

Airway Resistance

The major *nonelastic* source of resistance to gas flow is friction, or drag, encountered in the respiratory passageways. The following equation gives the relationship between gas flow (F), pressure (P), and resistance (R):

$$F = \frac{\Delta P}{R}$$

Notice that the factors determining gas flow in the respiratory passages and blood flow in the blood vessels are equivalent.

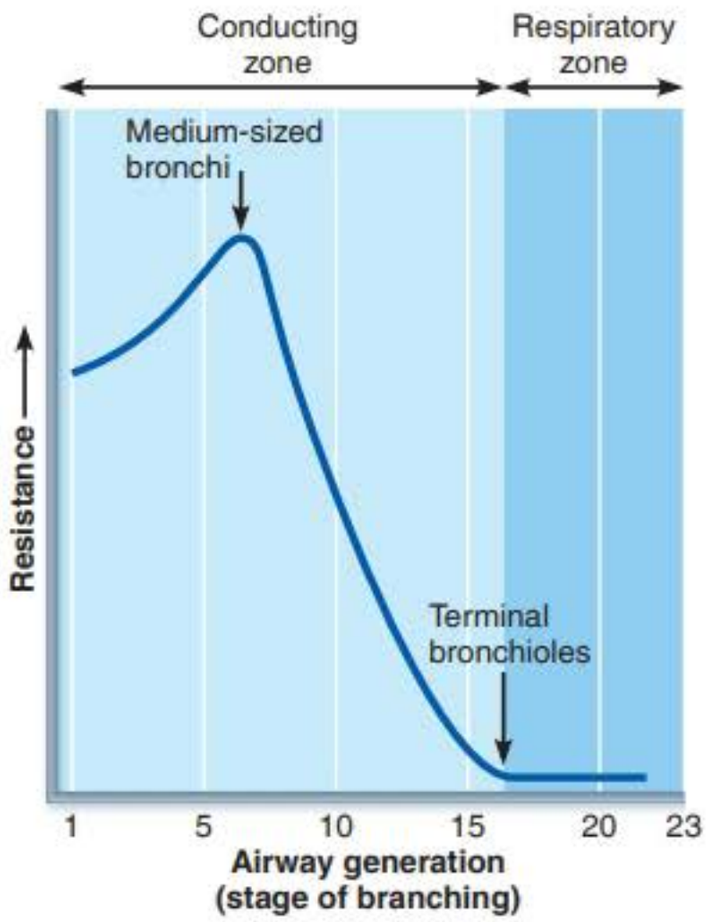

Figure 22.18 Resistance in respiratory passageways. Airway resistance peaks in the medium-sized bronchi and then declines sharply as the total cross-sectional area of the airways increases rapidly.

The amount of gas flowing into and out of the alveoli is directly proportional to ΔP, the *difference* in pressure, or pressure gradient, between the external atmosphere and the alveoli.

Normally, very small differences in pressure produce large changes in gas flow. The average pressure gradient during normal quiet breathing is 2 mm Hg or less, and yet it is sufficient to move 500 ml of air in and out of the lungs with each breath.

But, as the equation also indicates, gas flow changes *inversely* with resistance. In other words, gas flow decreases as resistance increases. As in the cardiovascular system, resistance in the respiratory tree is determined mostly by the diameters of the conducting tubes. However, as a rule, airway resistance is insignificant for two reasons:

- Airway diameters in the first part of the conducting zone are huge, relative to the low viscosity of air.
- As the airways get progressively smaller, there are progressively more branches. As a result, although individual bronchioles are tiny, there are an enormous number of them in parallel, so the total cross-sectional area is huge.

Consequently, the greatest resistance to gas flow occurs in the medium-sized bronchi (**Figure 22.18**). At the terminal bronchioles, gas flow stops and diffusion takes over as the main force driving gas movement, so resistance is no longer an issue.

HOMEOSTATIC IMBALANCE 22.8 — CLINICAL

Smooth muscle of the bronchiolar walls is exquisitely sensitive to neural controls and certain chemicals. For example, inhaled irritants activate a reflex of the parasympathetic division of the nervous system that causes vigorous constriction of the bronchioles and dramatically reduces air passage. During an acute *asthma attack*, histamine and other inflammatory chemicals can cause such strong bronchoconstriction that pulmonary ventilation almost completely stops, regardless of the pressure gradient. Conversely, epinephrine released during sympathetic nervous system activation or administered as a drug dilates bronchioles and reduces airway resistance. Local accumulations of mucus, infectious material, or solid tumors in the passageways are important sources of airway resistance in those with respiratory disease.

Whenever airway resistance rises, breathing movements become more strenuous, but such compensation has its limits. When the bronchioles are severely constricted or obstructed, even the most extreme respiratory efforts cannot restore ventilation to life-sustaining levels.

Alveolar Surface Tension

At any gas-liquid boundary, the molecules of the liquid are more strongly attracted to each other than to the gas molecules. This unequal attraction produces a state of tension at the liquid surface, called **surface tension**, that (1) draws the liquid molecules closer together and reduces their contact with the dissimilar gas molecules, and (2) resists any force that tends to increase the surface area of the liquid.

Water is composed of highly polar molecules and has a very high surface tension (◀ p. 35). As the major component of the liquid film that coats the alveolar walls, water is always acting to reduce the alveoli to their smallest possible size.

If the film were pure water, the alveoli would collapse between breaths. But the alveolar film also contains **surfactant** (ser-fak′tant), a detergent-like complex of lipids and proteins produced by the type II alveolar cells (◀ p. 831). Surfactant decreases the cohesiveness of water molecules, much the way laundry detergent reduces the attraction of water for water, allowing water to interact with and pass through fabric. As a result, the surface tension of alveolar fluid is reduced, and less energy is needed to overcome those forces to expand the lungs and discourage alveolar collapse. Breaths that are deeper than normal stimulate type II cells to secrete more surfactant.

HOMEOSTATIC IMBALANCE 22.9 — CLINICAL

When too little surfactant is present, surface tension can collapse the alveoli. Once this happens, the alveoli must be completely reinflated during each inspiration, an effort that uses tremendous amounts of energy. This is the problem faced by newborns with **infant respiratory distress syndrome (IRDS)**, a condition common in premature babies. Since fetal lungs do not produce adequate amounts of surfactant until the last two months of development, babies born prematurely often are unable to keep their alveoli inflated between breaths.

IRDS is treated by spraying natural or synthetic surfactant into the newborn's respiratory passageways. In addition, devices that maintain positive airway pressure throughout the respiratory cycle can keep the alveoli open between breaths. Severe cases require mechanical ventilators.

Many IRDS survivors suffer from *bronchopulmonary dysplasia*, a chronic lung disease, during childhood and beyond. This condition seems to be caused by a combination of factors including prolonged therapy with oxygen and mechanical ventilation.

Lung Compliance

Healthy lungs are unbelievably stretchy, and this distensibility is called **lung compliance**. Specifically, lung compliance (C_L) is a measure of the change in lung volume (ΔV_L) that occurs with a given change in transpulmonary pressure [$\Delta(P_{pul} - P_{ip})$]. This relationship is stated as

$$C_L = \frac{\Delta V_L}{\Delta(P_{pul} - P_{ip})}$$

The more a lung expands for a given rise in transpulmonary pressure, the greater its compliance. Said another way, the higher the lung compliance, the easier it is to expand the lungs at any given transpulmonary pressure.

Lung compliance is determined largely by two factors:

- Distensibility of the lung tissue
- Alveolar surface tension

Because lung distensibility is generally high and surfactant keeps alveolar surface tension low, healthy lungs tend to have high compliance, which favors efficient ventilation.

HOMEOSTATIC IMBALANCE 22.10 CLINICAL

Any decrease in the natural resilience of the lungs diminishes lung compliance. Chronic inflammation, or infections such as tuberculosis, can cause nonelastic scar tissue to replace normal lung tissue (*fibrosis*). Decreased production of surfactant can also impair lung compliance. The lower the lung compliance, the more energy is needed just to breathe.

Since the lungs are contained within the thoracic cavity, we also need to consider the compliance (distensibility) of the thoracic wall. Factors that reduce the compliance of the thoracic wall hinder lung expansion. The total compliance of the respiratory system is comprised of lung compliance and thoracic wall compliance.

HOMEOSTATIC IMBALANCE 22.11 CLINICAL

Deformities of the thorax, ossified costal cartilages (common during old age), and paralyzed intercostal muscles all hinder thoracic expansion, reducing total respiratory compliance.

Check Your Understanding

22.5 Measuring respiratory volumes, capacities, and flow rates helps us assess ventilation

Learning Outcomes

- **Explain and compare the various lung volumes and capacities.**
- **Define dead space.**
- **Indicate types of information that can be gained from pulmonary function tests.**

The amount of air flushed in and out of the lungs depends on the conditions of inspiration and expiration. Consequently, several respiratory volumes can be described. Specific combinations of these respiratory volumes, called *respiratory capacities*, are measured to gain information about a person's respiratory status.

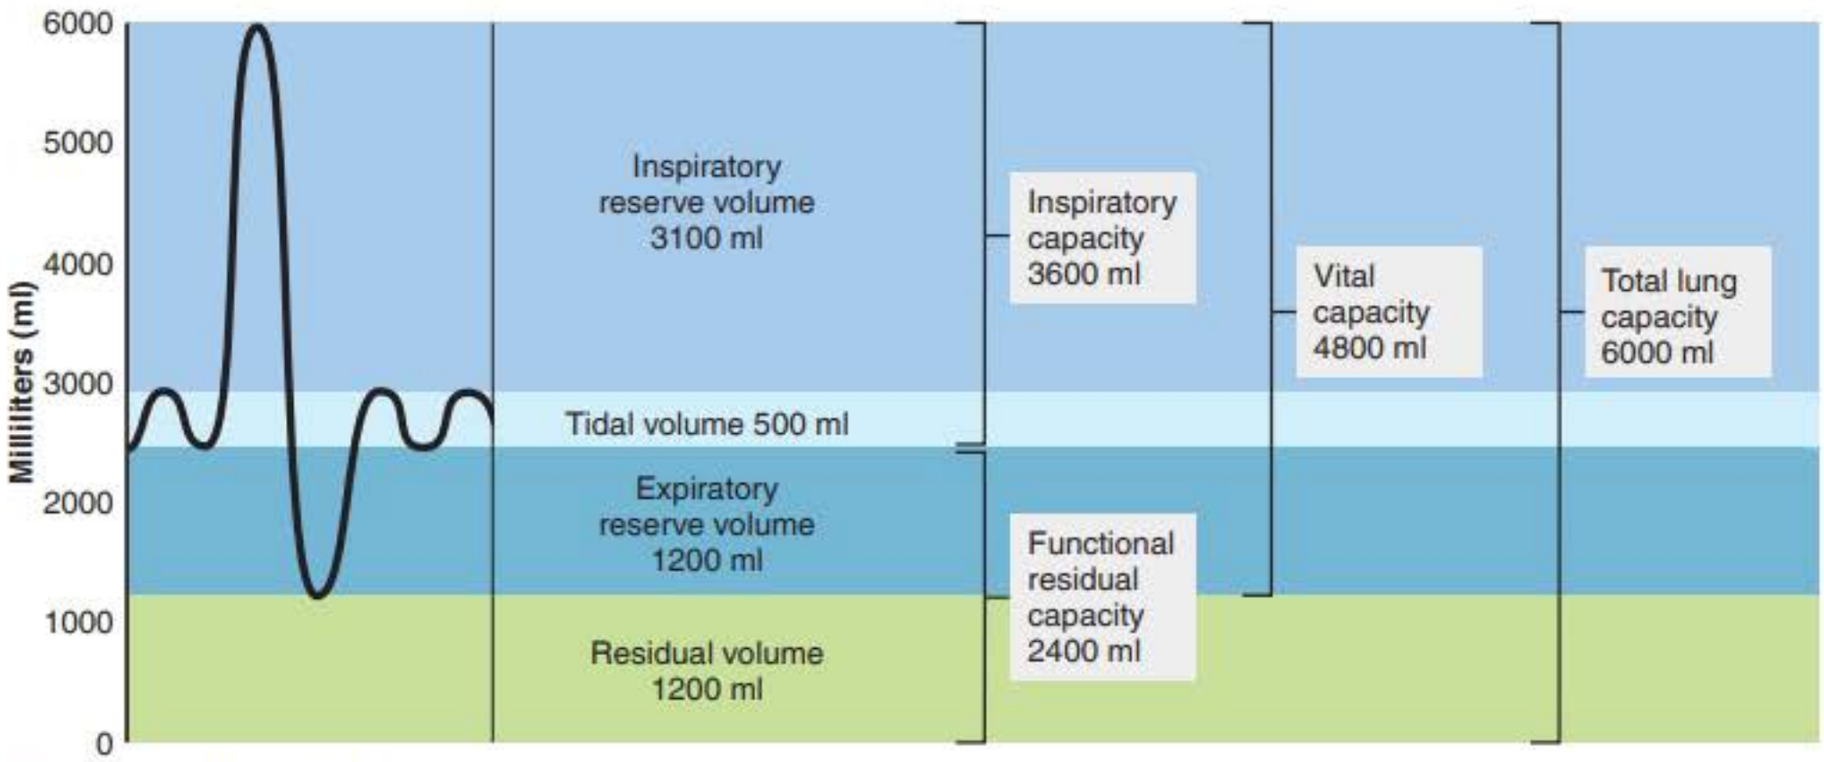
Lung volumes and capacities are often abnormal in people with pulmonary disorders. The original clinical measuring tool, a **spirometer** (spi-rom′ĕ-ter), was a cumbersome instrument utilizing a hollow bell inverted over water. Now patients simply blow into a small electronic measuring device.

Respiratory Volumes

The four **respiratory volumes** of interest are tidal, inspiratory reserve, expiratory reserve, and residual. The values recorded in **Figure 22.19a** represent normal values. Figure 22.19b provides average values for males and females.

During normal quiet breathing, about 500 ml of air moves into and out of the lungs with each breath. This respiratory volume is the **tidal volume (TV)**. The amount of air that can be inspired forcibly beyond the tidal volume (2100 to 3200 ml) is the **inspiratory reserve volume (IRV)**.

The **expiratory reserve volume (ERV)** is the amount of air—normally 1000 to 1200 ml—that can be expelled from the lungs after a normal tidal volume expiration. Even after the most strenuous expiration, about 1200 ml of air remains



(a) Spirographic record for a male

	Measurement	Adult male average value	Adult female average value	Description
Respiratory volumes	Tidal volume (TV)	500 ml	500 ml	Amount of air inhaled or exhaled with each breath under resting conditions
	Inspiratory reserve volume (IRV)	3100 ml	1900 ml	Amount of air that can be forcefully inhaled after a normal tidal volume inspiration
	Expiratory reserve volume (ERV)	1200 ml	700 ml	Amount of air that can be forcefully exhaled after a normal tidal volume expiration
	Residual volume (RV)	1200 ml	1100 ml	Amount of air remaining in the lungs after a forced expiration
Respiratory capacities	Total lung capacity (TLC)	6000 ml	4200 ml	Maximum amount of air contained in lungs after a maximum inspiratory effort: TLC = TV + IRV + ERV + RV
	Vital capacity (VC)	4800 ml	3100 ml	Maximum amount of air that can be expired after a maximum inspiratory effort: VC = TV + IRV + ERV
	Inspiratory capacity (IC)	3600 ml	2400 ml	Maximum amount of air that can be inspired after a normal tidal volume expiration: IC = TV + IRV
	Functional residual capacity (FRC)	2400 ml	1800 ml	Volume of air remaining in the lungs after a normal tidal volume expiration: FRC = ERV + RV

(b) Summary of respiratory volumes and capacities for males and females

Figure 22.19 Respiratory volumes and capacities. Idealized spirographic record of respiratory volumes in (a) is for a healthy adult male (70 kg, age 20).

in the lungs; this is the **residual volume (RV)**, which helps to keep the alveoli open and prevent lung collapse.

Respiratory Capacities

The **respiratory capacities** include inspiratory, functional residual, vital, and total lung capacities (Figure 22.19). The respiratory capacities always consist of two or more lung volumes.

- **Inspiratory capacity (IC)** is the total amount of air that can be inspired after a normal tidal volume expiration, so it is the sum of TV and IRV.
- **Functional residual capacity (FRC)** represents the amount of air remaining in the lungs after a normal tidal volume expiration and is the combined RV and ERV.
- **Vital capacity (VC)** is the total amount of exchangeable air. It is the sum of TV, IRV, and ERV.
- **Total lung capacity (TLC)** is the sum of all lung volumes.

As indicated in Figure 22.19b, lung volumes and capacities (with the possible exception of TV) tend to be smaller in women than in men because of women's smaller size.

Dead Space

Some of the inspired air fills the conducting respiratory passageways and never contributes to gas exchange in the alveoli. The volume of these conducting zone conduits, which make up the **anatomical dead space**, typically amounts to about 150 ml. (The rule of thumb is that the anatomical dead space volume in

Table 22.3 Effects of Breathing Rate and Depth on Alveolar Ventilation of Three Hypothetical Patients

BREATHING PATTERN OF HYPOTHETICAL PATIENT	DEAD SPACE VOLUME (DSV)	TIDAL VOLUME (TV)	RESPIRATORY RATE*	MINUTE VENTILATION (MVR)	ALVEOLAR VENTILATION (AVR)	% EFFECTIVE VENTILATION (AVR/MVR)
I—Normal rate and depth	150 ml	500 ml	20/min	10,000 ml/min	7000 ml/min	70%
II—Slow, deep breathing	150 ml	1000 ml	10/min	10,000 ml/min	8500 ml/min	85%
III—Rapid, shallow breathing	150 ml	250 ml	40/min	10,000 ml/min	4000 ml/min	40%

*Respiratory rate values are artificially adjusted to provide equivalent minute ventilation as a baseline for comparing alveolar ventilation.

a healthy young adult is equal to 1 ml per pound of ideal body weight.) This means that if TV is 500 ml, only 350 ml of it is involved in alveolar ventilation. The remaining 150 ml of the tidal breath is in the anatomical dead space.

If some alveoli cease to act in gas exchange (due to alveolar collapse or obstruction by mucus, for example), the **alveolar dead space** is added to the anatomical dead space. The sum of the nonuseful volumes is the **total dead space**.

Pulmonary Function Tests

Spirometry is most useful for evaluating losses in respiratory function and for following the course of certain respiratory diseases. It cannot provide a specific diagnosis, but it can distinguish between *obstructive pulmonary diseases* involving increased airway resistance (such as chronic bronchitis) and *restrictive diseases* involving reduced total lung capacity. (These changes might be due to diseases such as tuberculosis, or to fibrosis due to exposure to certain environmental agents such as asbestos). In obstructive diseases, TLC, FRC, and RV may increase because the lungs hyperinflate, whereas in restrictive diseases, VC, TLC, FRC, and RV decline because lung expansion is limited.

We can obtain more information by assessing the *rate* at which gas moves into and out of the lungs.

- **Forced vital capacity (FVC)** measures the amount of gas expelled when a subject takes a deep breath and then forcefully exhales maximally and as rapidly as possible.
- **Forced expiratory volume (FEV)** determines the amount of air expelled during specific time intervals of the FVC test. For example, the volume exhaled during the first second is FEV_1. Those with healthy lungs can exhale about 80% of the FVC within 1 second. Those with obstructive pulmonary disease exhale considerably less than 80% of the FVC within 1 second, while those with restrictive disease can exhale 80% or more of FVC in 1 second even though their FVC is reduced.

Alveolar Ventilation

The **minute ventilation** is the total amount of gas that flows into or out of the respiratory tract in 1 minute. During normal quiet breathing, the minute ventilation in healthy people is about 6 L/min (500 ml per breath multiplied by 12 breaths per minute). During vigorous exercise, the minute ventilation may reach 200 L/min.

Minute ventilation values provide a rough yardstick for assessing respiratory efficiency, but the **alveolar ventilation rate (AVR)** is a better index of effective ventilation. The AVR takes into account the volume of air wasted in the dead space and measures the flow of fresh gases in and out of the alveoli during a particular time interval. We can compute AVR using this equation:

$$\underset{\text{(ml/min)}}{\text{AVR}} = \underset{\text{(breaths/min)}}{\text{frequency}} \times \underset{\text{(ml/breath)}}{(\text{TV} - \text{dead space})}$$

In healthy people, AVR is usually about 12 breaths per minute times the difference of 500 – 150 ml per breath, or 4200 ml/min.

Because anatomical dead space is constant in a particular individual, increasing the volume of each inspiration (breathing depth) enhances AVR and gas exchange more than raising the respiratory rate. AVR drops dramatically during rapid shallow breathing because most of the inspired air never reaches the exchange sites. Furthermore, as tidal volume approaches the dead space value, effective ventilation approaches zero, regardless of how fast a person is breathing. **Table 22.3** summarizes the effects of breathing rate and breathing depth on alveolar ventilation for three hypothetical patients.

15. Explain why slow, deep breaths ventilate the alveoli more effectively than do rapid, shallow breaths.
16. What is the difference between respiratory volumes and respiratory capacities?

For answers, see Answers Appendix.

22.6 Gases exchange by diffusion between the blood, lungs, and tissues

Learning Outcomes

- **State Dalton's law of partial pressures and Henry's law.**
- **Describe how atmospheric and alveolar air differ in composition, and explain these differences.**
- **Relate Dalton's and Henry's laws to events of external and internal respiration.**

As you've discovered, during *external respiration* oxygen enters and carbon dioxide leaves the blood in the lungs by diffusion.

At the body tissues, where the process is called *internal respiration*, the same gases move in opposite directions, also by diffusion. To understand these processes, let's examine the physical properties of gases and consider the composition of alveolar gas.

Basic Properties of Gases

Beyond Boyle's law, two more gas laws provide most of the information we need—*Dalton's law of partial pressures* reveals how a gas behaves when it is part of a mixture of gases, and *Henry's law* helps us understand how gases move into and out of solution.

Dalton's Law of Partial Pressures

Dalton's law of partial pressures states that the total pressure exerted by a mixture of gases is the sum of the pressures exerted independently by each gas in the mixture. Further, the pressure exerted by each gas—its **partial pressure**—is directly proportional to the percentage of that gas in the gas mixture.

As indicated in **Table 22.4**, nitrogen makes up about 79% of air, and the partial pressure of nitrogen P_{N_2} is 78.6% × 760 mm Hg, or 597 mm Hg. Oxygen, which accounts for nearly 21% of air, has a partial pressure P_{O_2} of 159 mm Hg (20.9% × 760 mm Hg). Together nitrogen and oxygen contribute about 99% of the total atmospheric pressure. Air also contains 0.04% carbon dioxide, up to 0.5% water vapor, and insignificant amounts of inert gases (such as argon and helium).

At high altitudes, partial pressures decline in direct proportion to the decrease in atmospheric pressure. For example, at 10,000 feet above sea level where the atmospheric pressure is 523 mm Hg, P_{O_2} is 110 mm Hg.

Moving in the opposite direction, atmospheric pressure increases by 1 atm (760 mm Hg) for each 33 feet of descent (in water) below sea level. At 99 feet below sea level, the total pressure exerted on the body is equivalent to 4 atm, or 3040 mm Hg, and the partial pressure exerted by each component gas is also quadrupled.

Henry's Law

Henry's law states that when a gas is in contact with a liquid, the gas will dissolve in the liquid in proportion to its partial pressure. Accordingly, the greater the concentration of a particular gas in the gas phase, the more and the faster that gas will go into solution in the liquid.

At equilibrium, the partial pressures in the gas and liquid phases are the same. If, however, the partial pressure of the gas later becomes greater in the liquid than in the adjacent gas phase, some of the dissolved gas molecules will reenter the gaseous phase. So the direction and amount of movement of a gas are determined by its partial pressure in the two phases. This flexible situation is exactly what occurs when gases are exchanged in the lungs and tissues. For example, when P_{CO_2} in the pulmonary capillaries is higher than in the lungs, CO_2 diffuses out of the blood and enters the air in the alveoli.

How much of a gas will dissolve in a liquid at any given partial pressure also depends on the *solubility* of the gas in the liquid and the *temperature* of the liquid. The gases in air have very different solubilities in water (and in blood plasma). Carbon dioxide is most soluble. Oxygen is only 1/20 as soluble as CO_2, and N_2 is only half as soluble as O_2. For this reason, at a given partial pressure, much more CO_2 than O_2 dissolves in water, and practically no N_2 goes into solution.

When a liquid's temperature rises, gas solubility decreases. Think of club soda, which is produced by forcing CO_2 gas to dissolve in water under high pressure. If you take the cap off a bottle of club soda and leave it in the fridge, it will slowly go flat. But if you leave it at room temperature, it will very quickly go flat. In both cases, you end up with plain water—all the CO_2 gas has escaped from solution.

In summary, the amount of gas that will dissolve in a liquid depends on:

- The partial pressure of the gas in contact with the liquid
- The solubility of the gas in the liquid
- The temperature of the liquid

Hyperbaric oxygen chambers provide clinical applications of Henry's law. These chambers contain O_2 gas at pressures higher than 1 atm and are used to force greater-than-normal amounts of O_2 into the blood of patients suffering from carbon monoxide poisoning (see p. 852). (They are also used to treat gas gangrene and tissue damage following radiation therapy.)

Scuba diving provides another illustration of Henry's law. If divers rise rapidly from the depths, dissolved nitrogen forms bubbles in their blood, causing "the bends."

Table 22.4 Comparison of Gas Partial Pressures and Approximate Percentages in the Atmosphere and in the Alveoli

	ATMOSPHERE (SEA LEVEL)		*ALVEOLI*	
GAS	APPROXIMATE PERCENTAGE	PARTIAL PRESSURE (mm Hg)	APPROXIMATE PERCENTAGE	PARTIAL PRESSURE (mm Hg)
N_2	78.6	597	74.9	569
O_2	20.9	159	13.7	104
CO_2	0.04	0.3	5.2	40
H_2O	0.46	3.7	6.2	47
	100.0%	760	100.0%	760

HOMEOSTATIC IMBALANCE 22.12 CLINICAL

Although breathing O_2 gas at 2 atm is not a problem for short periods, **oxygen toxicity** develops rapidly when P_{O_2} is greater than 2.5–3 atm. Excessively high O_2 concentrations generate huge amounts of harmful free radicals, resulting in profound CNS disturbances, coma, and death.

Composition of Alveolar Gas

As shown in Table 22.4, the gaseous makeup of the atmosphere is quite different from that in the alveoli. The atmosphere is almost entirely O_2 and N_2; the alveoli contain more CO_2 and water vapor and much less O_2. These differences reflect the effects of:

- Gas exchanges occurring in the lungs (O_2 diffuses from the alveoli into the pulmonary blood and CO_2 diffuses in the opposite direction).
- Humidification of air by conducting passages.
- The mixing of alveolar gas that occurs with each breath. Because only 500 ml of air enter with each tidal inspiration, gas in the alveoli is actually a mixture of newly inspired gases and gases remaining in the respiratory passageways between breaths.

The alveolar partial pressures of O_2 and CO_2 are easily changed by increasing breathing depth and rate. A high AVR brings more O_2 into the alveoli, increasing alveolar P_{O_2} and rapidly eliminating CO_2 from the lungs.

External Respiration

During external respiration (pulmonary gas exchange), dark red blood flowing through the pulmonary circuit is transformed into the scarlet river that is returned to the heart for distribution by systemic arteries to all body tissues. This color change is due to O_2 uptake and binding to hemoglobin in red blood cells (RBCs), but CO_2 exchange (unloading) is occurring equally fast.

The following three factors influence external respiration:

- Partial pressure gradients and gas solubilities
- Thickness and surface area of the respiratory membrane
- Ventilation-perfusion coupling (matching alveolar ventilation with pulmonary blood perfusion)

Let's look at these factors one by one.

Partial Pressure Gradients and Gas Solubilities

Partial pressure gradients of O_2 and CO_2 drive the diffusion of these gases across the respiratory membrane. A steep gradient for the partial pressure of oxygen exists across the respiratory membrane because the P_{O_2} of deoxygenated blood in the pulmonary arteries is only 40 mm Hg, as opposed to a P_{O_2} of approximately 104 mm Hg in the alveoli. As a result, O_2 diffuses rapidly from the alveoli into the pulmonary capillary blood (**Figure 22.20**).

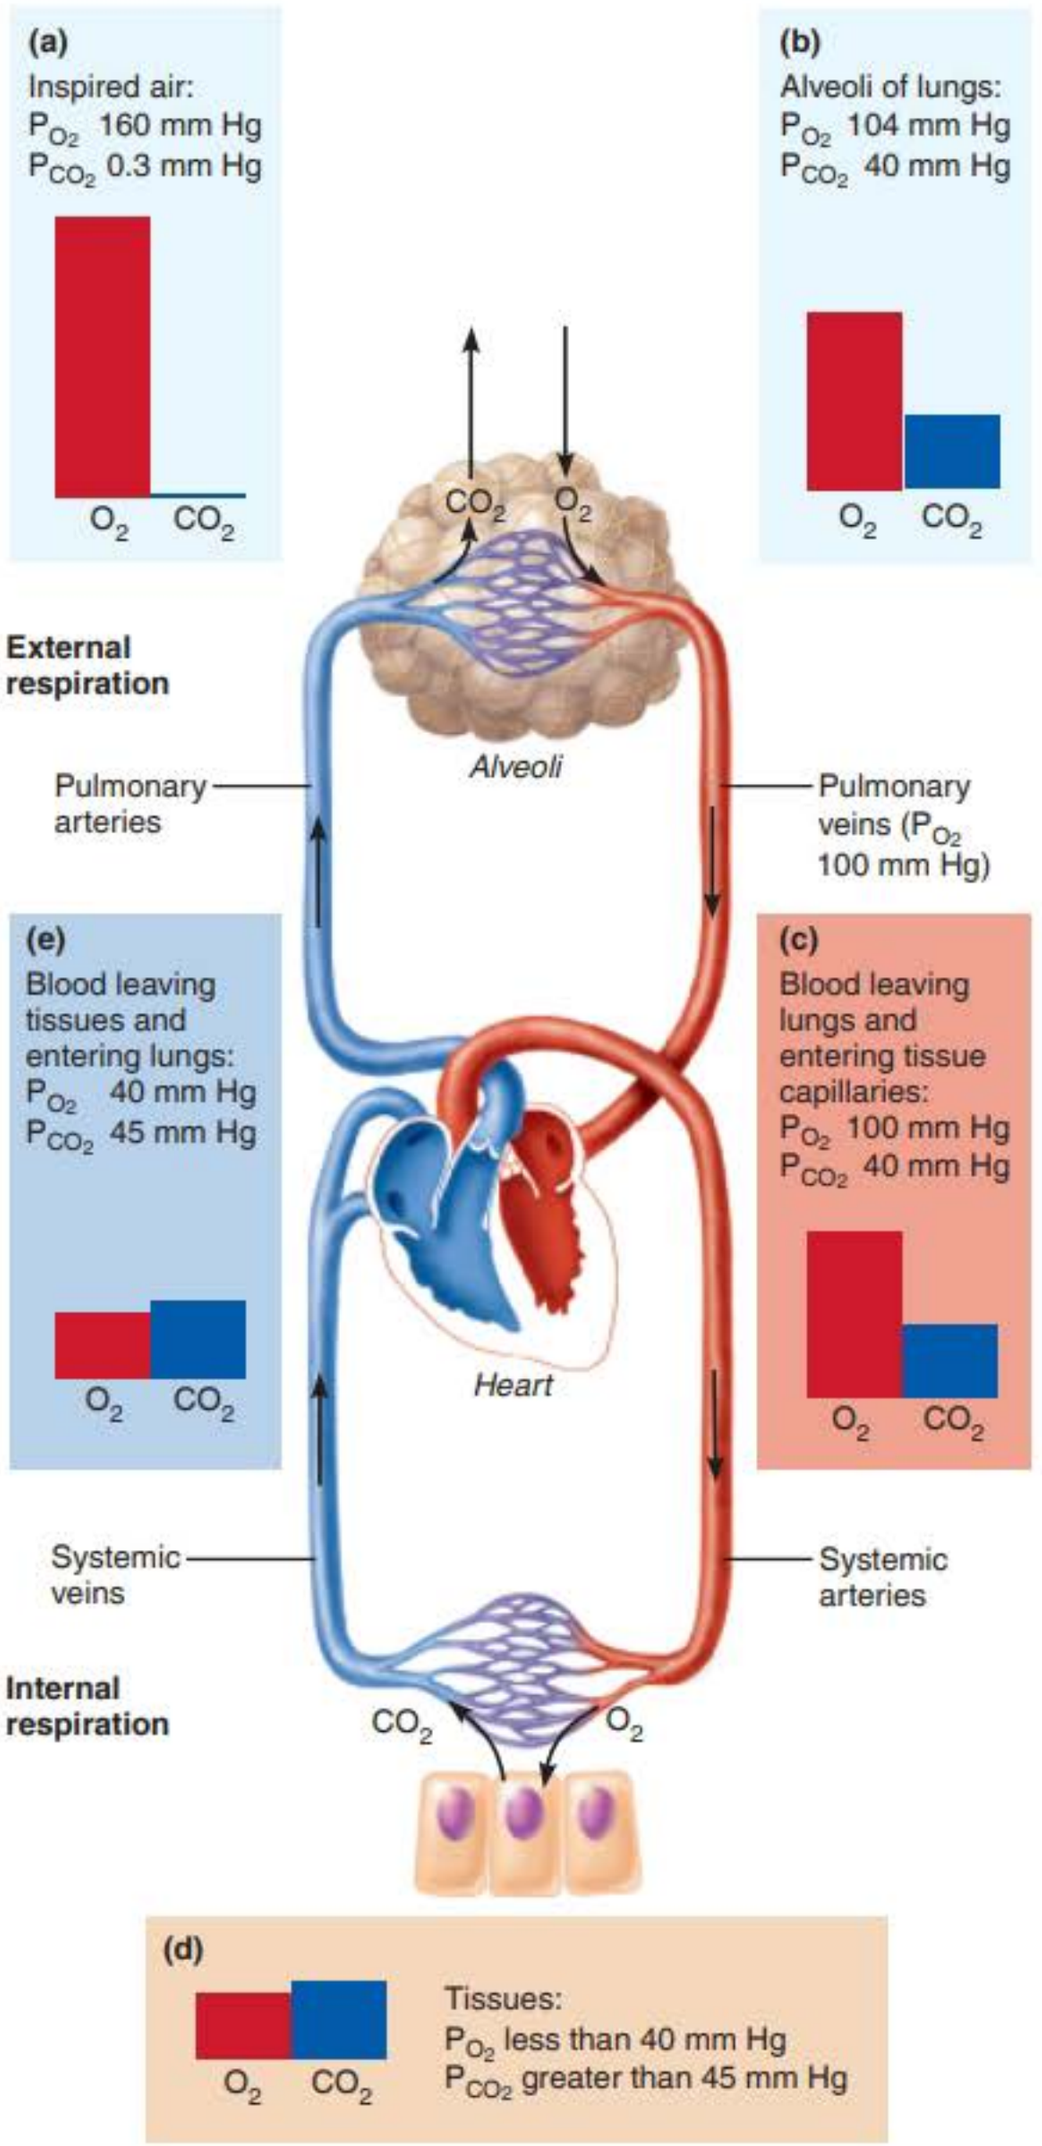

Figure 22.20 Partial pressure gradients promoting gas movements in the body. Gradients promoting O_2 and CO_2 exchange across the respiratory membrane in the lungs [**(b)↔(e)**] and across systemic capillary membranes in body tissues [**(c)↔(d)**]. (The small decrease in P_{O_2} in blood leaving lungs is due to partial dilution of pulmonary capillary blood with less oxygenated blood.)

Equilibrium—that is, a P_{O_2} of 104 mm Hg on both sides of the respiratory membrane—usually occurs in 0.25 second, which is about one-third of the time a red blood cell spends in a pulmonary capillary (**Figure 22.21**). The lesson here is that

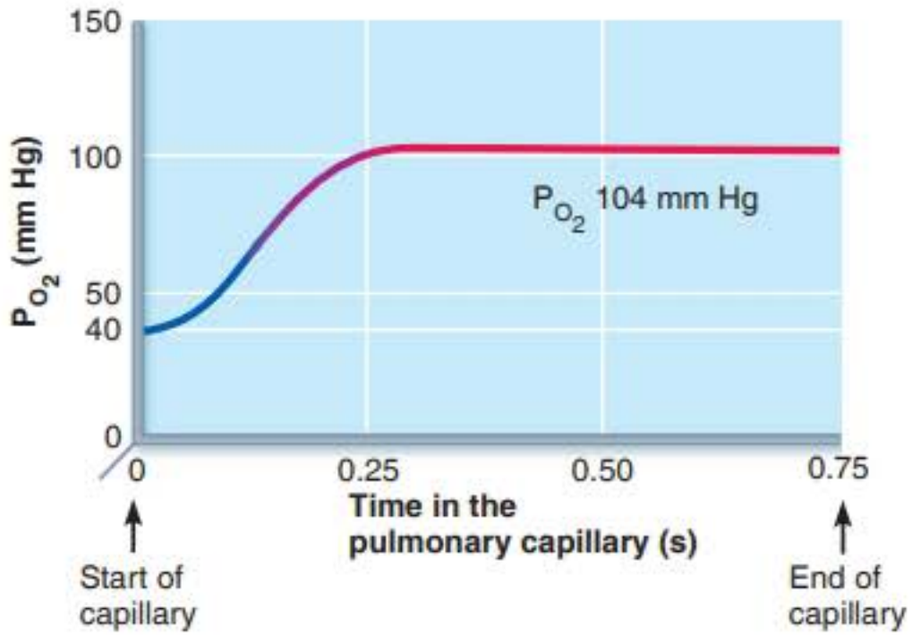

Figure 22.21 Oxygenation of blood in the pulmonary capillaries at rest. Oxygen loading only takes about one-third of the time a red blood cell spends in the pulmonary capillary.

blood can flow through the pulmonary capillaries three times as quickly and still be adequately oxygenated.

Carbon dioxide diffuses in the opposite direction along a much gentler partial pressure gradient of about 5 mm Hg (45 mm Hg to 40 mm Hg) until equilibrium occurs at 40 mm Hg. Expiration then gradually expels carbon dioxide from the alveoli.

Even though the O_2 pressure gradient for oxygen diffusion is much steeper than the CO_2 gradient, equal amounts of these gases are exchanged. Why? The reason is that CO_2 is 20 times more soluble in plasma and alveolar fluid than O_2.

Thickness and Surface Area of the Respiratory Membrane

In healthy lungs, the respiratory membrane is only 0.5 to 1 μm thick, and gas exchange is usually very efficient.

HOMEOSTATIC IMBALANCE 22.13 CLINICAL

The effective thickness of the respiratory membrane increases dramatically if the lungs become waterlogged and edematous, as in pneumonia or left heart failure (◀ p. 700). Under such conditions, even the 0.75 s that red blood cells spend in transit through the pulmonary capillaries may not be enough for adequate gas exchange, and body tissues suffer from oxygen deprivation.

The greater the surface area of the respiratory membrane, the more gas can diffuse across it in a given time period. In healthy lungs, the alveolar surface area is enormous. Spread flat, the total gas exchange surface of these tiny sacs in an adult male's lungs is about 90 m^2—approximately 40 times greater than the surface area of his skin!

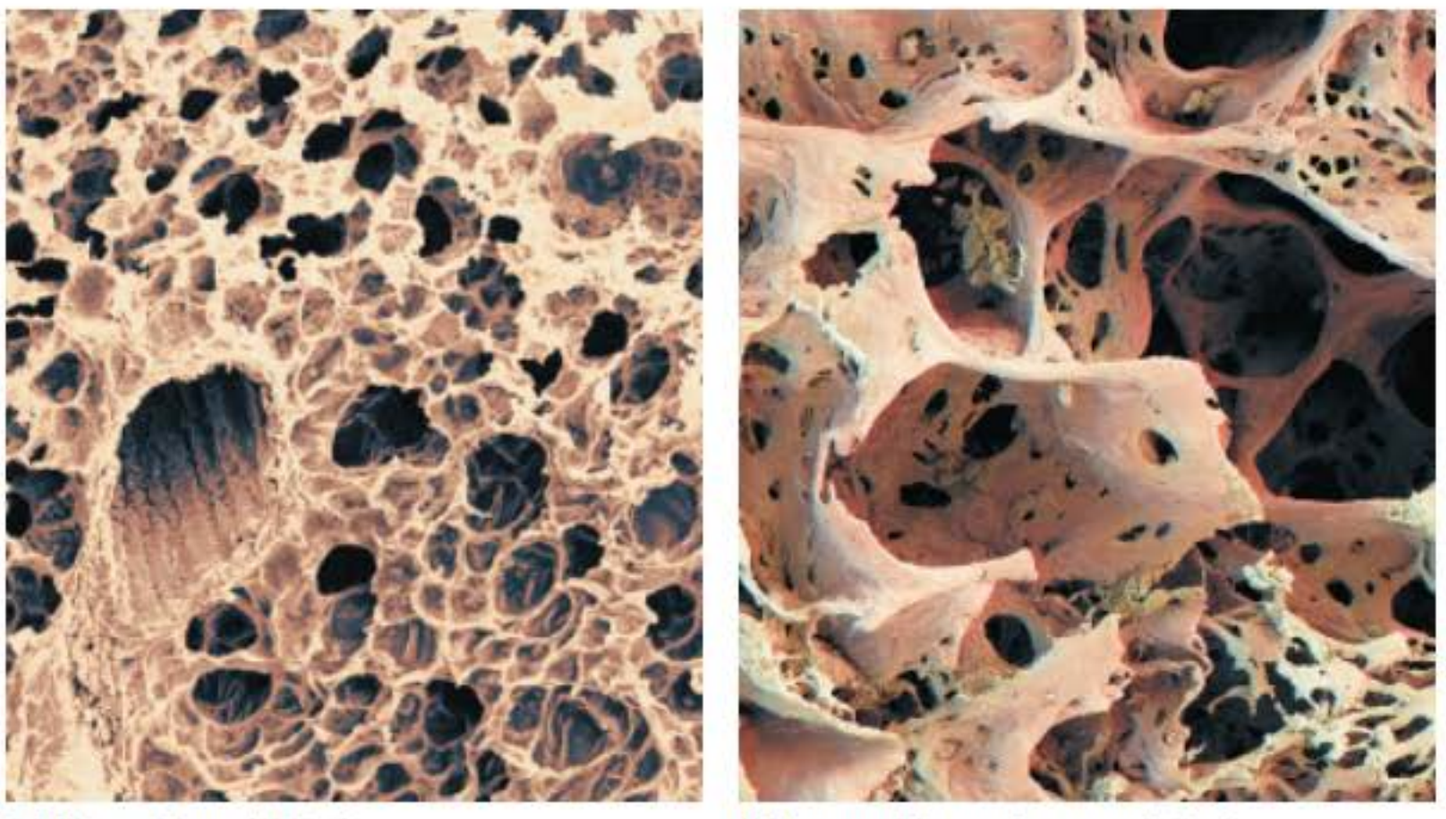
HOMEOSTATIC IMBALANCE 22.14 CLINICAL

Certain pulmonary diseases drastically reduce the alveolar surface area. For instance, in *emphysema* the walls of adjacent alveoli break down and the alveolar chambers enlarge (**Figure 22.22**). Tumors, mucus, or inflammatory material also reduce surface area by blocking gas flow into the alveoli.

Ventilation-Perfusion Coupling

For optimal gas exchange, there must be a close match, or coupling, between *ventilation* (the amount of gas reaching the alveoli) and *perfusion* (the blood flow in pulmonary capillaries). Both are controlled by local autoregulatory mechanisms that continuously respond to local conditions. For the most part:

- P_{O_2} controls perfusion by changing *arteriolar* diameter.
- P_{CO_2} controls ventilation by changing *bronchiolar* diameter.



(a) Normal lung (150×) **(b) Lung with emphysema** (150×)

Figure 22.22 Tissue changes in emphysema. Scanning electron micrographs. Notice the enlargement of the alveoli due to the destruction of alveolar walls.

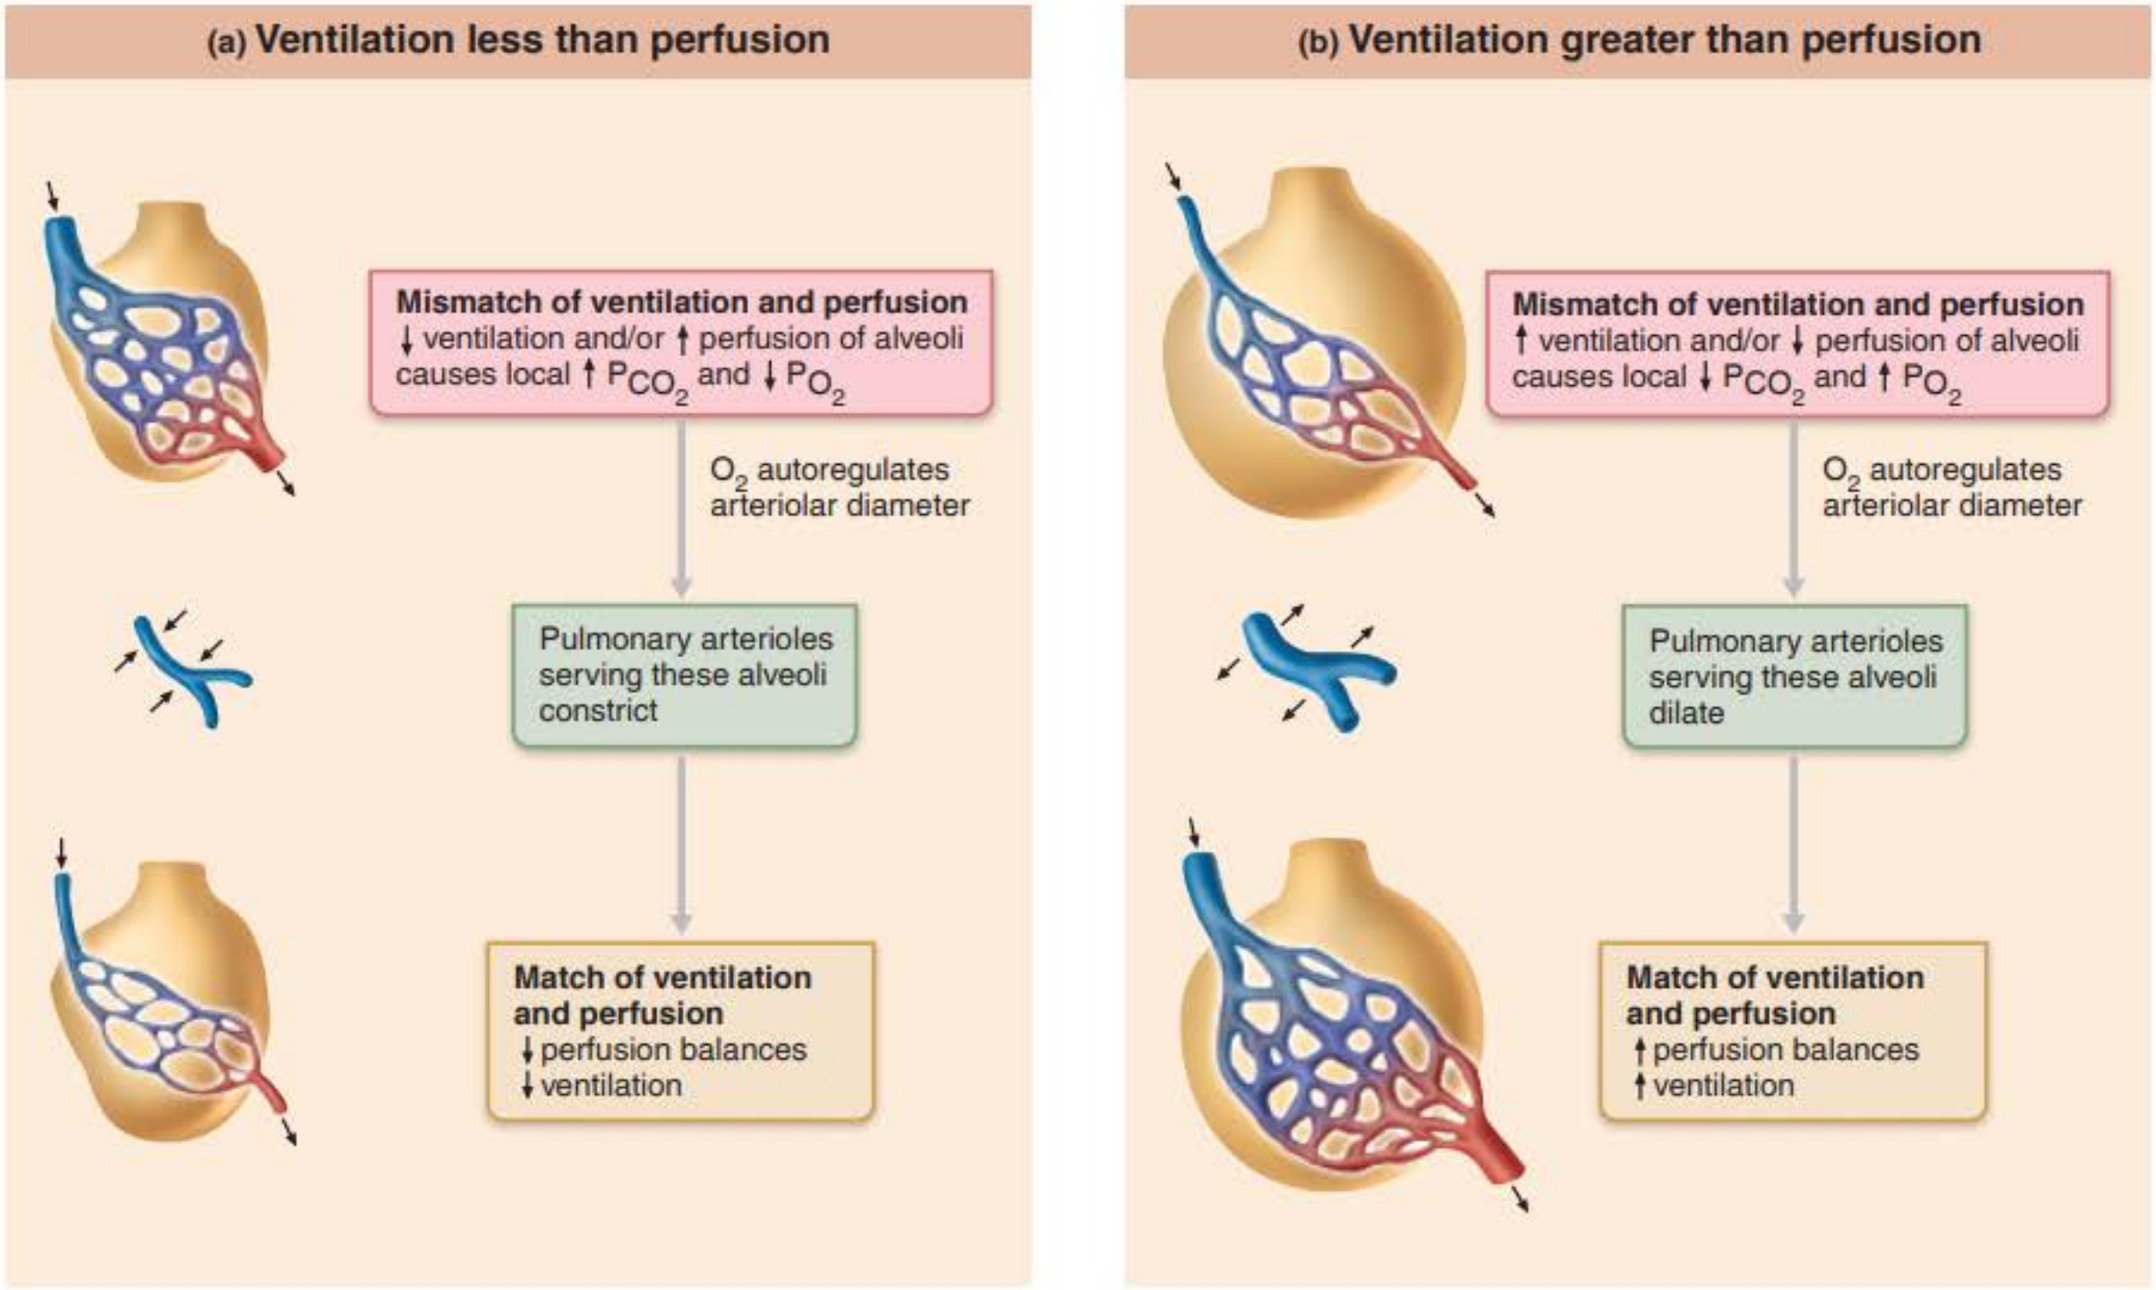


Figure 22.23 Ventilation-perfusion coupling. Autoregulatory events result in local matching of blood flow (perfusion) through the pulmonary capillaries with the amount of alveolar ventilation.

Influence of Local P_{O_2} on Perfusion We begin with perfusion because we introduced its autoregulatory control in Chapter 19 (◀ p. 729). If alveolar ventilation is inadequate, local P_{O_2} is low because blood takes O_2 away more quickly than ventilation can replenish it (**Figure 22.23a**). As a result, the terminal arterioles constrict, redirecting blood to respiratory areas where P_{O_2} is high and oxygen pickup is more efficient.

In alveoli where ventilation is maximal, high P_{O_2} dilates pulmonary arterioles and blood flow into the associated pulmonary capillaries increases (Figure 22.23b). Notice that the autoregulatory mechanism controlling pulmonary vascular muscle is the opposite of the mechanism controlling arterioles in the systemic circulation.

Influence of Local P_{CO_2} on Ventilation Bronchioles servicing areas where alveolar CO_2 levels are high dilate, allowing CO_2 to be eliminated from the body more rapidly. Bronchioles serving areas where P_{CO_2} is low constrict.

Balancing Ventilation and Perfusion The changing diameter of local bronchioles and arterioles synchronizes alveolar ventilation and pulmonary perfusion. Poor alveolar ventilation results in low oxygen and high carbon dioxide levels in the alveoli. Consequently, pulmonary arterioles constrict and airways dilate, bringing blood flow and air flow into closer physiological match. High P_{O_2} and low P_{CO_2} in the alveoli cause bronchioles serving the alveoli to constrict, and promote flushing of blood into the pulmonary capillaries.

Although these homeostatic mechanisms provide appropriate conditions for efficient gas exchange, they never completely balance ventilation and perfusion in every alveolus due to other factors. In particular, (1) gravity causes regional variations in blood and air flow in the lungs, and (2) the occasional alveolar duct plugged with mucus creates unventilated areas. These factors, together with blood shunted from the bronchial veins, account for the slight drop in P_{O_2} from alveolar air (104 mm Hg) to pulmonary venous blood (100 mm Hg), as shown in Figure 22.20.

Internal Respiration

Internal respiration involves capillary gas exchange in body tissues. In internal respiration, the partial pressure and diffusion gradients are reversed from the situation we have just described for external respiration and pulmonary gas exchange. However, the factors promoting gas exchanges between systemic capillaries and tissue cells are essentially identical to those acting in the lungs (see Figure 22.20).

Tissue cells continuously use O_2 for their metabolic activities and produce CO_2. Because P_{O_2} is always lower in tissues than

it is in systemic arterial blood (40 mm Hg versus 100 mm Hg), O_2 moves rapidly from blood into tissues until equilibrium is reached. At the same time, CO_2 moves quickly along its pressure gradient into blood. As a result, venous blood draining the tissue capillary beds and returning to the heart has a P_{O_2} of 40 mm Hg and a P_{CO_2} of 45 mm Hg.

In summary, the gas exchanges that occur between blood and alveoli and between blood and tissue cells take place by simple diffusion. They are driven by the partial pressure gradients of O_2 and CO_2 that exist on the opposite sides of the exchange membranes.

Check Your Understanding

17. P_{O_2} in the alveoli is about 56 mm Hg lower than in the inspired air. Explain this difference.

18. Suppose a patient is receiving oxygen by mask. Are the arterioles leading into the O_2-enriched alveoli dilated or constricted? What is the advantage of this response?

19. WHAT IF? Suppose you are given a sealed container of water and air. The P_{CO_2} and P_{O_2} in the air are both 100 mm Hg. What are the P_{CO_2} and P_{O_2} in the water? Which gas has more molecules dissolved in the water? Why?

For answers, see Answers Appendix.

22.7 Oxygen is transported by hemoglobin, and carbon dioxide is transported in three different ways

Learning Outcomes

- **Describe how oxygen is transported in blood.**
- **Explain how temperature, pH, BPG, and P_{CO_2} affect oxygen loading and unloading.**
- **Describe carbon dioxide transport in the blood.**

We have considered external and internal respiration consecutively to emphasize their similarities, but keep in mind that it is blood that transports O_2 and CO_2 between these two exchange sites.

Oxygen Transport

Molecular oxygen is carried in blood in two ways: bound to hemoglobin within red blood cells and dissolved in plasma. Oxygen is poorly soluble in water, so only about 1.5% of the oxygen transported is carried in the dissolved form. Indeed, if this were the *only* means of oxygen transport, a P_{O_2} of 3 atm or a cardiac output of 15 times normal would be required to provide the oxygen levels needed by body tissues! Hemoglobin, of course, solves this problem—98.5% of the oxygen is carried from lungs to tissues in a loose chemical combination with hemoglobin.

Association of Oxygen and Hemoglobin

As we described in Chapter 17, hemoglobin (Hb) is composed of four polypeptide chains, each bound to an iron-containing heme group (◀ Figure 17.4, p. 646). Because the iron atoms bind oxygen, each hemoglobin molecule can combine with four molecules of O_2, and oxygen loading is rapid and reversible.

The hemoglobin-oxygen combination, called **oxyhemoglobin** (ok″sĭ-he″mo-glo′bin), is written **HbO_2**. Hemoglobin that has released oxygen is called **reduced hemoglobin**, or **deoxyhemoglobin**, and is written **HHb**. A single reversible equation describes the loading and unloading of O_2:

$$HHb + O_2 \underset{\text{Tissues}}{\overset{\text{Lungs}}{\rightleftharpoons}} HbO_2 + H^+$$

After the first O_2 molecule binds to iron, the Hb molecule changes shape. As a result, it more readily takes up two more O_2 molecules, and uptake of the fourth is even more facilitated. When one, two, or three oxygen molecules are bound, a hemoglobin molecule is *partially saturated*. When all four of its heme groups are bound to O_2, the hemoglobin is *fully saturated*.

By the same token, unloading of one oxygen molecule enhances the unloading of the next, and so on. In this way, the *affinity* (binding strength) of hemoglobin for oxygen changes with the extent of oxygen saturation, and both loading and unloading of oxygen are very efficient.

The rate at which Hb reversibly binds or releases O_2 is regulated by P_{O_2}, temperature, blood pH, P_{CO_2}, and blood concentration of an organic chemical called BPG. These factors interact to ensure that adequate O_2 is delivered to tissue cells.

Influence of P_{O_2} on Hemoglobin Saturation The **oxygen-hemoglobin dissociation curve** shows how local P_{O_2} controls oxygen loading and unloading from hemoglobin. *Focus on the Oxygen-Hemoglobin Dissociation Curve* (**Focus Figure 22.1** on pp. 848–849) walks you through this graph step by step, explaining how hemoglobin ensures adequate oxygen delivery under a variety of conditions.

Under normal resting conditions (P_{O_2} = 100 mm Hg), arterial blood hemoglobin is 98% saturated, and 100 ml of systemic arterial blood contains about 20 ml of O_2. This *oxygen content* of arterial blood is written as 20 vol % (volume percent). As arterial blood flows through systemic capillaries, it releases about 5 ml of O_2 per 100 ml of blood, yielding an Hb saturation of 75% and an O_2 content of 15 vol % in venous blood. This means that substantial amounts of O_2 are normally still available in venous blood (the *venous reserve*), which can be used if needed.

The nearly complete saturation of Hb in arterial blood explains why breathing deeply increases both the alveolar and arterial blood P_{O_2} but causes very little increase in the O_2 saturation of hemoglobin. Remember, P_{O_2} measurements indicate only the amount of O_2 dissolved in plasma, not the amount bound to hemoglobin. However, P_{O_2} values are a good index of lung function, and when arterial P_{O_2} is significantly less than alveolar P_{O_2} some degree of respiratory impairment exists.

Influence of Other Factors on Hemoglobin Saturation Temperature, blood pH, P_{CO_2}, and the amount of BPG in the blood all influence hemoglobin saturation at a given P_{O_2}. Red blood cells (RBCs) produce BPG (2,3-bisphosphoglycerate) as they

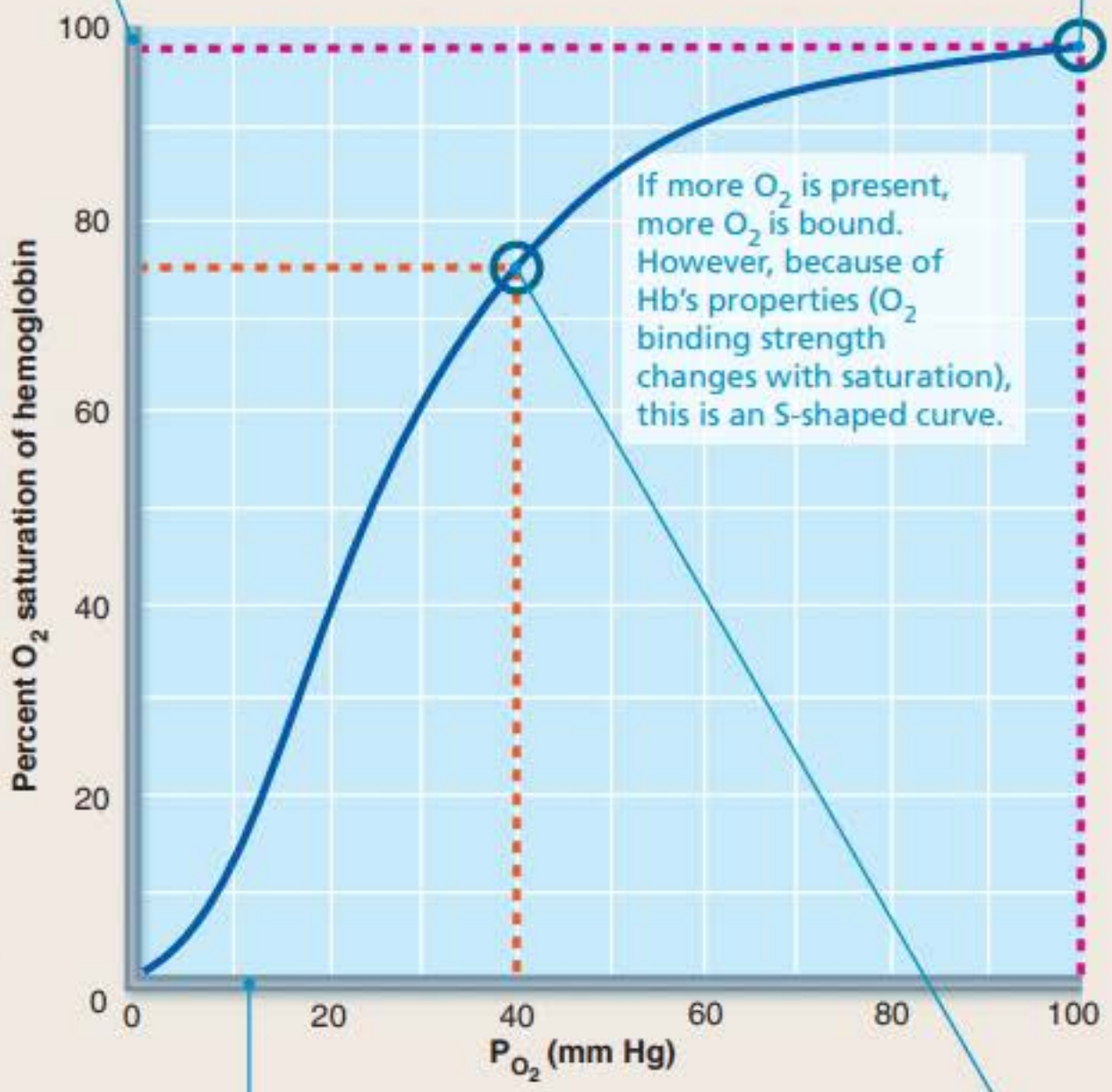
(Text continues on p. 850.)

FOCUS FIGURE 22.1 The Oxygen-Hemoglobin Dissociation Curve

The amount of oxygen carried by hemoglobin depends on the P_{O_2} (the amount of oxygen) available locally. This relationship ensures optimal oxygen pickup and delivery.

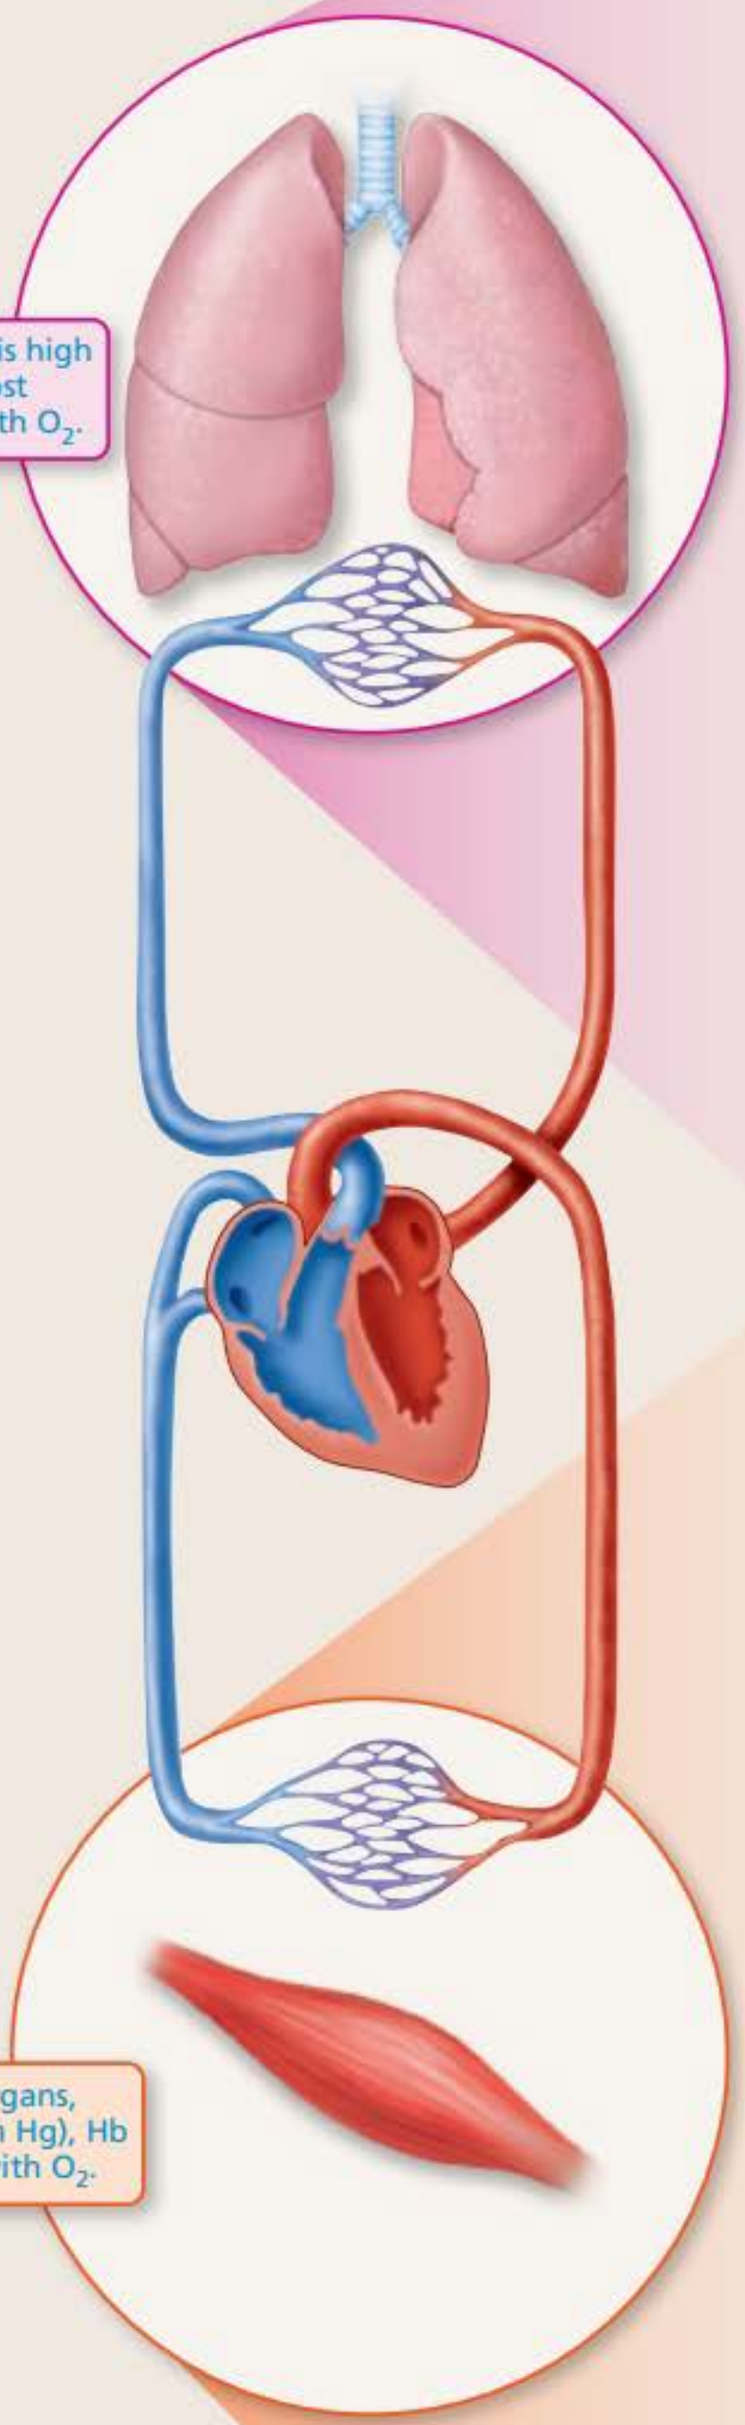
The oxygen-hemoglobin dissociation curve will help you understand how the properties of hemoglobin (Hb) affect oxygen binding in the lungs and oxygen release in the tissues.

This axis tells you how much O_2 is bound to Hb. At 100%, each Hb molecule has 4 bound oxygen molecules.



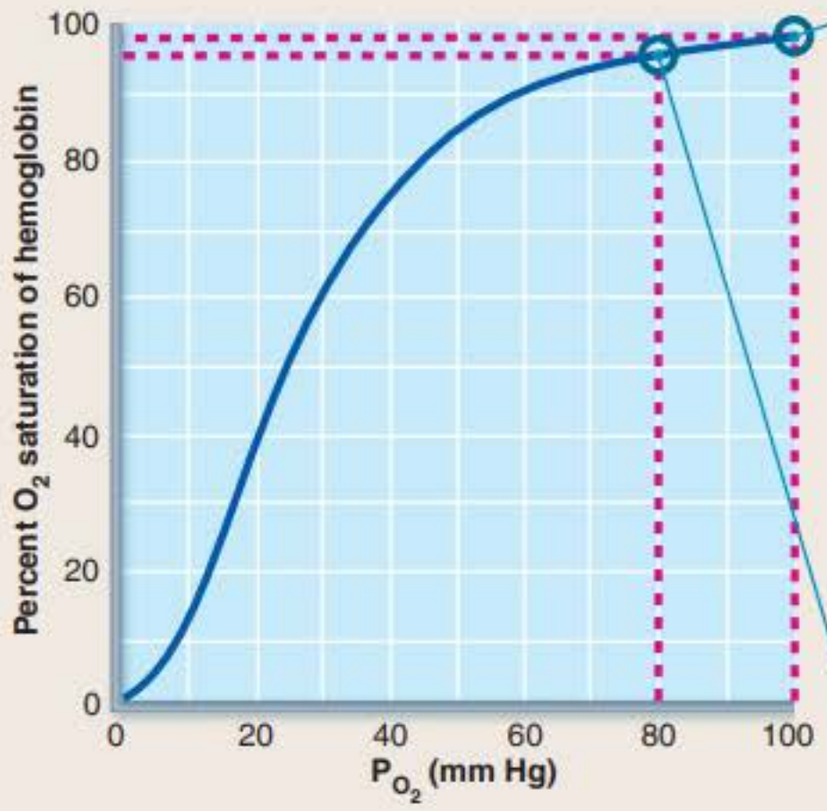
This axis tells you the relative amount (partial pressure) of O_2 dissolved in the fluid surrounding the Hb.

In the lungs, where P_{O_2} is high (100 mm Hg), Hb is almost fully saturated (98%) with O_2.



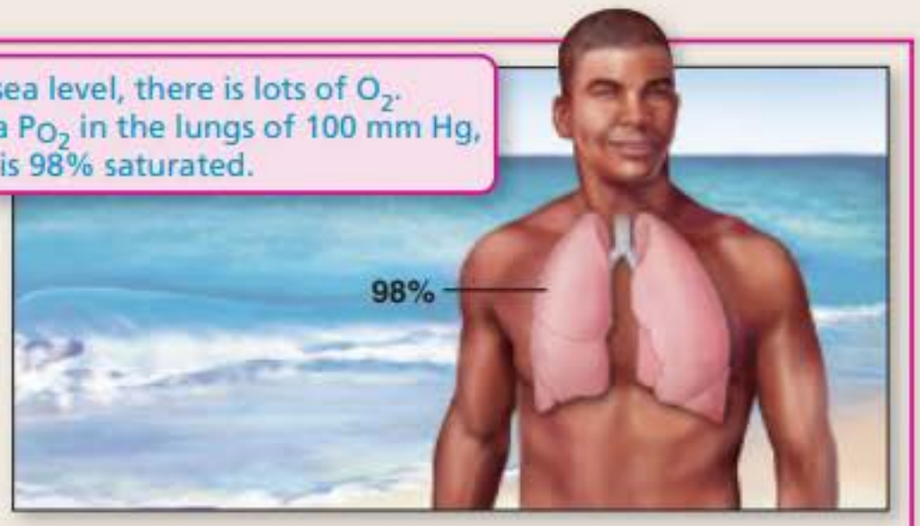
In the tissues of other organs, where P_{O_2} is low (40 mm Hg), Hb is less saturated (75%) with O_2.

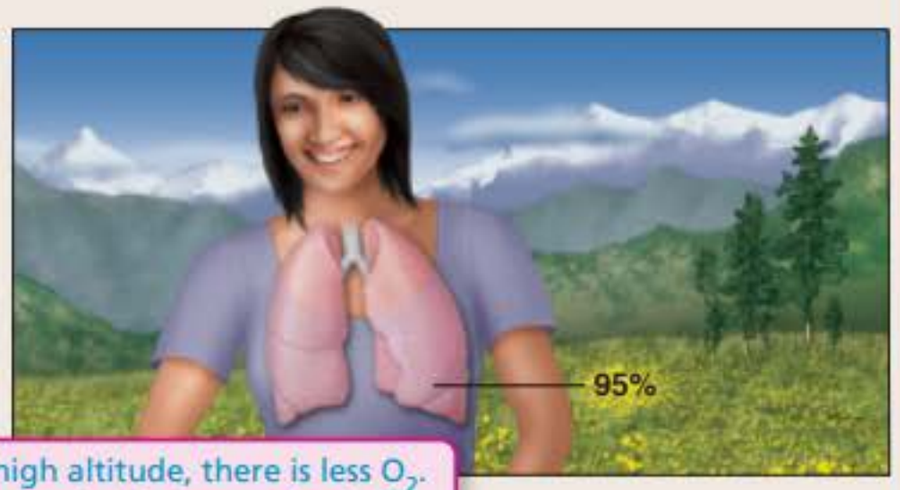
In the lungs



At high P_{O_2}, large changes in P_{O_2} cause only small changes in Hb saturation. Notice that the curve is relatively flat here. Hb's properties produce a *safety margin* that ensures that Hb is almost fully saturated even with a substantial P_{O_2} decrease. As a result, Hb remains saturated even at high altitude or with lung disease.

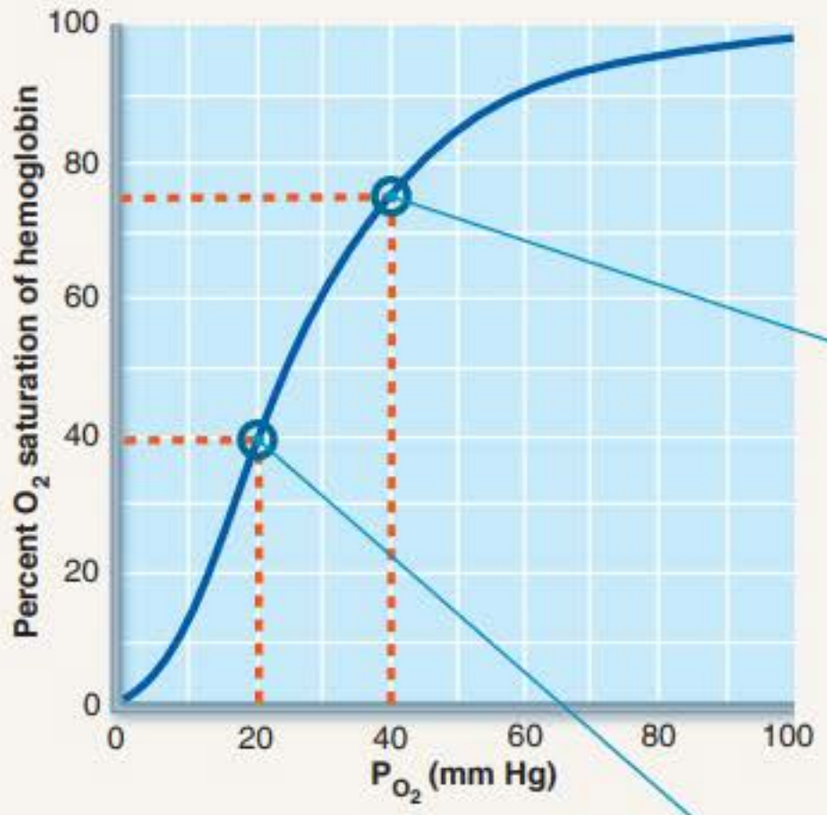
At sea level, there is lots of O_2. At a P_{O_2} in the lungs of 100 mm Hg, Hb is 98% saturated.





At high altitude, there is less O_2. At a P_{O_2} in the lungs of only 80 mm Hg, Hb is still 95% saturated.

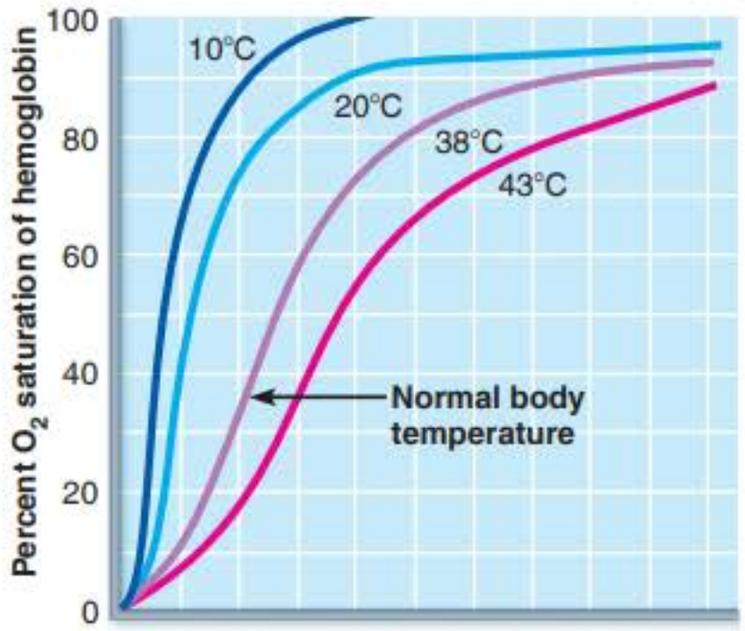
In the tissues



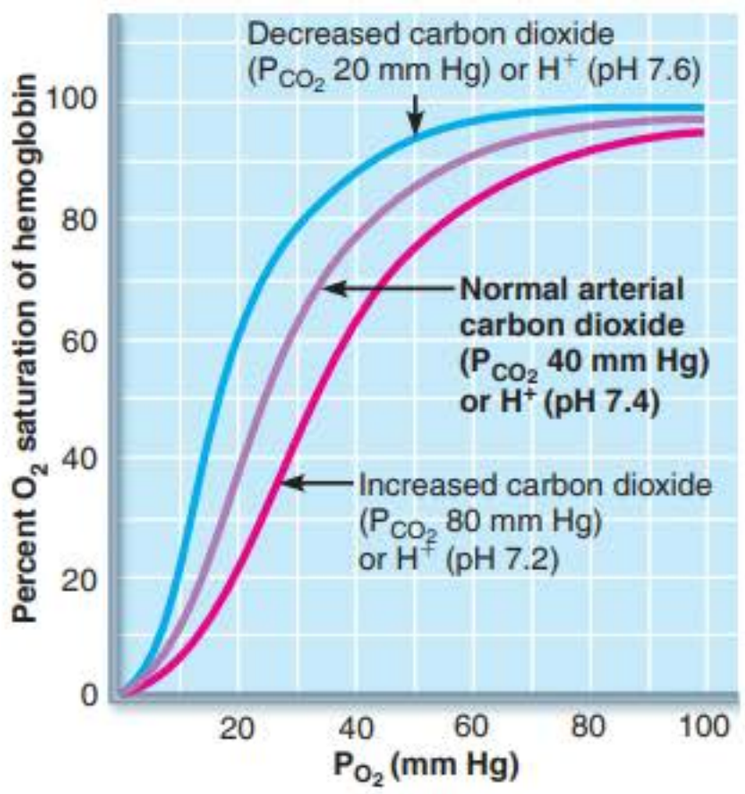
At low P_{O_2}, large changes in P_{O_2} cause large changes in Hb saturation. Tissues other than lungs have a low P_{O_2} because they consume O_2. Notice that the curve is relatively steep at low P_{O_2}. Hb's properties ensure that oxygen is delivered where it is most needed—when tissues need more, they get more.

In resting tissues, at a P_{O_2} of 40 mm Hg, Hb is 75% saturated—only 23% of O_2 carried by Hb is released.

In metabolically active tissues (e.g., exercising muscle), the P_{O_2} is even lower. At a P_{O_2} of 20 mm Hg, Hb is only 40% saturated—an additional 35% of O_2 has been unloaded for tissue use.



(a)



(b)

Figure 22.24 Effect of temperature, P_{CO_2}, and blood pH on the oxygen-hemoglobin dissociation curve. Oxygen unloading is enhanced by **(a)** increased temperature, **(b)** increased P_{CO_2}, and/or hydrogen ion concentration (decreased pH), causing the dissociation curve to shift to the right. This response is called the Bohr effect.

metabolize glucose. BPG binds reversibly with hemoglobin, and its levels rise when oxygen levels are chronically low.

All of these factors influence Hb saturation by modifying hemoglobin's three-dimensional structure, thereby changing its affinity for O_2. An *increase* in temperature, P_{CO_2}, H^+, or BPG levels in blood lowers Hb's affinity for O_2, enhancing oxygen unloading from the blood. This is shown by the rightward shift of the oxygen-hemoglobin dissociation curve in **Figure 22.24**.

Conversely, a *decrease* in any of these factors increases hemoglobin's affinity for oxygen, decreasing oxygen unloading. This change shifts the dissociation curve to the left.

If you give a little thought to how these factors are related, you'll realize that they all tend to be highest in the systemic capillaries, where oxygen unloading is the goal. As cells metabolize glucose and use O_2, they release CO_2, which increases the P_{CO_2} and H^+ levels in capillary blood. Both declining blood pH (acidosis) and increasing P_{CO_2} weaken the Hb-O_2 bond, a phenomenon called the **Bohr effect**. This enhances oxygen unloading where it is most needed.

Heat is a by-product of metabolic activity, and active tissues are warmer than less active ones. A rise in temperature decreases hemoglobin's affinity for O_2 both directly and indirectly (via its influence on RBC metabolism and BPG synthesis). Collectively, these factors see to it that Hb unloads much more O_2 in the vicinity of hard-working tissue cells.

Carbon Dioxide Transport

Normally active body cells produce about 200 ml of CO_2 each minute—exactly the amount excreted by the lungs. Blood transports CO_2 from the tissue cells to the lungs in three forms (**Figure 22.25**):

1. **Dissolved in plasma** (7–10%). The smallest amount of CO_2 is transported simply dissolved in plasma.
2. **Chemically bound to hemoglobin** (just over 20%). Dissolved CO_2 is bound and carried in the RBCs as **carbaminohemoglobin** (kar-bam″ĭ-no-he″mo-glo′bin):

$$CO_2 + Hb \rightleftharpoons HbCO_2$$

carbaminohemoglobin

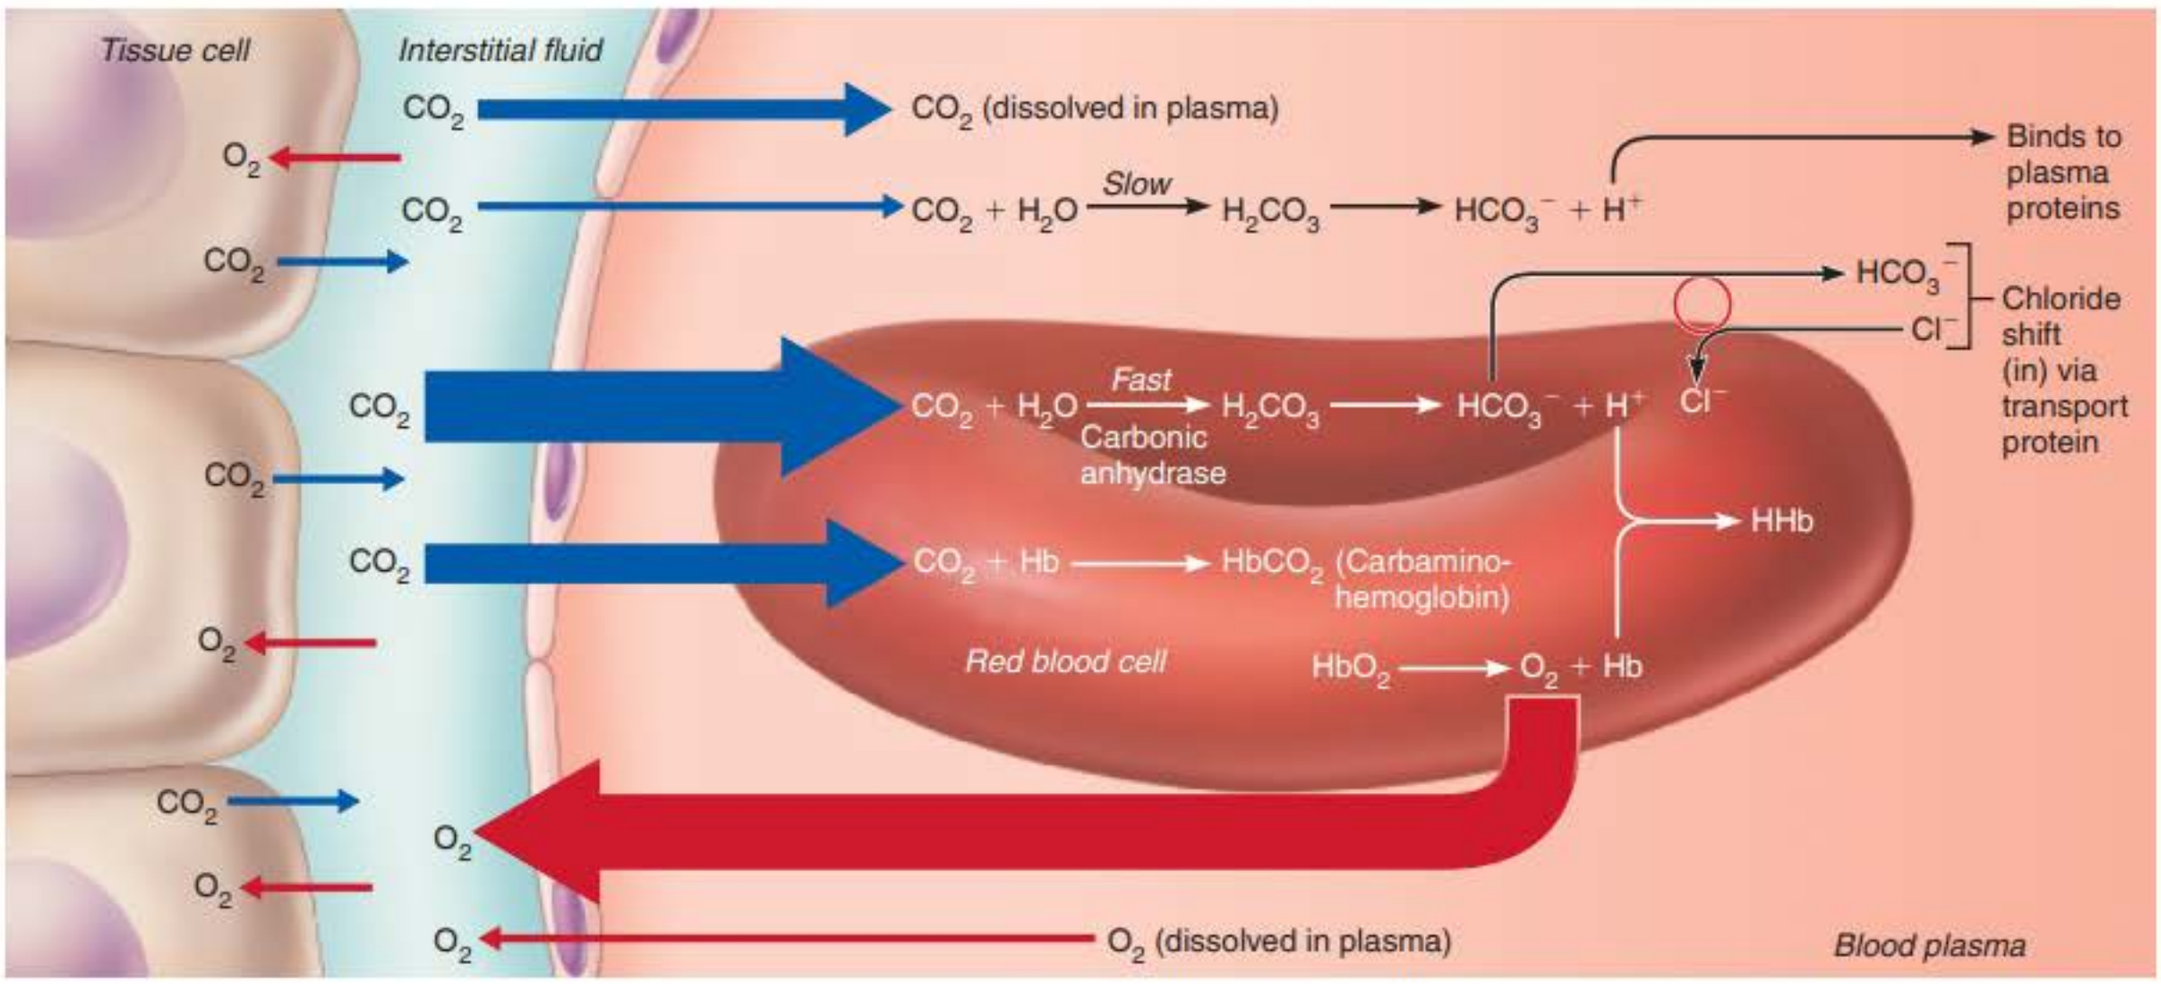
This reaction is rapid and does not require a catalyst. Carbon dioxide transport in RBCs does not compete with oxyhemoglobin transport because carbon dioxide binds directly to the amino acids of globin (not to the heme).

CO_2 loading and unloading are directly influenced by the P_{CO_2} and the degree of Hb oxygenation. Carbon dioxide rapidly dissociates from hemoglobin in the lungs, where the P_{CO_2} of alveolar air is lower than that in blood. Carbon dioxide readily binds with hemoglobin in the tissues, where the P_{CO_2} is higher than that in blood. Deoxygenated hemoglobin combines more readily with carbon dioxide than does oxygenated hemoglobin, as we will see in the discussion of the Haldane effect below.

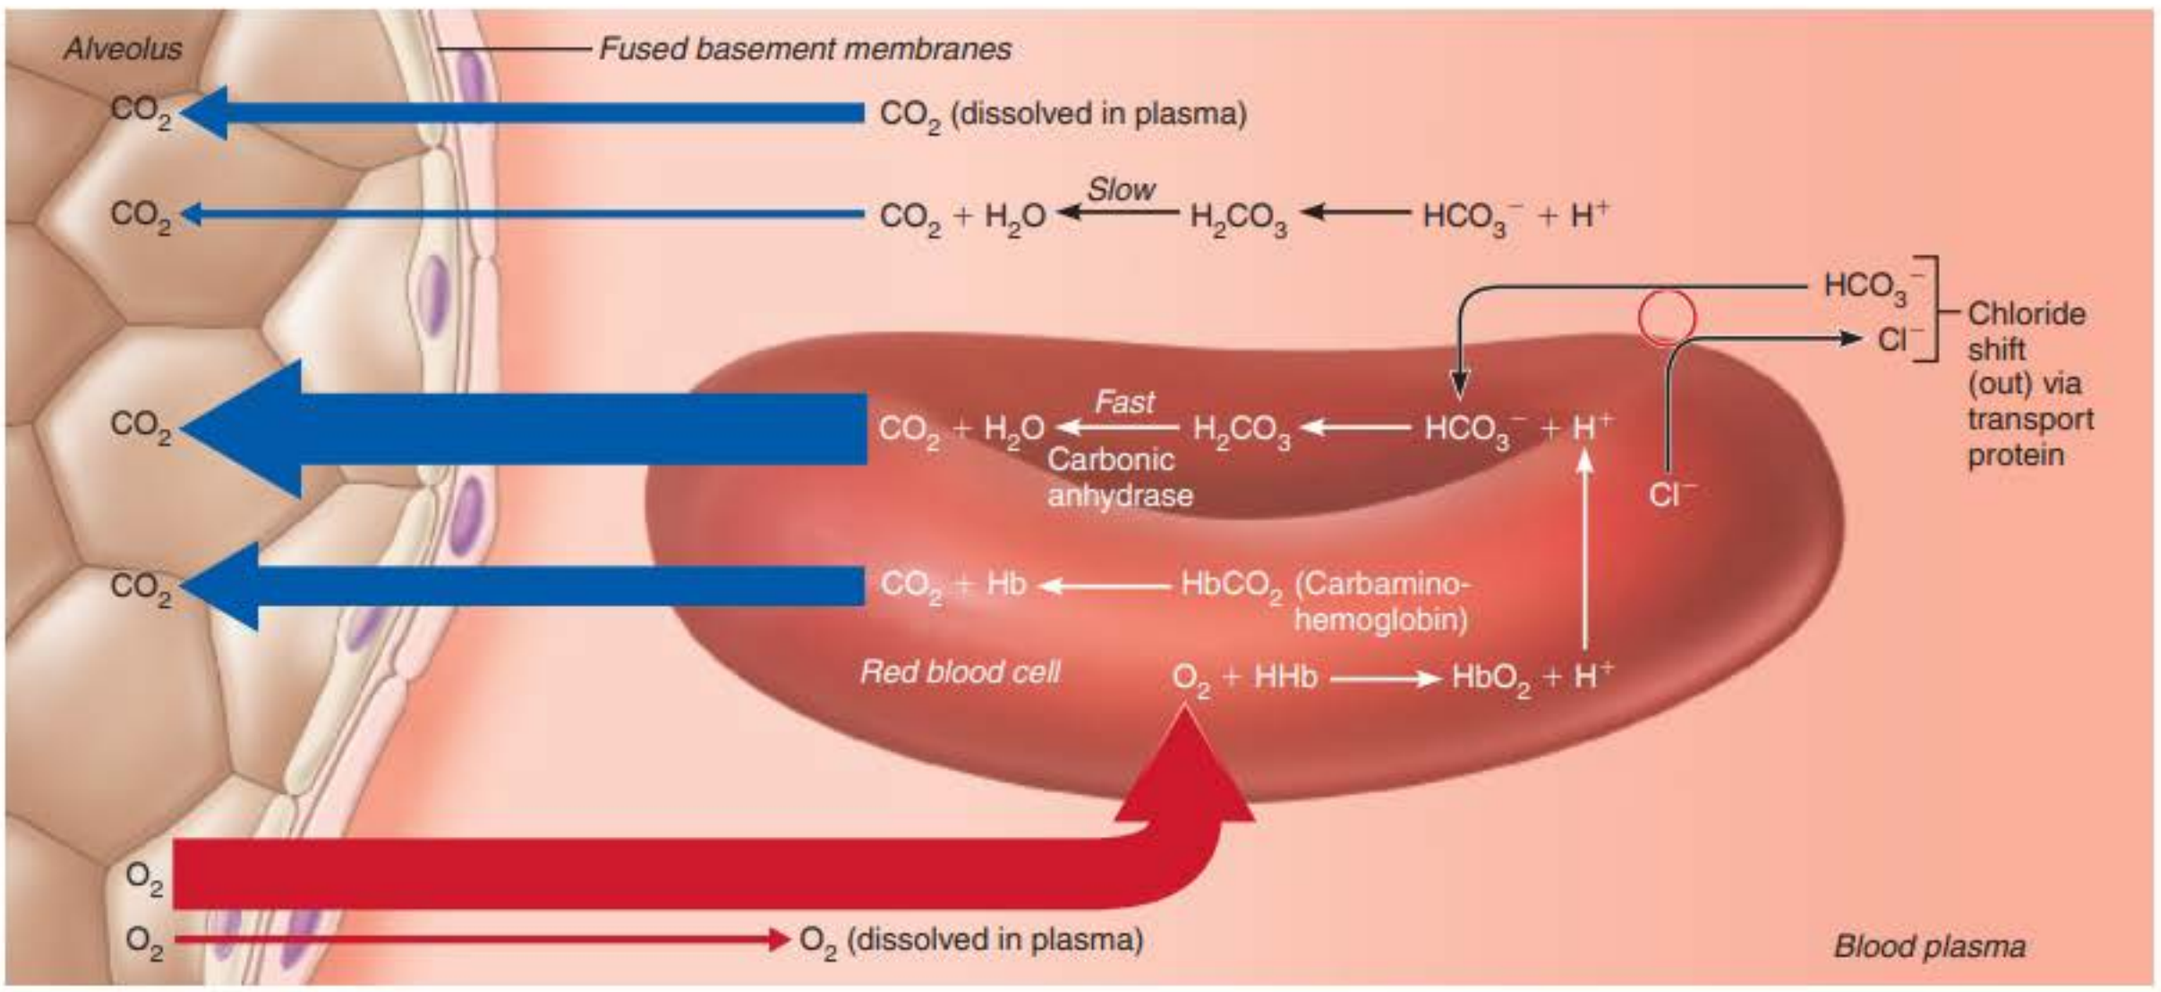
3. **As bicarbonate ions in plasma** (about 70%). Most carbon dioxide molecules entering the plasma quickly enter RBCs. The reactions that convert carbon dioxide to **bicarbonate ions (HCO_3^-)** for transport mostly occur inside RBCs. As illustrated in Figure 22.25a, when dissolved CO_2 diffuses into RBCs, it combines with water, forming carbonic acid (H_2CO_3). H_2CO_3 is unstable and dissociates into hydrogen ions and bicarbonate ions:

$$\underset{\text{carbon dioxide}}{CO_2} + \underset{\text{water}}{H_2O} \rightleftharpoons \underset{\text{carbonic acid}}{H_2CO_3} \rightleftharpoons \underset{\text{hydrogen ion}}{H^+} + \underset{\text{bicarbonate ion}}{HCO_3^-}$$

Although this reaction also occurs in plasma, it is thousands of times faster in RBCs because they (and not plasma) contain **carbonic anhydrase** (kar-bon′ik an-hi′drās), an enzyme that reversibly catalyzes the conversion of carbon dioxide and water to carbonic acid. Hydrogen ions released during the reaction (as well as CO_2 itself) bind to Hb, triggering the Bohr effect. In this way CO_2 loading enhances O_2 release. Because of the buffering



(a) Oxygen release and carbon dioxide pickup at the tissues



(b) Oxygen pickup and carbon dioxide release in the lungs

Figure 22.25 Transport and exchange of CO_2 and O_2. Relative sizes of the transport arrows indicate the proportionate amounts of O_2 and CO_2 moved by each method. (H_2CO_3 = carbonic acid, HCO_3^- = bicarbonate, HHb = reduced hemoglobin, HbO_2 = oxyhemoglobin)

effect of Hb, the liberated H^+ causes little change in pH under resting conditions. As a result, blood becomes only slightly more acidic (the pH declines from 7.4 to 7.34) as it passes through the tissues.

Once generated, HCO_3^- moves quickly from the RBCs into the plasma, where it is carried to the lungs. To counterbalance the rapid outrush of these anions from the RBCs, chloride ions (Cl^-) move from the plasma into the RBCs. This ion exchange process, called the **chloride**

shift, occurs via facilitated diffusion through an RBC membrane protein.

In the lungs, the process is reversed (Figure 22.25b). As blood moves through the pulmonary capillaries, its P_{CO_2} declines from 45 mm Hg to 40 mm Hg. For this to occur, CO_2 must first be freed from its "bicarbonate housing." HCO_3^- reenters the RBCs (and Cl^- moves into the plasma) and binds with H^+ to form carbonic acid. Carbonic anhydrase then splits carbonic acid to release CO_2 and water. This CO_2, along with that released from hemoglobin and from solution in plasma, then diffuses along its partial pressure gradient from the blood into the alveoli.

The Haldane Effect

The amount of carbon dioxide transported in blood is markedly affected by the degree to which blood is oxygenated. The lower the P_{O_2} and the lower the Hb saturation with oxygen, the more CO_2 that blood can carry. This phenomenon, called the **Haldane effect**, reflects the greater ability of reduced hemoglobin to form carbaminohemoglobin and to buffer H^+ by combining with it. As CO_2 enters the systemic bloodstream, it causes more oxygen to dissociate from Hb (Bohr effect). The dissociation of O_2 allows more CO_2 to combine with Hb (Haldane effect).

The Haldane effect encourages CO_2 exchange in both the tissues and lungs. In the pulmonary circulation, the situation that we just described is reversed—uptake of O_2 facilitates release of CO_2 (Figure 22.25b). As Hb becomes saturated with O_2, the H^+ released combines with HCO_3^-, helping to unload CO_2 from the pulmonary blood.

Influence of CO_2 on Blood pH

Typically, the H^+ released during carbonic acid dissociation is buffered by Hb or other proteins within the RBCs or in plasma. The HCO_3^- generated in the red blood cells diffuses into the plasma, where it acts as the *alkaline reserve* (weak base) part of the blood's bicarbonate buffer system (◀ p. 41).

The **bicarbonate buffer system** is very important in resisting shifts in blood pH, as shown in the equation in point 3 concerning CO_2 transport (see p. 850). For example, if the hydrogen ion concentration in blood begins to rise, excess H^+ is removed by combining with HCO_3^- to form carbonic acid (a weak acid). If H^+ concentration in blood drops below desirable levels, carbonic acid dissociates, releasing hydrogen ions and lowering the pH again.

Changes in respiratory rate or depth can alter blood pH dramatically by altering the amount of carbonic acid in blood. Slow, shallow breathing allows CO_2 to accumulate in blood. As a result, carbonic acid levels increase and blood pH drops. Conversely, rapid, deep breathing quickly flushes CO_2 out of blood, reducing carbonic acid levels and increasing blood pH.

In this way, respiratory ventilation provides a fast-acting system to adjust blood pH (and P_{CO_2}) when it is disturbed by metabolic factors. Respiratory adjustments play a major role in the acid-base balance of the blood, as we will discuss in Chapter 26.

Hypoxia

CLINICAL

Inadequate oxygen delivery to body tissues is called **hypoxia** (hi-pok′se-ah). Hypoxia is more visible in fair-skinned people because their skin and mucosae take on a bluish cast (become *cyanotic*) when Hb saturation falls below 75%. The mucosae and nail beds are often the easiest places to observe this color change.

Hypoxia is classified based on cause:

- **Anemic hypoxia** reflects poor O_2 delivery resulting from too few RBCs or from RBCs that contain abnormal or too little Hb.
- **Ischemic (stagnant) hypoxia** results from impaired or blocked blood circulation.
- **Histotoxic hypoxia** occurs when body cells are unable to use O_2 even though adequate amounts are delivered. Metabolic poisons, such as cyanide, can cause histotoxic hypoxia.
- **Hypoxemic hypoxia** is indicated by reduced arterial P_{O_2}. Possible causes include disordered or abnormal ventilation-perfusion coupling, pulmonary diseases that impair ventilation, and breathing air containing scant amounts of O_2.
- **Carbon monoxide poisoning** is a unique type of hypoxemic hypoxia and a leading cause of death from fire. Carbon monoxide (CO) is an odorless, colorless gas. Because Hb's affinity for CO is more than 200 times greater than its affinity for oxygen, CO outcompetes O_2 for the heme binding sites. Even at minuscule partial pressures, carbon monoxide can drastically reduce hemoglobin's ability to carry O_2.

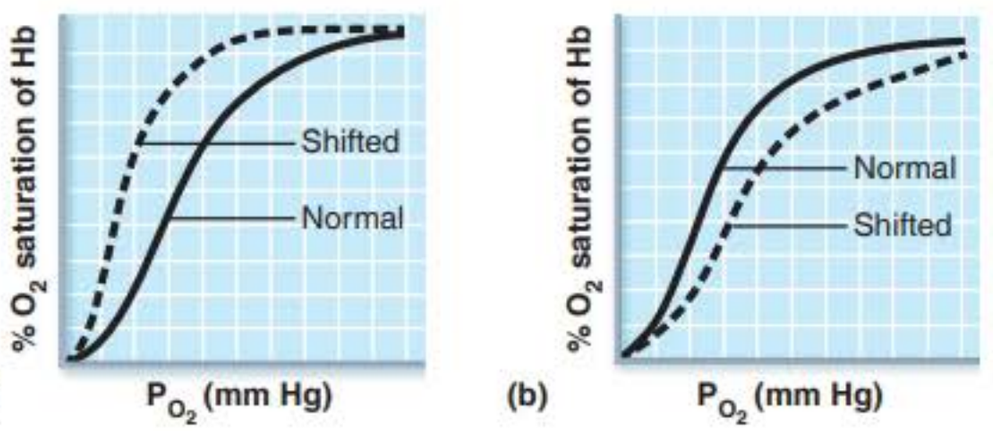
  CO poisoning is particularly dangerous because it does not produce the characteristic signs of hypoxia—cyanosis and respiratory distress. Instead the victim is confused and has a throbbing headache. In rare cases, fair skin becomes cherry red. Patients with CO poisoning are given hyperbaric therapy (if available) or 100% O_2 until the CO has been cleared from the body.

Check Your Understanding

20. List the three ways CO_2 is transported in blood.

21. What is the relationship between CO_2 and pH in the blood? Explain.

22. The dotted lines in the two graphs below represent a shift in the oxygen-hemoglobin dissociation curve. Which shift would allow more oxygen delivery to the tissues? [Hint: Ask yourself which curve allows Hb to "let go" of more O_2 (hold *less* O_2).] Name three conditions in the tissues that would cause the curve to shift this way.



For answers, see Answers Appendix.

22.8 Respiratory centers in the brain stem control breathing with input from chemoreceptors and higher brain centers

Learning Outcomes

- **Describe the neural controls of respiration.**
- **Compare and contrast the influences of arterial pH, arterial partial pressures of oxygen and carbon dioxide, lung reflexes, volition, and emotions on respiratory rate and depth.**

Although our tidelike breathing seems so beautifully simple, its control is more complex than you might think. Higher brain centers, chemoreceptors, and other reflexes all modify the basic respiratory rhythms generated in the brain stem.

Neural Mechanisms

Control of respiration primarily involves neurons in the reticular formation of the medulla and pons. Because the medulla sets the respiratory rhythm, we will begin there.

Medullary Respiratory Centers

Clustered neurons in two areas of the medulla oblongata appear to be critically important in respiration (**Figure 22.26**). These are:

- The **ventral respiratory group (VRG)**, a network of neurons that extends in the ventral brain stem from the spinal cord to the pons-medulla junction
- The **dorsal respiratory group (DRG)**, located dorsally near the root of cranial nerve IX

Ventral Respiratory Group (VRG) The VRG appears to be a rhythm-generating and integrative center. It contains groups of neurons that fire during inspiration and others that fire during expiration in a dance of mutual inhibition. (Recent evidence suggests that forced expiration and passive expiration may involve separate groups of neurons.)

When its inspiratory neurons fire, a burst of impulses travels along the **phrenic** and **intercostal nerves** to excite the diaphragm and external intercostal muscles, respectively (Figure 22.26). As a result, the thorax expands and air rushes into the lungs. When the VRG's expiratory neurons fire, the output stops, and expiration occurs as the inspiratory muscles relax and the lungs recoil.

This cyclic on/off activity of the inspiratory and expiratory neurons repeats continuously and produces a respiratory rate of 12–16 breaths per minute, with inspiratory phases lasting about 2 seconds followed by expiratory phases lasting about 3 seconds. This normal respiratory rate and rhythm is called **eupnea** (ūp-ne′ah; *eu* = good, *pne* = breath).

During severe hypoxia, VRG networks generate gasping (perhaps in a last-ditch effort to restore O_2 to the brain). Respiration stops when a certain cluster of VRG neurons is completely suppressed, as by an overdose of morphine or alcohol.

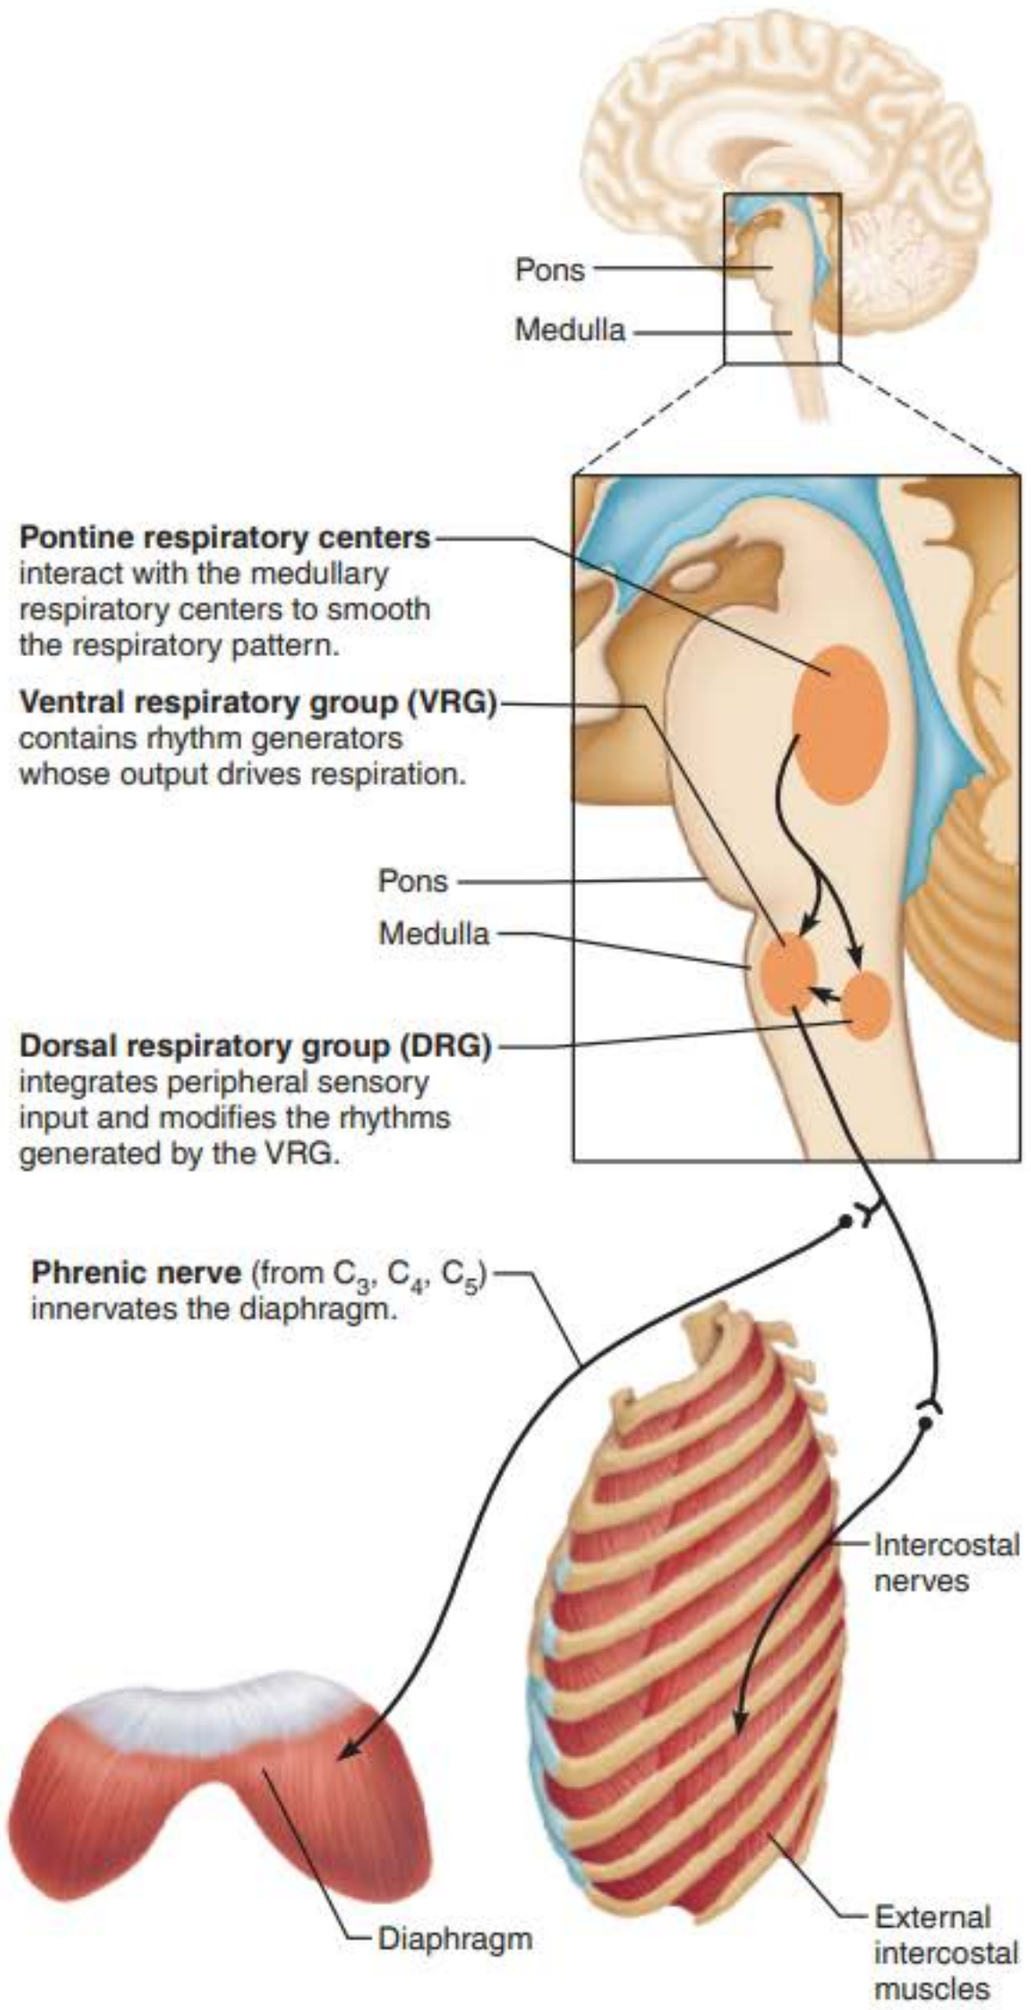


Figure 22.26 Respiratory centers in the brain stem. The synapses in the spinal cord with somatic motor neurons to the inspiratory muscles are shown schematically.

Dorsal Respiratory Group (DRG) Until recently, it was thought that the DRG acts as an inspiratory center, performing many of the tasks now known to be performed by the VRG. In almost all mammals, including humans, the DRG integrates input from peripheral stretch and chemoreceptors (which we will describe shortly) and communicates this information to the VRG. It may seem surprising, but many of the details of this system so essential to life are still being worked out.

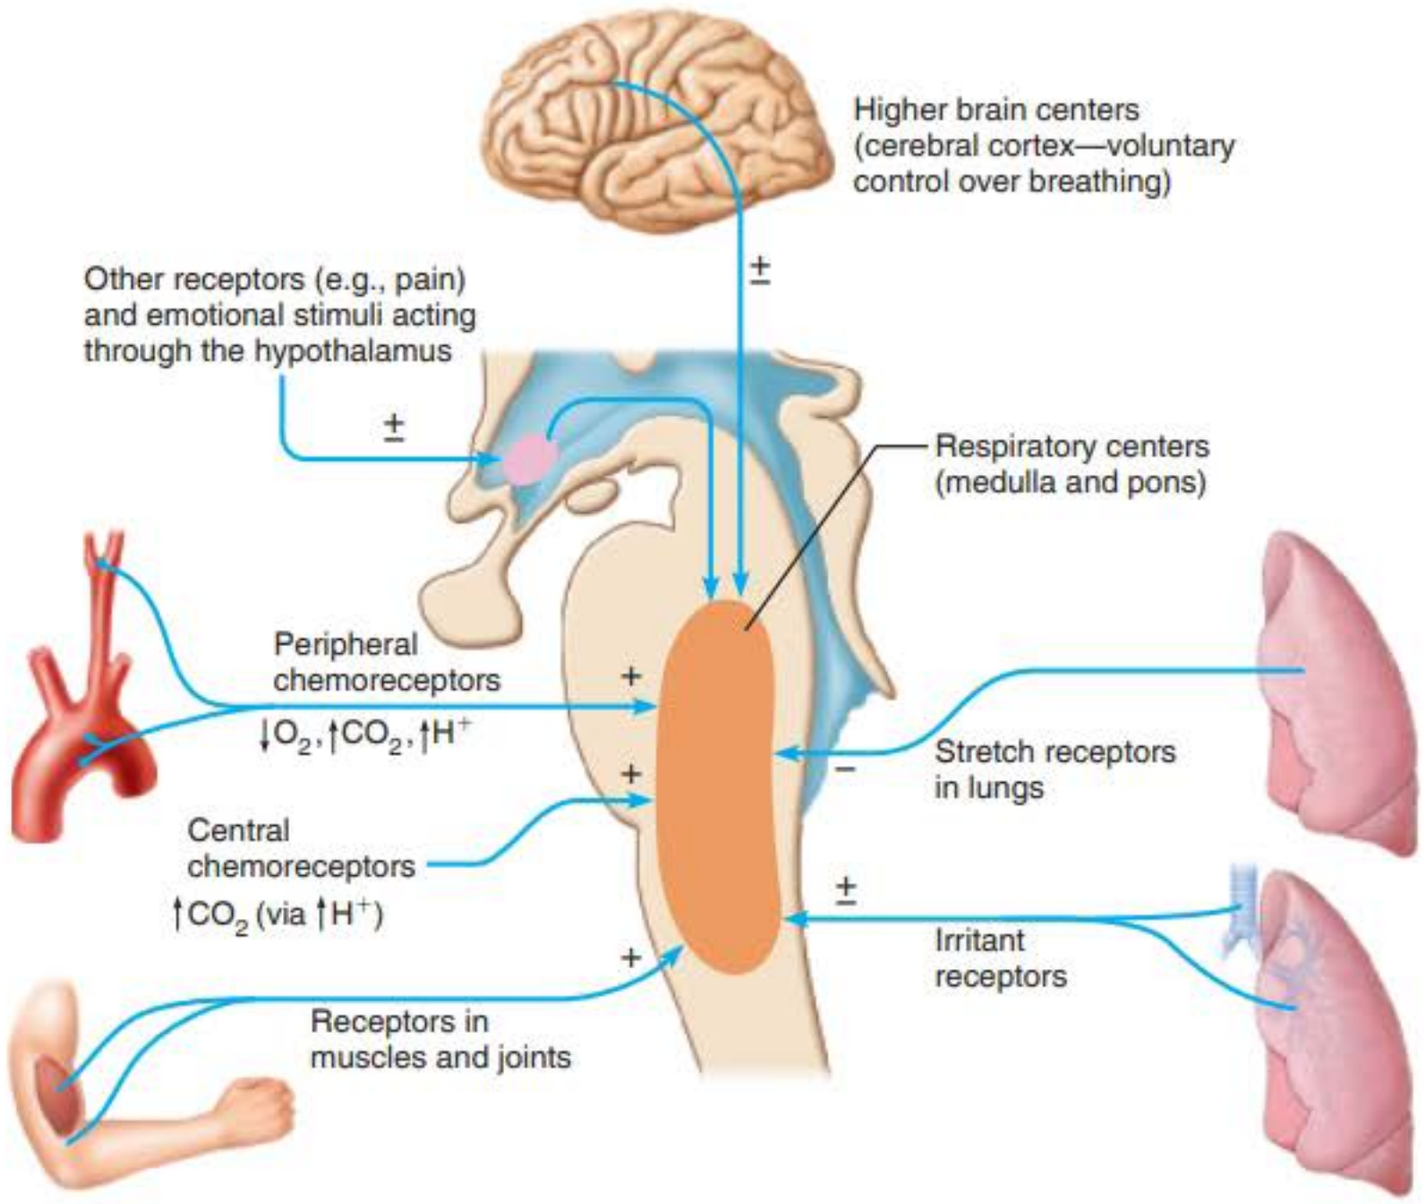

Figure 22.27 Neural and chemical influences on brain stem respiratory centers. Excitatory influences (+) increase the frequency of impulses sent to the muscles of respiration and recruit additional motor units, resulting in deeper, faster breathing. Inhibitory influences (–) have the reverse effect. In some cases, the influences may be excitatory or inhibitory (±), depending on which receptors or brain regions are activated. The cerebral cortex also directly innervates respiratory muscle motor neurons (not shown).

Pontine Respiratory Centers

Although the VRG generates the basic respiratory rhythm, the *pontine respiratory centers* influence and modify the activity of medullary neurons. For example, pontine centers appear to smooth out the transitions from inspiration to expiration, and vice versa. When lesions are made in its superior region, inspirations become very prolonged, a phenomenon called *apneustic breathing*.

The **pontine respiratory group** and other pontine centers transmit impulses to the VRG of the medulla (Figure 22.26). This input modifies and fine-tunes the breathing rhythms generated by the VRG during certain activities such as vocalization, sleep, and exercise. As you would expect from these functions, the pontine respiratory centers, like the DRG, receive input from higher brain centers and from various sensory receptors in the periphery.

Generation of the Respiratory Rhythm

There is little question that breathing is rhythmic, but we still cannot fully explain the origin of its rhythm. One hypothesis is that there are *pacemaker neurons,* which have intrinsic (automatic) rhythmicity like the pacemaker cells found in the heart. Pacemaker-like activity has been demonstrated in certain VRG neurons, but suppressing their activity does not abolish breathing.

This leads us to the second (and more widely accepted) hypothesis: Normal respiratory rhythm results from reciprocal inhibition of interconnected neuronal networks in the medulla. Rather than a single set of pacemaker neurons, there are two (or possibly three) sets that inhibit each other and cycle their activity to generate the rhythm.

Factors Influencing Breathing Rate and Depth

Inspiratory depth is determined by how actively the respiratory centers stimulate the motor neurons serving the respiratory muscles. The greater the stimulation, the greater the number of motor units excited and the greater the force of respiratory muscle contractions. Respiratory rate is determined by how long the inspiratory center is active or how quickly it is switched off.

Changing body demands can modify depth and rate of breathing. The respiratory centers in the medulla and pons are sensitive to both excitatory and inhibitory stimuli, as summarized in **Figure 22.27**.

Chemical Factors

Among the factors that influence breathing rate and depth, the most important are changing levels of CO_2, O_2, and H^+ in

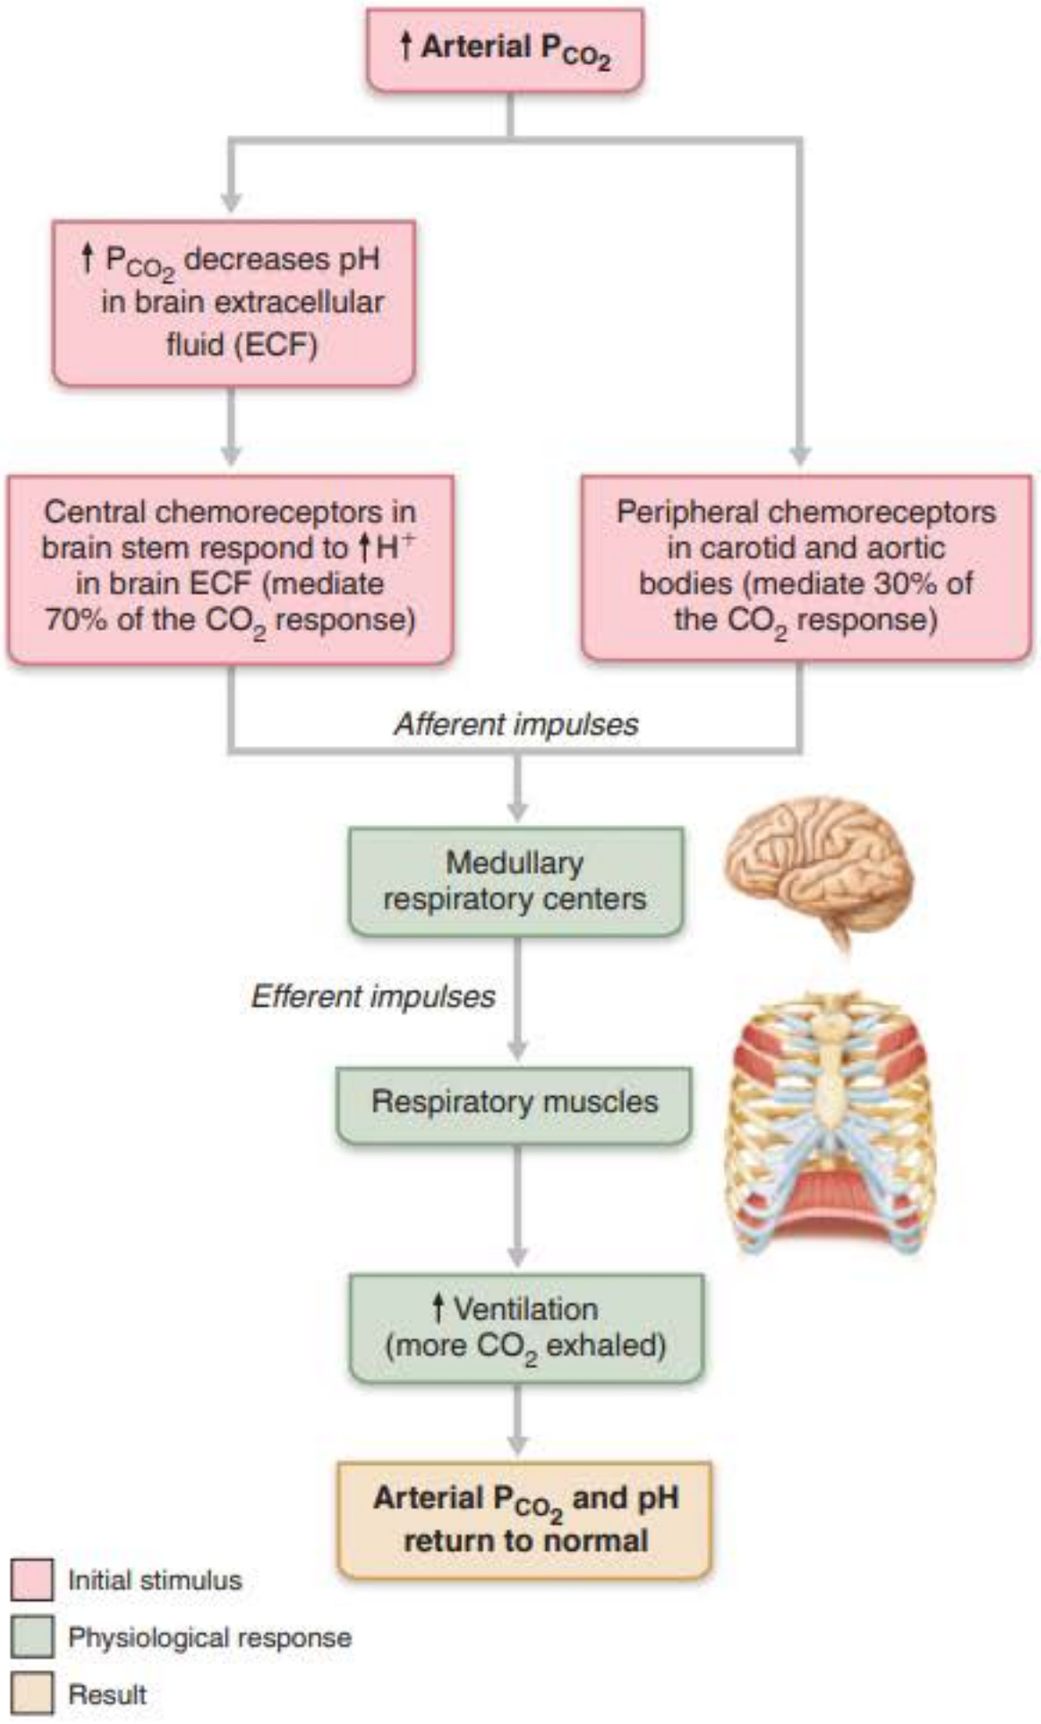

Figure 22.28 Changes in P_{CO_2} regulate ventilation by a negative feedback mechanism.

arterial blood. Sensors responding to such chemical fluctuations, called **chemoreceptors**, are found in two major body locations:

- **Central chemoreceptors** are located throughout the brain stem, including the ventrolateral medulla.
- **Peripheral chemoreceptors** are found in the aortic arch and carotid arteries.

Influence of P_{CO_2} Of all the chemicals influencing respiration, CO_2 is the most potent and the most closely controlled. Normally, arterial P_{CO_2} is 40 mm Hg and is maintained within ±3 mm Hg of this level by an exquisitely sensitive homeostatic mechanism that is mediated mainly by the effect of rising CO_2 levels on the central chemoreceptors of the brain stem (**Figure 22.28**).

As P_{CO_2} levels rise in the blood, a condition referred to as **hypercapnia** (hi″per-kap′ne-ah), CO_2 accumulates in the brain. As CO_2 accumulates, it is hydrated to form carbonic acid. The acid dissociates, H^+ is liberated, and the pH drops. This is the same reaction that occurs when CO_2 enters RBCs (see p. 850).

The increase in H^+ excites the central chemoreceptors, which make abundant synapses with the respiratory regulatory centers. As a result, the depth and rate of breathing increase. This enhanced alveolar ventilation quickly flushes CO_2 out of the blood, raising blood pH.

An elevation of only 5 mm Hg in arterial P_{CO_2} doubles alveolar ventilation, even when arterial O_2 levels and pH haven't changed. When P_{O_2} and pH are below normal, the response to elevated P_{CO_2} is even greater. Increased ventilation is normally self-limiting, ending when homeostatic blood P_{CO_2} levels are restored.

Notice that while rising blood CO_2 levels act as the initial stimulus, it is rising levels of H^+ generated within the brain that prod the central chemoreceptors into increased activity. (CO_2 readily diffuses across the blood brain barrier between the brain and the blood, but H^+ does not.) In the final analysis, control of breathing during rest is aimed primarily at *regulating the H^+ concentration in the brain.*

HOMEOSTATIC IMBALANCE 22.15 CLINICAL

Hyperventilation is an increase in the rate and depth of breathing that exceeds the body's need to remove CO_2. A person experiencing an anxiety attack may hyperventilate involuntarily. As the person blows off CO_2, the low CO_2 levels in the blood (**hypocapnia**) constrict cerebral blood vessels. This reduces brain perfusion, producing cerebral ischemia that causes dizziness or fainting. Earlier symptoms of hyperventilation are tingling and involuntary muscle spasms (tetany) in the hands and face caused by blood Ca^{2+} levels falling as pH rises.

The symptoms of hyperventilation may be averted by breathing into a paper bag. The air being inspired from the bag is expired air, rich in carbon dioxide, which causes carbon dioxide to be retained in the blood.

When P_{CO_2} is abnormally low, respiration is inhibited and becomes slow and shallow. In fact, periods of **apnea** (breathing cessation) may occur until arterial P_{CO_2} rises and again stimulates respiration.

Sometimes swimmers voluntarily hyperventilate so they can hold their breath longer during swim meets. This is dangerous. Blood O_2 content rarely drops much below 60% of normal during regular breath-holding, because as P_{O_2} drops, P_{CO_2} rises enough to make breathing unavoidable. However, strenuous hyperventilation can lower P_{CO_2} so much that a lag period occurs before P_{CO_2} rebounds enough to stimulate respiration again. This lag may allow oxygen levels to fall well below 50 mm Hg, causing the swimmer to black out (and perhaps drown) before he or she has the urge to breathe.

Influence of P_{O_2} The peripheral chemoreceptors—found in the **aortic bodies** of the aortic arch and in the **carotid bodies**

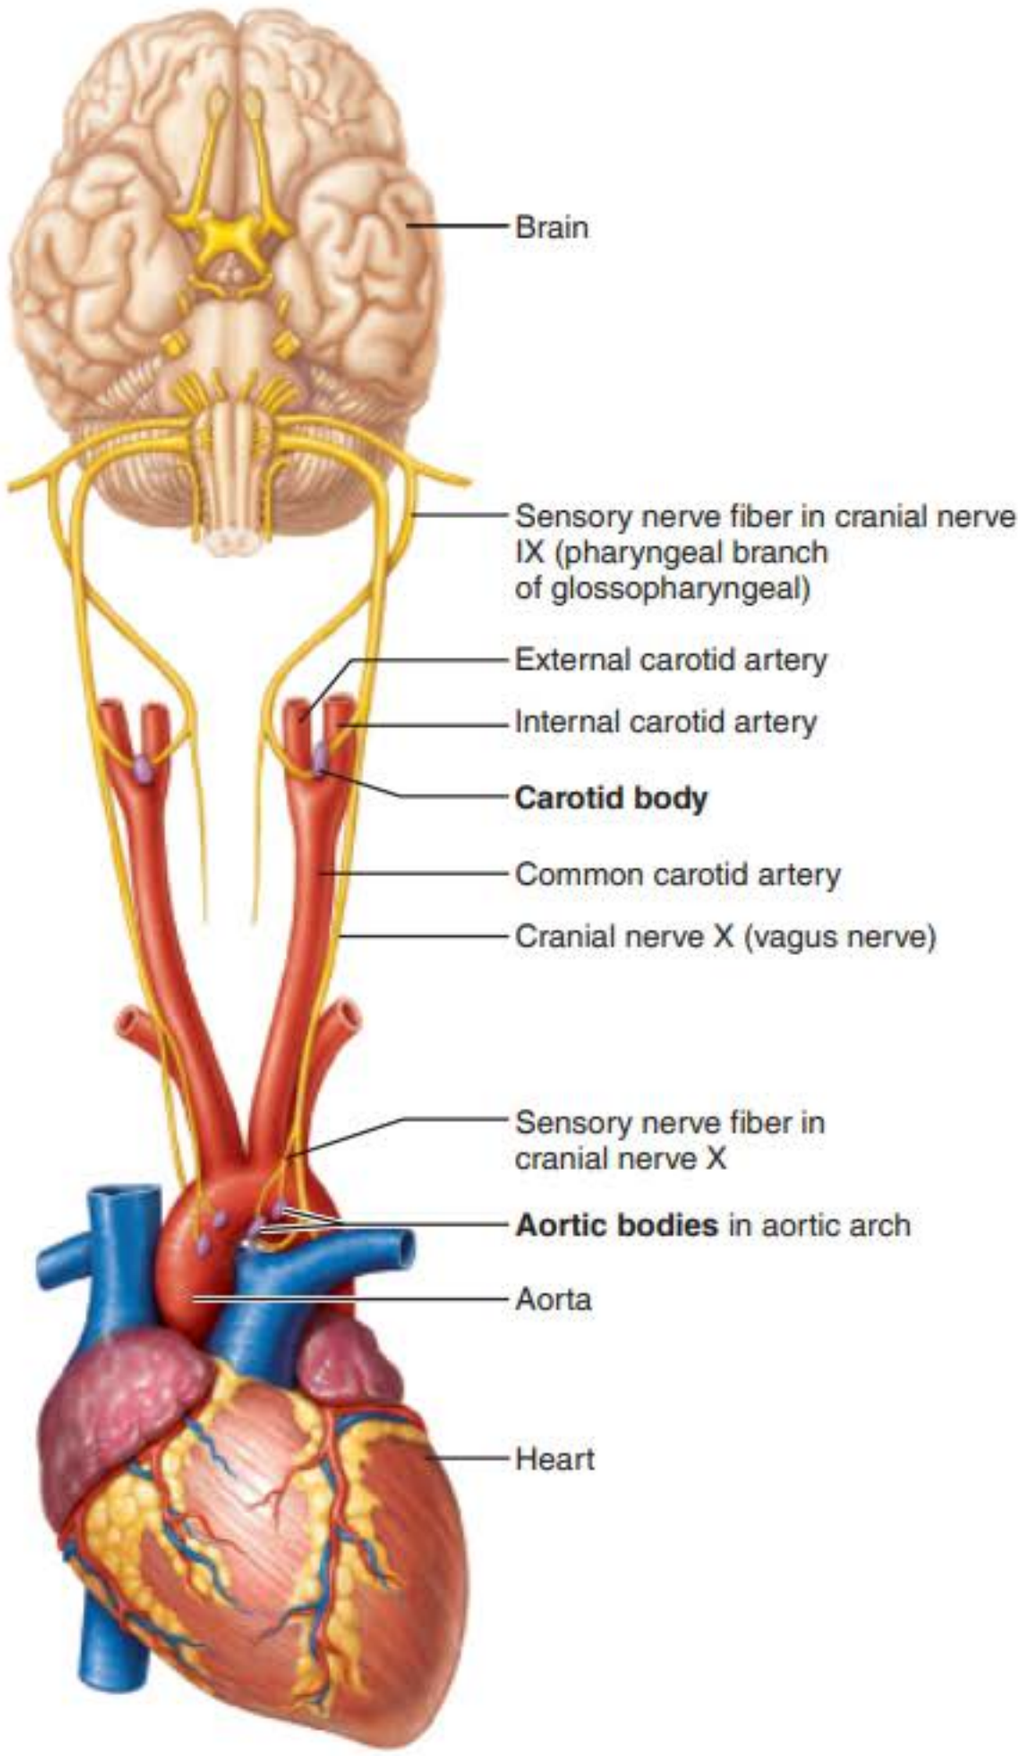

Figure 22.29 Location and innervation of the peripheral chemoreceptors in the carotid and aortic bodies.

at the bifurcation of the common carotid arteries—contain cells sensitive to arterial O_2 levels (**Figure 22.29**). The main oxygen sensors are in the carotid bodies.

Under normal conditions, declining P_{O_2} has only a slight effect on ventilation, mostly limited to enhancing the sensitivity of peripheral receptors to increased P_{CO_2}. Arterial P_{O_2} must drop *substantially*, to at least 60 mm Hg, before O_2 levels become a major stimulus for increased ventilation.

This is not as strange as it may appear. Remember, there is a huge reservoir of O_2 bound to Hb, and Hb remains almost entirely saturated unless or until the P_{O_2} of alveolar gas and arterial blood falls below 60 mm Hg. The brain stem centers then begin to suffer from O_2 starvation, and their activity is depressed. At the same time, the peripheral chemoreceptors become excited and stimulate the respiratory centers to increase ventilation, even if P_{CO_2} is normal. In this way, the peripheral chemoreceptor system can maintain ventilation even though the brain stem centers are depressed by hypoxia.

Influence of Arterial pH Changes in arterial pH can modify respiratory rate and rhythm even when CO_2 and O_2 levels are normal. Because H^+ does not cross the blood brain barrier, the increased ventilation that occurs in response to falling arterial pH is mediated through the peripheral chemoreceptors.

Although changes in P_{CO_2} and H^+ concentration are interrelated, they are distinct stimuli. A drop in blood pH may reflect CO_2 retention, but it may also result from metabolic causes, such as accumulation of lactic acid during exercise or of fatty acid metabolites (ketone bodies) in patients with poorly controlled diabetes mellitus. Regardless of cause, as arterial pH declines, respiratory system controls attempt to compensate and raise the pH. They do this by increasing respiratory rate and depth to eliminate CO_2 (and carbonic acid) from the blood.

Summary of Interactions of P_{CO_2}, P_{O_2}, and Arterial pH The body's need to rid itself of CO_2 is the most important stimulus for breathing in a healthy person. However, CO_2 does not act in isolation, and various chemical factors enforce or inhibit one another's effects. These interactions are summarized here:

- *Rising CO_2 levels are the most powerful respiratory stimulant.* As CO_2 is hydrated in brain tissue, liberated H^+ acts directly on the central chemoreceptors, causing a reflexive increase in breathing rate and depth. Low P_{CO_2} levels depress respiration.
- *Under normal conditions, blood P_{O_2} affects breathing only indirectly.* It does so by influencing peripheral chemoreceptor sensitivity to changes in P_{CO_2}. Low P_{O_2} augments P_{CO_2} effects, and high P_{O_2} levels diminish the effectiveness of CO_2 stimulation.
- *When arterial P_{O_2} falls below 60 mm Hg, it becomes the major stimulus for respiration.* The peripheral chemoreceptors respond, reflexively increasing ventilation. This may increase O_2 loading into the blood, but it also causes hypocapnia (low P_{CO_2} blood levels) and an increase in blood pH, both of which inhibit respiration.
- *Changes in arterial pH due to CO_2 retention or metabolic factors act through the peripheral chemoreceptors.* The resulting changes in ventilation in turn modify arterial P_{CO_2} and pH. Arterial pH does not influence the central chemoreceptors directly.

Influence of Higher Brain Centers

Hypothalamic Controls Acting through the hypothalamus and the rest of the limbic system, strong emotions and pain send signals to the respiratory centers, modifying respiratory rate and depth. For example, have you ever touched something cold and clammy and gasped? That response was mediated through the hypothalamus. So too is the breath-holding that occurs when we are angry and the increased respiratory rate that occurs when we are excited. A rise in body temperature raises the respiratory rate, while a drop in body temperature produces the opposite effect. Sudden chilling (a dip in the North Atlantic Ocean in late

October) can stop your breathing (apnea)—or at the very least, leave you gasping.

Cortical Controls Although the brain stem respiratory centers normally regulate breathing involuntarily, we can also exert conscious (voluntary) control over the rate and depth of our breathing. We can choose to hold our breath or take an extra-deep breath, for example. During voluntary control, the cerebral motor cortex sends signals to the motor neurons that stimulate the respiratory muscles, bypassing the medullary centers.

Our ability to voluntarily hold our breath is limited, however, because the brain stem respiratory centers automatically reinitiate breathing when the blood concentration of CO_2 reaches critical levels. That explains why drowning victims typically have water in their lungs.

Pulmonary Irritant Reflexes

The lungs contain receptors that respond to an enormous variety of irritants. When activated, these receptors communicate with the respiratory centers via vagal nerve afferents. Accumulated mucus, inhaled debris such as dust, or noxious fumes stimulate receptors in the bronchioles that promote reflex constriction of those air passages. In the trachea or bronchi, the same irritants stimulate a cough. Stimulation in the nasal cavity triggers a sneeze.

The Inflation Reflex

The visceral pleurae and conducting passages in the lungs contain numerous stretch receptors that are vigorously stimulated when the lungs are inflated. These receptors signal the medullary respiratory centers via afferent fibers of the vagus nerves, sending inhibitory impulses that end inspiration and allow expiration to occur.

As the lungs recoil, the stretch receptors become quiet, and inspiration is initiated once again. This reflex, called the **inflation reflex**, or **Hering-Breuer reflex** (her′ing broy′er), is thought to be more a protective response (to prevent the lungs from being stretched excessively) than a normal regulatory mechanism.

Check Your Understanding

23. Which brain stem respiratory area is thought to generate the respiratory rhythm?

24. Which chemical factor in blood normally provides the most powerful stimulus to breathe? Which chemoreceptors are most important for this response?

For answers, see Answers Appendix.

22.9 Exercise and high altitude bring about respiratory adjustments

Learning Outcomes

- **Compare and contrast the hyperpnea of exercise with hyperventilation.**
- **Describe the process and effects of acclimatization to high altitude.**

Exercise

Respiratory adjustments during exercise are geared to both the intensity and duration of the exercise. Working muscles consume tremendous amounts of O_2 and produce large amounts of CO_2, so ventilation can increase 10- to 20-fold during vigorous exercise. Increased ventilation in response to metabolic needs is called **hyperpnea** (hi″perp-ne′ah).

How does hyperpnea differ from hyperventilation? The respiratory changes in hyperpnea do not alter blood O_2 and CO_2 levels significantly. In contrast, hyperventilation is excessive ventilation, and is characterized by low P_{CO_2} and alkalosis.

Exercise-enhanced ventilation does *not* appear to be prompted by rising P_{CO_2} and declining P_{O_2} and pH in the blood for two reasons.

- Ventilation increases abruptly as exercise begins, followed by a gradual increase, and then reaches a steady state. When exercise stops, there is a small but abrupt decline in ventilation rate, followed by a gradual decrease to the pre-exercise value.
- Although venous levels change, arterial P_{CO_2} and P_{O_2} levels remain surprisingly constant during exercise. In fact, P_{CO_2} may fall below normal and P_{O_2} may rise slightly because the respiratory adjustments are so efficient.

The most widely accepted explanation for the abrupt increase in ventilation that occurs as exercise begins reflects interaction of three neural factors:

- Psychological stimuli (our conscious anticipation of exercise)
- Simultaneous cortical motor activation of skeletal muscles and respiratory centers
- Excitatory input reaching respiratory centers from proprioceptors in moving muscles, tendons, and joints

The subsequent gradual increase and then plateauing of respiration probably reflect the rate of CO_2 delivery to the lungs (the "CO_2 flow").

The rise in lactic acid levels during exercise results from anaerobic respiration. However, it is *not* a result of inadequate respiratory function, because alveolar ventilation and pulmonary perfusion are as well matched during exercise as during rest (hemoglobin remains fully saturated). Rather, it reflects cardiac output limitations or inability of the skeletal muscles to further increase their oxygen consumption.

In light of this fact, the practice of inhaling pure O_2 by mask, used by some football players to replenish their "oxygen-starved" bodies as quickly as possible, is useless. The panting athlete *does* need more oxygen, but inspiring extra oxygen will not help, because the shortage is in the muscles—not the lungs.

High Altitude

Most people live between sea level and an altitude of approximately 2400 m (8000 feet). In this range, differences in atmospheric pressure are not great enough to cause healthy people any problems when they spend brief periods in higher-altitude areas.

However, if you travel quickly from sea level to elevations above 8000 ft, where atmospheric pressure and P_{O_2} are lower,

your body responds with symptoms of *acute mountain sickness* (*AMS*)—headaches, shortness of breath, nausea, and dizziness. AMS is sometimes seen in travelers to ski resorts such as Vail, Colorado (8120 ft). In severe cases of AMS, lethal pulmonary and cerebral edema may occur.

When you move on a *long-term* basis from sea level to the mountains, your body makes respiratory and hematopoietic adjustments via an adaptive response called **acclimatization**. As we have already explained, decreases in arterial P_{O_2} cause the peripheral chemoreceptors to become more responsive to increases in P_{CO_2}, and a substantial decline in P_{O_2} directly stimulates them. As a result, ventilation increases as the brain attempts to restore gas exchange. Increased ventilation also reduces arterial CO_2 levels, so the P_{CO_2} of individuals living at high altitudes is typically below 40 mm Hg (its value at sea level).

High-altitude conditions result in lower-than-normal hemoglobin saturation levels because less O_2 is available to be loaded. For example, at about 19,000 ft above sea level, O_2 saturation of arterial blood is only 67% (compared to nearly 98% at sea level). But Hb unloads only 20–25% of its oxygen at sea level, which means that even at the reduced saturations at high altitudes, the O_2 needs of the tissues are still met under resting conditions.

Additionally, at high altitudes hemoglobin's affinity for O_2 is reduced because BPG concentrations increase. This releases more O_2 to the tissues during each circulatory round.

When blood O_2 levels decline, the kidneys produce more erythropoietin, which stimulates bone marrow production of RBCs (◀ p. 648). This phase of acclimatization, which occurs slowly, provides long-term compensation for living at high altitudes.

Check Your Understanding

25. What long-term adjustments does the body make when living at high altitude?

26. APPLY An injured soccer player arrives by ambulance in the emergency room. She is in obvious distress, breathing rapidly. Her blood P_{CO_2} is 26 mm Hg and pH is 7.5. Is she suffering from hyperventilation or hyperpnea? Explain.

For answers, see Answers Appendix.

22.10 Respiratory diseases are major causes of disability and death CLINICAL

Learning Outcome

- **Compare the causes and consequences of chronic bronchitis, emphysema, asthma, tuberculosis, and lung cancer.**

The respiratory system is particularly vulnerable to infectious diseases because it is wide open to airborne pathogens. However, some of the most disabling respiratory disorders are *chronic obstructive pulmonary disease* (*COPD*), *asthma*, *tuberculosis*, and *lung cancer*. COPD and lung cancer are living proof of the devastating effects of tobacco smoke on the body. Long known to promote cardiovascular disease, smoking is perhaps even more effective at destroying the lungs.

Chronic Obstructive Pulmonary Disease (COPD)

The **chronic obstructive pulmonary diseases** (**COPD**), exemplified best by emphysema and chronic bronchitis, are a major cause of disability and death in North America. The key physiological feature of these diseases is an irreversible decrease in the ability to force air out of the lungs. Other features they share in common are (**Figure 22.30**):

- More than 80% of patients have a history of smoking.
- **Dyspnea** (disp-ne′ah), difficult or labored breathing often referred to as "air hunger," gets progressively worse.
- Coughing and frequent pulmonary infections are common.
- Most COPD patients develop respiratory failure manifested as **hypoventilation** (insufficient ventilation in relation to metabolic needs, causing them to retain CO_2), respiratory acidosis, and hypoxemia.

Emphysema

Emphysema is distinguished by permanent enlargement of the alveoli, accompanied by destruction of the alveolar walls (see Figure 22.22 on p. 845). Invariably the lungs lose their elasticity. This has three important consequences:

- Accessory muscles must be enlisted to breathe, and victims are perpetually exhausted because breathing requires 15–20% of their total body energy supply (as opposed to 5% in healthy individuals).

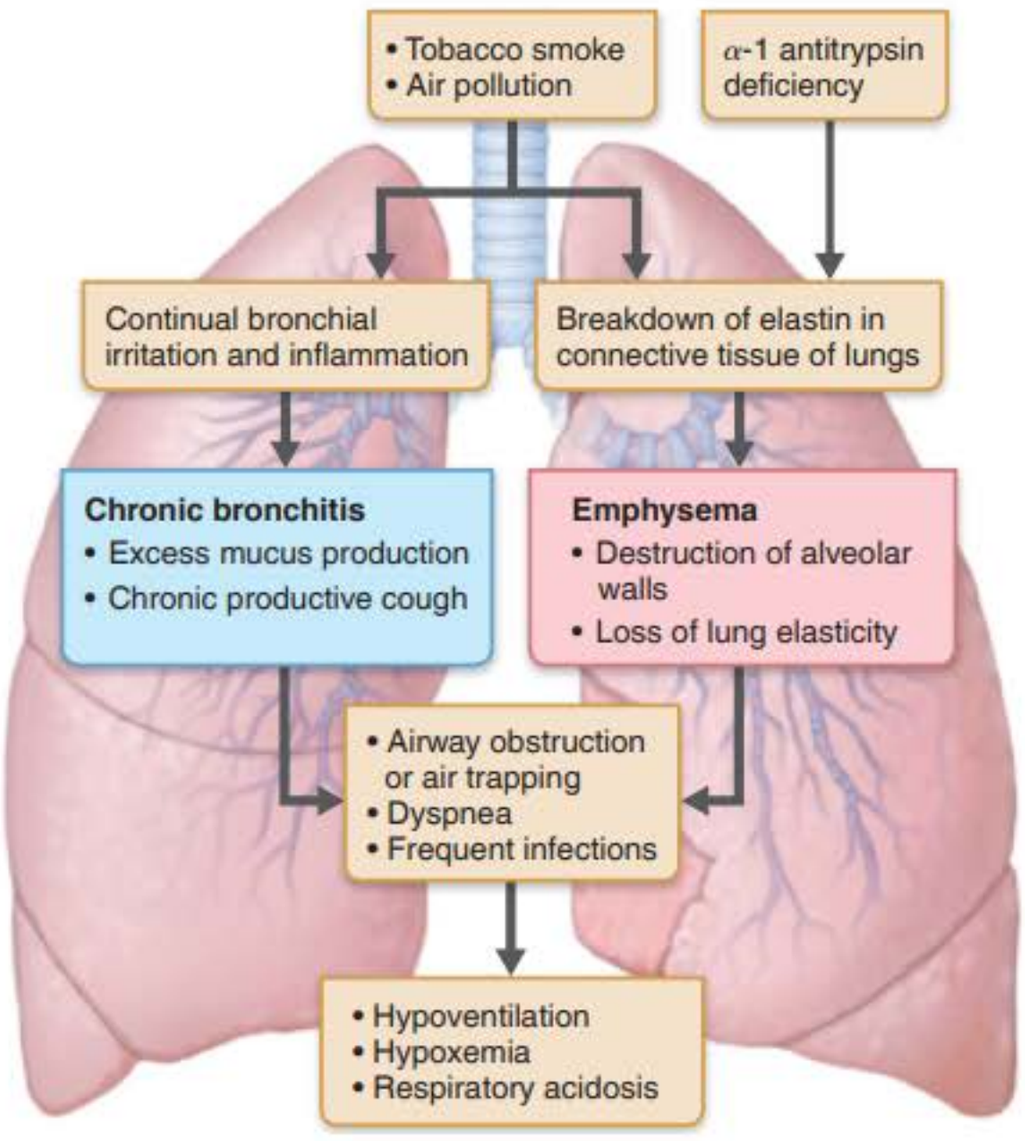

Figure 22.30 The pathogenesis of COPD.

- For complex reasons, the bronchioles open during inspiration but collapse during expiration, trapping huge volumes of air in the alveoli. This hyperinflation leads to development of a permanently expanded "barrel chest" and flattens the diaphragm, thus reducing ventilation efficiency.
- Damage to the pulmonary capillaries as the alveolar walls disintegrate increases resistance in the pulmonary circuit, forcing the right ventricle to overwork and consequently become enlarged.

Emphysema is usually caused by smoking, but hereditary factors (e.g., alpha-1 antitrypsin deficiency) cause emphysema in some patients.

Chronic Bronchitis

In **chronic bronchitis**, inhaled irritants lead to chronic production of excessive mucus. The mucosae of the lower respiratory passageways become inflamed and fibrosed. These responses obstruct the airways, severely impairing lung ventilation and gas exchange. Pulmonary infections are frequent because bacteria thrive in the stagnant pools of mucus. Smoking is a major risk factor. Environmental pollution also promotes chronic bronchitis.

COPD: Symptoms and Treatments

In the clinical setting you might see two very different patterns that represent the extremes of patients with COPD. One pattern has traditionally been called the "pink puffer": These patients work so hard to maintain adequate ventilation that they lose weight, becoming thin but still having nearly normal blood gases. In contrast, "blue bloaters," commonly of stocky build, become sufficiently hypoxic that they are obviously cyanotic. The hypoxia causes constriction of pulmonary blood vessels, leading to pulmonary hypertension and right-sided heart failure.

Traditionally, "pink puffers" were associated with emphysema while "blue bloaters" were associated with chronic bronchitis. As usual, things are not that clear-cut. It turns out that patients with the same underlying disease can display either of these clinical patterns, and this may depend on a third factor—the strength of their innate respiratory drive. Most COPD patients fall between these two clinical extremes.

COPD is routinely treated with inhaled bronchodilators and corticosteroids. Severe dyspnea and hypoxia mandate oxygen use, but oxygen must be administered with care. In some of these patients, giving pure oxygen can increase the blood P_{CO_2} (and lower blood pH) to life-threatening levels. The solution is to use the minimum concentration of oxygen that relieves the patient's hypoxia.

Asthma

Asthma is characterized by episodes of coughing, dyspnea, wheezing, and chest tightness—alone or in combination. A sense of panic accompanies most acute attacks. Although sometimes classed with COPD because it is an obstructive disorder, asthma is marked by acute episodes followed by symptom-free periods—that is, the obstruction is *reversible*.

The cause of asthma has been hard to pin down. Initially it was viewed as a consequence of bronchospasms triggered by various factors such as cold air, exercise, or allergens. However, researchers have found that in allergic asthma (the most common kind), active inflammation of the airways comes first. The inflammation is an immune response controlled by a subset of T lymphocytes that stimulate the production of IgE antibodies and recruit inflammatory cells to the site.

Once someone has allergic asthma, the inflammation persists even during symptom-free periods and makes the airways hypersensitive. (The most common triggers are in the home—the allergens from dust mites, cockroaches, cats, dogs, and fungi.) Once the airway walls are thickened with inflammatory exudate, the effect of bronchospasm is vastly magnified and can dramatically reduce air flow.

About one in ten people in North America suffer from asthma—children more than adults. Over the past 20 years, the number of cases rose dramatically, plateaued, and may now be declining.

While asthma remains a major health problem, better treatment options have reduced the number of asthma-related deaths. Instead of merely treating the symptoms with fast-acting bronchodilators, we now treat the underlying inflammation using inhaled corticosteroids and a variety of other drugs.

Tuberculosis (TB)

Tuberculosis (TB), the infectious disease caused by the bacterium *Mycobacterium tuberculosis*, is spread by coughing and primarily enters the body in inhaled air. TB mostly affects the lungs but can spread through the lymphatics to other organs.

One-third of the world's population is infected, but most people never develop active TB because a massive inflammatory and immune response usually contains the primary infection in fibrous, or calcified, nodules (tubercles) in the lungs. However, the bacteria survive in the nodules and when the person's immunity is weakened, they may break out and cause symptomatic TB. Symptoms include fever, night sweats, weight loss, racking cough, and coughing up blood.

Deadly strains of drug-resistant (even multidrug-resistant) TB can develop when treatment is incomplete or inadequate. Resistant strains are found elsewhere in the world and have appeared in North America.

Lung Cancer

Lung cancer is the leading cause of cancer death for both men and women in North America, killing more people every year than breast, prostate, and colorectal cancer combined. This is tragic, because lung cancer is largely preventable—nearly 90% of cases result from smoking.

The cure rate for lung cancer is notoriously low, with most people dying within one year of diagnosis. The five-year survival rate is about 16%. Because lung cancer is aggressive and metastasizes rapidly and widely, most cases are not diagnosed until they are well advanced.

Lung cancer appears to follow closely the oncogene-activating steps outlined in *A Closer Look* in Chapter 4 (◀ p. 144). Ordinarily, nasal hairs, sticky mucus, and cilia do a fine job of protecting the lungs from chemical and biological irritants, but when a person smokes, these defenses are overwhelmed and eventually stop functioning. In particular, smoking paralyzes the cilia that clear mucus from the airways, allowing irritants and pathogens to accumulate. The "cocktail" of free radicals and other carcinogens in tobacco smoke eventually translates into lung cancer.

The most common types of lung cancer are:

- **Adenocarcinoma** (about 40% of cases), which originates in peripheral lung areas as solitary nodules that develop from bronchial glands and alveolar cells.
- **Squamous cell carcinoma** (about 20%), which arises in the epithelium of the bronchi or their larger subdivisions and tends to form masses that may cavitate (hollow out) and bleed.
- **Small cell carcinoma** (about 15%), round lymphocyte-sized cells that originate in the main bronchi and grow aggressively in small grapelike clusters within the mediastinum. Metastasis from the mediastinum is especially rapid. Some small cell carcinomas cause additional problems because they produce certain hormones. For example, some secrete antidiuretic hormone (ADH), resulting in the syndrome of inappropriate ADH secretion (◀ p. 614).

Because lung cancers metastasize aggressively and early, the key to survival is early detection. If the cancer has not metastasized before it is discovered, complete removal of the diseased lung has the greatest potential for prolonging life and providing a cure. With metastatic lung cancer, radiation therapy and chemotherapy are the only options, but these have low success rates.

Sleep Apnea

Sleep apnea is a common disorder that is characterized by the temporary cessation of breathing during sleep. Although they are usually not aware of it, people with sleep apnea wake themselves up many times each night (in severe cases, more than 30 times per hour). As a result, people with sleep apnea may feel as tired when they get up as when they went to sleep, leaving them with excessive daytime sleepiness. Loud snoring, particularly when respiration resumes, is often reported by others sleeping in the same room because it disturbs their sleep as well.

Obstructive sleep apnea, the most common kind, is caused by collapse of the upper airway. This occurs because the muscles of the pharynx relax during sleep, which allows the soft tissues of the pharynx to sag and obstruct the airway. Obstructive sleep apnea is more common in men, and is made worse by obesity.

With what you have learned about the regulation of respiration, it will not surprise you to learn that there is another kind of sleep apnea—**central sleep apnea**. Central sleep apnea is caused by a reduced drive from the respiratory centers of the brain stem during sleep rather than by obstruction of the airway.

Consequences of disrupted sleep are an increased susceptibility to accidents and an increase in a variety of chronic illnesses such as hypertension, heart disease, stroke, and diabetes.

Obstructive sleep apnea is often treated using a continuous positive airway pressure (CPAP) device. By gently blowing air into the airway, it provides a positive air pressure that holds the airway open and prevents its collapse.

Check Your Understanding

27. What distinguishes the obstruction in asthma from that in chronic bronchitis?

28. MAKE CONNECTIONS Your patient, Mr. Singh, has COPD. As a result, his pulmonary alveoli are poorly ventilated. Would you expect his pulmonary arterial blood pressure to be higher or lower than normal? Explain. Over the long term, this change in blood pressure may cause Mr. Singh to develop heart failure (Chapter 18). Which side of the heart will fail? Edema is one sign of heart failure. Where would you expect to see edema in Mr. Singh?

For answers, see Answers Appendix.

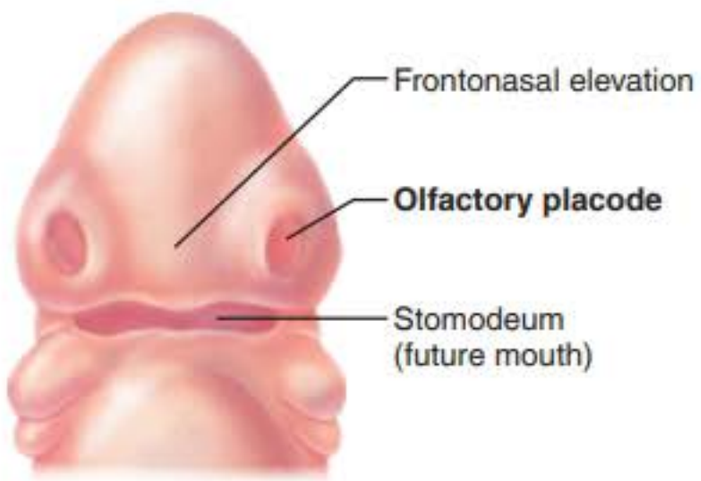
Developmental Aspects of the Respiratory System

Because embryos develop in a cephalocaudal (head-to-tail) direction, the upper respiratory structures appear first. By the fourth week of development, two thickened plates of ectoderm, the **olfactory placodes** (plak′ōds), are present on the anterior aspect of the head (**Figure 22.31**). These quickly invaginate to form **olfactory pits** that form the nasal cavity. The olfactory pits then extend posteriorly to connect with the developing pharynx, which forms at the same time from the endodermal germ layer.

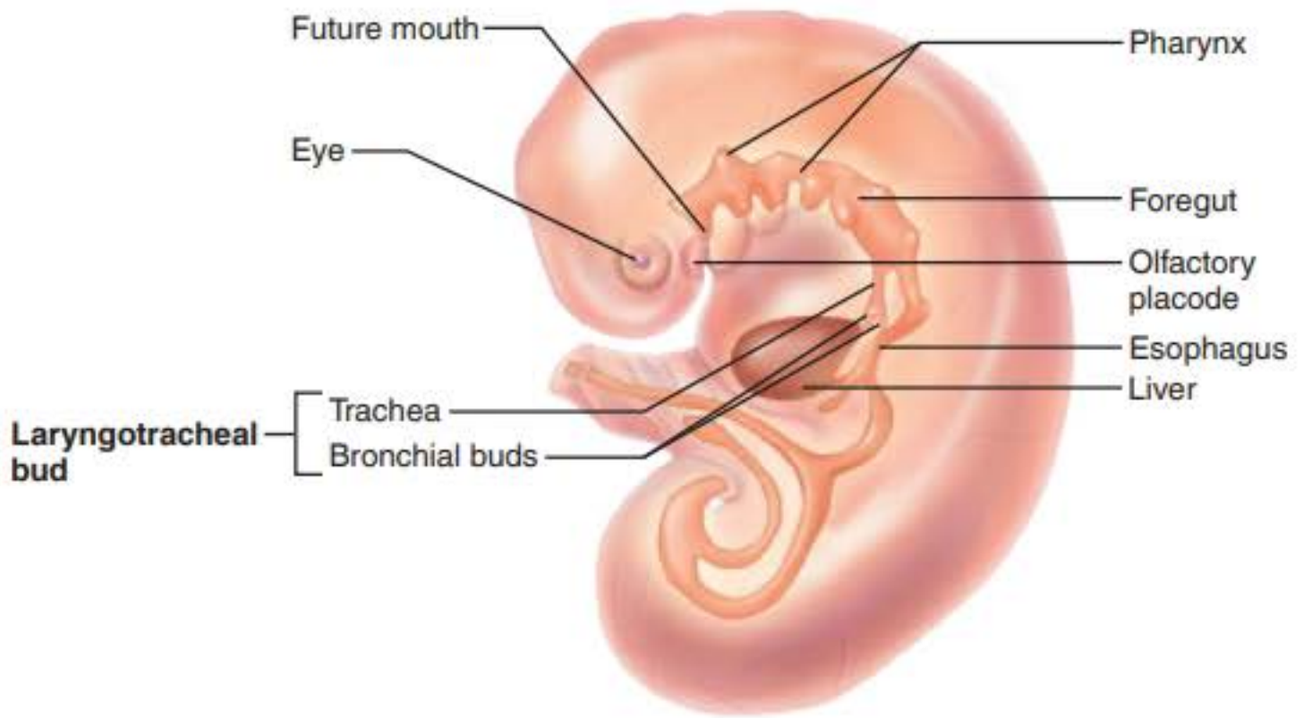
The epithelium of the lower respiratory organs develops as an outpocketing of the foregut endoderm, which becomes the pharyngeal mucosa. This protrusion, called the **laryngotracheal bud**, is present by the fifth week of development. The proximal part of the bud forms the tracheal lining, and its distal end splits and forms the mucosae of the bronchi and all their subdivisions, including (eventually) the lung alveoli. Mesoderm covers these endoderm-derived linings and forms the walls of the respiratory passageways and the stroma of the lungs.

By 28 weeks, the respiratory system has developed sufficiently to allow most babies born prematurely to breathe on their own. As we noted earlier, infants born at or before this time often exhibit infant respiratory distress syndrome resulting from inadequate surfactant production.

During fetal life, the lungs are filled with fluid and the placenta makes all respiratory exchanges. Vascular shunts cause circulating blood to largely bypass the lungs (see Chapter 28). At birth, the respiratory passageways fill with air. As the P_{CO_2} in the baby's blood rises, the respiratory centers are excited, causing the baby to take its first breath. The alveoli inflate and begin to function in gas exchange, but it is nearly two weeks before the lungs are fully inflated.



(a) 4 weeks: anterior superficial view of the embryo's head



(b) 5 weeks: left lateral view of the developing lower respiratory passageway mucosae

Figure 22.31 Embryonic development of the respiratory system.

HOMEOSTATIC IMBALANCE 22.16 CLINICAL

Important birth defects of the respiratory system include *cleft palate* (◀ p. 246) and cystic fibrosis. **Cystic fibrosis (CF)**, the most common lethal genetic disease in North America, strikes in one out of every 3000 births. In CF, abnormally viscous mucus clogs the respiratory passages, providing a breeding ground for airborne bacteria and predisposing the child to respiratory infections.

At the root of CF is a faulty gene that codes for the *CFTR* (cystic fibrosis transmembrane conductance regulator) *protein*. The normal CFTR protein works as a membrane channel to control Cl^- flow in and out of cells. In one common mutation, CFTR lacks a critical amino acid and so does not fold correctly. As a result, it gets "stuck" in the endoplasmic reticulum, is marked for degradation, and never reaches the plasma membrane to perform its normal role. Consequently, less Cl^- is secreted and less water follows, resulting in the thick mucus typical of CF.

This thick mucus forms a perfect harbor for bacterial infection. By early adulthood, 80% of patients are colonized by *Pseudomonas aeruginosa*, which causes chronic inflammation and triggers the disabled cells to churn out a thick sludge of abnormal mucus. Repeated cycles of infection and inflammation eventually result in extensive tissue damage that can be treated only by a lung transplant.

Defects in the CFTR protein can affect other organ systems, too. The ducts of the pancreas become clogged with secretions, impairing food digestion. Obstructed reproductive ducts render 97% of males with CF infertile. Characteristically, sweat glands of CF patients produce extremely salty perspiration.

Conventional therapy for CF has included mucus-dissolving drugs, "clapping" the chest to loosen the thick mucus, and antibiotics to prevent infection. The goal of CF research is to restore normal salt and water movements. This can be done using a number of approaches:

- Introducing normal CFTR genes into respiratory tract mucosa cells
- Prodding another channel protein to take over the duties of transporting Cl^-
- Developing techniques to free the CFTR protein from the ER
- Using hypertonic saline to osmotically move water. This is a novel and surprisingly simple approach that involves inhaling hypertonic saline droplets. This draws water into the mucus, making it more liquid.

Alone or in combination, these therapies provide new hope to patients with CF.

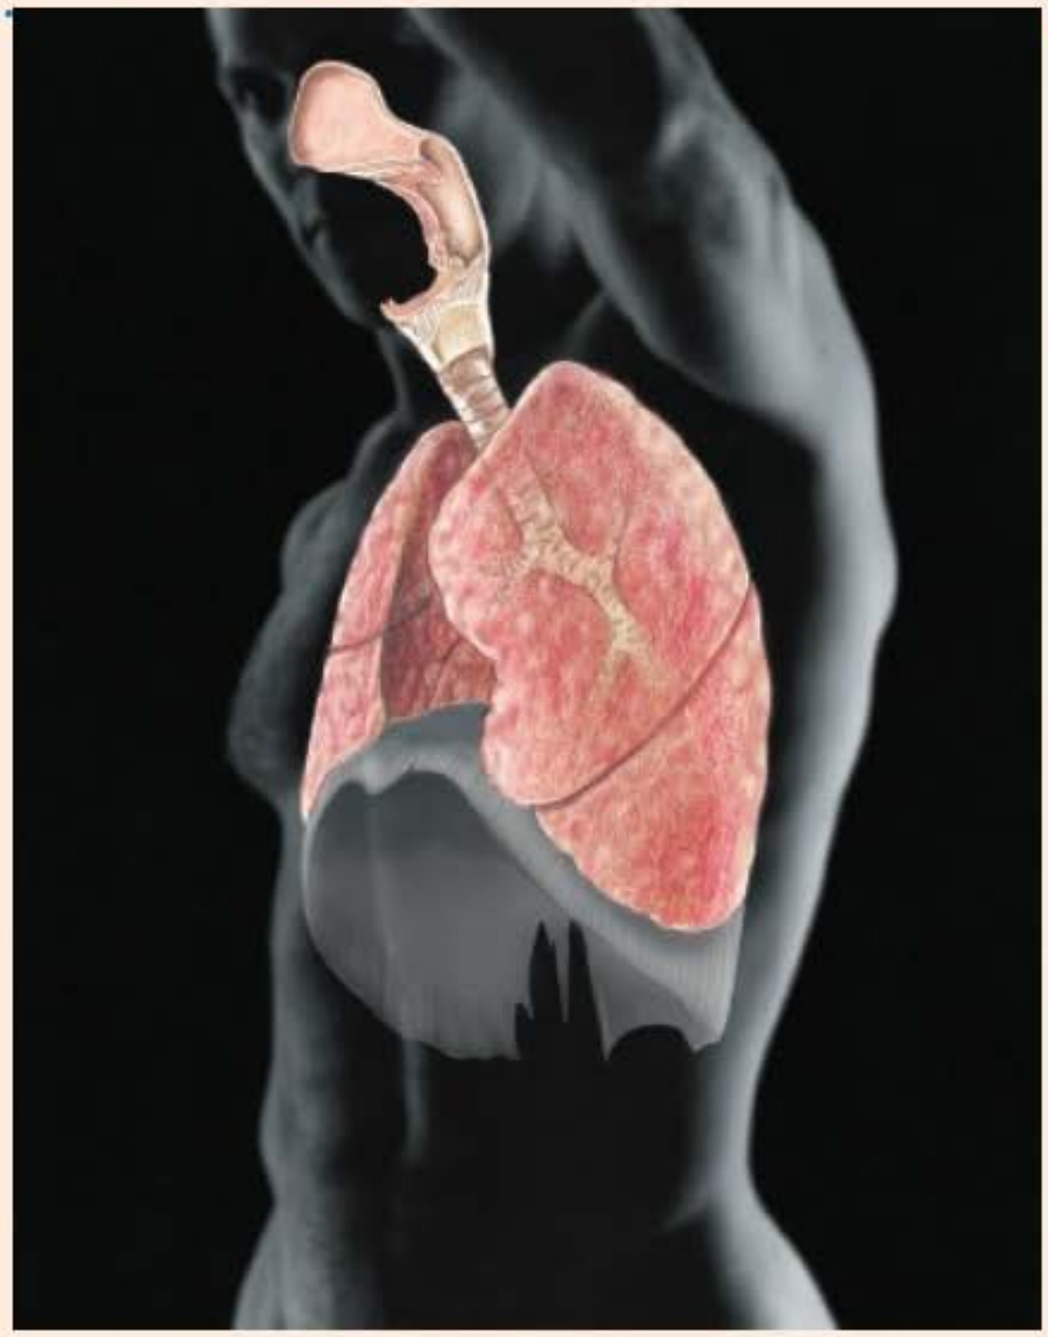
The respiratory rate is highest in newborn infants (40–80 breaths per minute). At five years of age it is around 25 per minute, and in adults it is between 12 and 16 per minute. In old age, the rate often increases again.

At birth, only about one-sixth of the final number of alveoli are present. The lungs continue to mature and form more alveoli until young adulthood. However, if a person begins smoking in the early teens, the lungs never completely mature, and those additional alveoli are lost forever.

In infants, the ribs take a nearly horizontal course. For this reason, infants rely almost entirely on descent of the diaphragm to increase thoracic volume for inspiration. By the second year, the ribs are more obliquely positioned, and the adult form of breathing is established.

The maximum amount of oxygen we can use during aerobic metabolism, $\dot{V}_{O_2max}$, declines about 9% per decade in inactive people beginning in their mid-20s. In those who remain active, $\dot{V}_{O_2max}$ still declines but much less. As we age, the thoracic wall becomes more rigid and the lungs gradually lose their elasticity, decreasing the ability to ventilate the lungs. Vital capacity declines by about one-third by age 70. Blood O_2 levels decline slightly, and many elderly people tend to become hypoxic during sleep. Sleep apnea becomes more common.

Homeostatic Interrelationships between the Respiratory System and Other Body Systems



Integumentary System Chapter 5

- Respiratory system provides oxygen and disposes of carbon dioxide
- Skin protects respiratory system organs by forming surface barriers

Skeletal System Chapters 6–8

- Respiratory system provides oxygen and disposes of carbon dioxide
- Bones protect lungs and bronchi by enclosure

Muscular System Chapters 9–10

- Respiratory system provides oxygen needed for muscle activity and disposes of carbon dioxide
- Activity of the diaphragm and intercostal muscles essential for producing volume changes that lead to pulmonary ventilation; regular exercise increases respiratory efficiency

Nervous System Chapters 11–15

- Respiratory system provides oxygen needed for normal neuronal activity and disposes of carbon dioxide
- Medullary and pontine centers regulate respiratory rate and depth; stretch receptors in lungs and chemoreceptors provide feedback

Endocrine System Chapter 16

- Respiratory system provides oxygen and disposes of carbon dioxide; angiotensin converting enzyme in lungs converts angiotensin I to angiotensin II
- Epinephrine dilates the bronchioles; testosterone promotes laryngeal enlargement in pubertal males; glucocorticoids promote surfactant production

Cardiovascular System Chapters 17–19

- Respiratory system provides oxygen and disposes of carbon dioxide; carbon dioxide present in blood as HCO_3^- and H_2CO_3 contributes to blood buffering
- Blood is the transport medium for respiratory gases

Lymphatic System/Immunity Chapters 20–21

- Respiratory system provides oxygen and disposes of carbon dioxide; tonsils in pharynx house immune cells
- Lymphatic system helps to maintain blood volume required for respiratory gas transport; immune system protects respiratory organs from bacteria, bacterial toxins, viruses, protozoa, fungi, and cancer

Digestive System Chapter 23

- Respiratory system provides oxygen and disposes of carbon dioxide
- Digestive system provides nutrients needed by respiratory system organs

Urinary System Chapters 25–26

- Respiratory system provides oxygen and disposes of carbon dioxide to provide short-term pH homeostasis
- Kidneys dispose of metabolic wastes of respiratory system organs (other than carbon dioxide) and maintain long-term pH homeostasis

Reproductive System Chapter 27

- Respiratory system provides oxygen and disposes of carbon dioxide

The number of glands in the nasal mucosa decreases with age, as does blood flow to this mucosa. For this reason, the nose dries and produces a thick mucus that makes us want to clear our throat. Additionally, many of the respiratory system's protective mechanisms become less effective. Mucosal cilia are less active, and the macrophages in the lungs become sluggish. The net result is that the elderly are more at risk for respiratory tract infections, particularly pneumonia and influenza.

RELATED CLINICAL TERMS

Adenoidectomy (adenotonsillectomy) Surgical removal of an infected pharyngeal tonsil (adenoids).

Adult respiratory distress syndrome (ARDS) A dangerous lung condition that can develop after severe illness or injury to the body. Neutrophils leave the body's capillaries in large numbers and then secrete chemicals that increase capillary permeability. The capillary-rich lungs are heavily affected. As the lungs fill with fluid, the patient suffocates. Even with mechanical ventilation, ARDS is hard to control and often lethal.

Aspiration (as″pĭ-ra′shun) (1) Inhaling or drawing something into the lungs or respiratory passages. (2) Withdrawing fluid by suction (use of an aspirator); done during surgery to keep an area free of blood or other body fluids. Mucus is aspirated from the trachea of tracheotomy patients.

Bronchoscopy (*scopy* = viewing) Use of a viewing tube inserted through the nose or mouth to examine the internal surface of the main bronchi in the lung. Forceps attached to the tip of the tube can remove trapped objects or take samples of mucus for examination.

Cheyne-Stokes breathing (chān′stōks) Abnormal breathing pattern sometimes seen just before death (the "death rattle") and in people with combined neurological and cardiac disorders. It consists of bursts of tidal volume breaths (increasing and then decreasing in depth) alternating with periods of apnea.

Deviated septum Condition in which the nasal septum takes a more lateral course than usual and may obstruct breathing.

Endotracheal tube A thin plastic tube threaded into the trachea through the nose or mouth; used to deliver oxygen to patients who are breathing inadequately, in a coma, or under anesthesia.

Epistaxis (ep″ĭ-stak′sis; *epistazo* = to bleed at the nose) Nosebleed; commonly follows trauma to the nose or excessive nose blowing. Most nasal bleeding is from the highly vascularized anterior septum and can be stopped by pinching the nostrils closed or packing them with cotton.

Nasal polyps Mushroomlike benign growths of the nasal mucosa; sometimes caused by infections, but most often cause is unknown. May block air flow.

Orthopnea (or″thop-ne′ah; *ortho* = straight, upright) Inability to breathe in the horizontal (lying down) position.

Otorhinolaryngology (o″to-ri″no-lar″in-gol′o-je; *oto* = ear; *rhino* = nose) Branch of medicine that deals with diagnosis and treatment of diseases of the ears, nose, and throat.

Pneumonia Infectious inflammation of the lungs, in which fluid accumulates in the alveoli; the eighth most common cause of death in the United States. Most of the more than 50 varieties of pneumonia are viral or bacterial.

Pulmonary embolism Obstruction of the pulmonary artery or one of its branches by an embolus (most often a blood clot that has been carried from the lower limbs and through the right side of the heart into the pulmonary circulation). Symptoms are chest pain, productive bloody cough, tachycardia, and rapid, shallow breathing. Can cause sudden death unless treated quickly.

Sudden infant death syndrome (SIDS) Unexpected death of an apparently healthy infant during sleep. Commonly called crib death, SIDS is one of the most frequent causes of death in infants under 1 year old. Believed to be a problem of immaturity of the respiratory control centers. Most cases occur in infants placed in a prone position (on their abdomen) to sleep—a position that may result in hypoxia and hypercapnia due to rebreathing exhaled (CO_2-rich) air.

Tracheotomy (tra″ke-ot′o-me) Surgical opening of the trachea; done to provide an alternate route for air to reach the lungs when more superior respiratory passageways are obstructed (as by food or a crushed larynx).

CHAPTER SUMMARY

1. Respiration involves four processes: pulmonary ventilation, external respiration, transport of respiratory gases in the blood, and internal respiration. Both the respiratory system and the cardiovascular system are involved in respiration.

PART 1
FUNCTIONAL ANATOMY

22.1 The upper respiratory system warms, humidifies, and filters air (pp. 820–824)

The Nose and Paranasal Sinuses (pp. 820–822)

1. The nose provides an airway for respiration; warms, moistens, and cleanses incoming air; and houses the olfactory receptors.
2. Bone and cartilage plates shape the external nose. The nasal cavity, which opens to the exterior, is divided by the nasal septum. Paranasal sinuses and nasolacrimal ducts drain into the nasal cavities.

The Pharynx (pp. 822–824)

3. The pharynx extends from the base of the skull to the level of C_6. The nasopharynx is an air conduit; the oropharynx and laryngopharynx are common passageways for food and air. Tonsils are found in the oropharynx and nasopharynx.

22.2 The lower respiratory system consists of conducting and respiratory zone structures (pp. 824–831)

1. Respiratory system organs are divided functionally into conducting zone structures (nose to terminal bronchioles), which filter, warm, and moisten incoming air; and respiratory zone structures (respiratory bronchioles to alveoli), where gas exchanges occur.

The Larynx (pp. 824–826)

2. The larynx, or voice box, contains the vocal folds (cords). It also provides a patent airway and serves as a switching mechanism to route food and air into the proper channels.
3. The epiglottis prevents food or liquids from entering the respiratory channels during swallowing.

The Trachea (pp. 826–828)

4. The trachea extends from the larynx to the main bronchi. C-shaped cartilage rings reinforce the trachea and keep the trachea patent. Its mucosa is ciliated.

The Bronchi and Subdivisions (pp. 828–831)

5. The right and left main bronchi run into their respective lungs, within which they subdivide into smaller and smaller passageways.
6. The terminal bronchioles lead into respiratory zone structures: respiratory bronchioles, alveolar ducts, alveolar sacs, and finally alveoli. Gas exchange occurs in the alveoli, across the respiratory membrane.
7. As the respiratory conduits become smaller, the amount of cartilage decreases and is finally lost; the mucosa thins, and smooth muscle in the walls increases.

22.3 Each multilobed lung occupies its own pleural cavity (pp. 833–834)

1. The lungs, the paired organs of gas exchange, flank the mediastinum in the thoracic cavity. Each is suspended in pleurae via its root and has a base, an apex, and medial and costal surfaces. The right lung has three lobes; the left has two.
2. The lungs are primarily air passageways/chambers, supported by an elastic connective tissue stroma.
3. The pulmonary arteries carry deoxygenated blood returned from the systemic circulation to the lungs, where gas exchange occurs. The pulmonary veins return newly oxygenated (and most bronchial venous) blood back to the heart to be distributed throughout the body. The bronchial arteries provide the nutrient blood supply of the lungs.
4. The parietal pleura lines the thoracic wall and mediastinum; the visceral pleura covers external lung surfaces. Pleural fluid reduces friction during breathing movements.

22

PART 2
RESPIRATORY PHYSIOLOGY

22.4 Volume changes cause pressure changes, which cause air to move (pp. 834–840)

Pressure Relationships in the Thoracic Cavity (pp. 835–836)

1. Intrapulmonary pressure is the pressure within the alveoli. Intrapleural pressure is the pressure within the pleural cavity; normally it is negative relative to intrapulmonary pressures.

Pulmonary Ventilation (pp. 836–838)

2. Gases travel from an area of higher pressure to an area of lower pressure.
3. Inspiration occurs when the diaphragm and external intercostal muscles contract, increasing the dimensions (and volume) of the thorax. As the intrapulmonary pressure drops, air rushes into the lungs until the intrapulmonary and atmospheric pressures are equalized.
4. Expiration is largely passive, occurring as the inspiratory muscles relax and the lungs recoil. When intrapulmonary pressure exceeds atmospheric pressure, gases flow from the lungs.

Physical Factors Influencing Pulmonary Ventilation (pp. 838–840)

5. Friction in the air passageways causes resistance, which decreases air passage and causes breathing movements to become more strenuous. The greatest resistance to air flow occurs in the midsize bronchi.
6. Surface tension of alveolar fluid acts to reduce alveolar size and collapse the alveoli. Surfactant reduces this tendency.
7. Premature infants have problems keeping their lungs inflated owing to the lack of surfactant in their alveoli, resulting in infant respiratory distress syndrome (IRDS). Surfactant formation begins late in fetal development.
8. Total respiratory compliance depends on elasticity of lung tissue and flexibility of the bony thorax. When compliance is impaired, inspiration becomes more difficult.

22.5 Measuring respiratory volumes, capacities, and flow rates helps us assess ventilation (pp. 840–842)

1. The four respiratory volumes are tidal, inspiratory reserve, expiratory reserve, and residual. The four respiratory capacities are vital, functional residual, inspiratory, and total lung. Spirometry measures respiratory volumes and capacities.
2. Anatomical dead space is the air-filled volume (about 150 ml) of the conducting passageways. If alveoli become nonfunctional in gas exchange, their volume is added to the anatomical dead space, and the sum is the total dead space.
3. The FVC and FEV tests, which determine the rate at which VC air can be expelled, are particularly valuable in distinguishing between obstructive and restrictive disease.
4. Alveolar ventilation is the best index of ventilation efficiency because it accounts for anatomical dead space.

$$\text{AVR} = (\text{TV} - \text{dead space}) \times \text{respiratory rate}$$

22.6 Gases exchange by diffusion between the blood, lungs, and tissues (pp. 842–847)

Basic Properties of Gases (pp. 843–844)

1. Dalton's law states that each gas in a mixture of gases exerts pressure in proportion to its percentage in the total mixture.
2. Henry's law states that the amount of gas that will dissolve in a liquid is proportional to the partial pressure of that gas. Other important factors are the solubility of the gas in the liquid and the temperature of the liquid.

Composition of Alveolar Gas (p. 844)

3. Alveolar gas contains more carbon dioxide and water vapor and considerably less oxygen than atmospheric air.

External Respiration (pp. 844–846)

4. External respiration is the process of gas exchange that occurs in the lungs. Oxygen enters the pulmonary capillaries; carbon dioxide leaves the blood and enters the alveoli. Factors influencing this process include the partial pressure gradients, the thickness of the respiratory membrane, surface area available, and ventilation-perfusion coupling (matching alveolar ventilation with pulmonary perfusion).

Internal Respiration (pp. 846–847)

5. Internal respiration is the gas exchange that occurs between the systemic capillaries and the tissues. Carbon dioxide enters the blood, and oxygen leaves the blood and enters the tissues.

22.7 Oxygen is transported by hemoglobin, and carbon dioxide is transported in three different ways (pp. 847–852)

Oxygen Transport (pp. 847–850)

1. Molecular oxygen is carried bound to hemoglobin in the red blood cells. The amount of oxygen bound to hemoglobin depends on the P_{O_2} and P_{CO_2} of blood, blood pH, the presence of BPG, and temperature. A small amount of oxygen gas is transported dissolved in plasma.

Carbon Dioxide Transport (pp. 850–852)

2. CO_2 is transported in the blood dissolved in plasma, chemically bound to hemoglobin, and (primarily) as bicarbonate ions in plasma. Loading and unloading of O_2 and CO_2 are mutually beneficial.
3. Accumulating CO_2 lowers blood pH; depletion of CO_2 from blood raises blood pH.

Hypoxia (p. 852)

4. Hypoxia occurs when inadequate amounts of oxygen are delivered to body tissues. When this occurs, the skin and mucosae may become cyanotic.

22.8 Respiratory centers in the brain stem control breathing with input from chemoreceptors and higher brain centers (pp. 853–857)

Neural Mechanisms (pp. 853–854)

1. Medullary respiratory centers are the ventral and dorsal respiratory groups. The ventral respiratory group is likely responsible for the rhythmicity of breathing.
2. The pontine respiratory centers influence the activity of the medullary respiratory centers.

Factors Influencing Breathing Rate and Depth (pp. 854–857)

3. Important chemical factors modifying baseline respiratory rate and depth are arterial levels of CO_2, H^+, and O_2.
4. An increasing arterial P_{CO_2} level (hypercapnia) is the most powerful respiratory stimulant. It acts (via formation of H^+ in brain tissue) on central chemoreceptors to cause a reflexive increase in the rate and depth of breathing.
5. Hypocapnia depresses respiration and results in decreased ventilation and, possibly, apnea.
6. Arterial P_{O_2} levels below 60 mm Hg strongly stimulate peripheral chemoreceptors.
7. Decreased pH and a decline in blood P_{O_2} act on peripheral chemoreceptors and enhance the response to CO_2.
8. Emotions, pain, body temperature changes, and other stressors can alter respiration by acting through hypothalamic centers. Respiration can also be controlled voluntarily for short periods.
9. Dust, mucus, fumes, and pollutants initiate pulmonary irritant reflexes.
10. The inflation (Hering-Breuer) reflex is a protective reflex initiated by extreme overinflation of the lungs; it acts to terminate inspiration.

22.9 Exercise and high altitude bring about respiratory adjustments (pp. 857–858)

Exercise (p. 857)

1. As exercise begins, there is an abrupt increase in ventilation (hyperpnea) followed by a more gradual increase. When exercise stops, there is an abrupt decrease in ventilation followed by a gradual decline to baseline values.
2. P_{O_2}, P_{CO_2}, and blood pH remain quite constant during exercise and hence do not appear to account for changes in ventilation. Inputs from higher centers and proprioceptors may contribute.

High Altitude (pp. 857–858)

3. At high altitudes, arterial P_{O_2} and hemoglobin saturation levels fall because of the decrease in atmospheric pressure compared to sea level. Increased ventilation helps restore P_{O_2} to physiological levels.
4. Long-term acclimatization involves increased erythropoiesis.

22.10 Respiratory diseases are major causes of disability and death (pp. 858–860)

1. Two major respiratory disorders are COPD (emphysema and chronic bronchitis) and lung cancer; smoking is a significant cause. A third major disorder is asthma. Multidrug-resistant tuberculosis may become a major public health problem.

Chronic Obstructive Pulmonary Disease (COPD) (pp. 858–859)

2. COPD is characterized by an irreversible decrease in the ability to force air out of the lungs.
3. In emphysema, alveoli enlarge permanently and disintegrate. The lungs lose their elasticity, and expiration becomes an active process.
4. Chronic bronchitis is characterized by excessive mucus production in the lower respiratory passageways, which severely impairs ventilation and gas exchange.

Asthma (p. 859)

5. Asthma is a reversible obstructive condition caused by an immune response that causes its victims to wheeze and gasp for air as their inflamed respiratory passages constrict. It is marked by acute episodes and symptom-free periods.

Tuberculosis (TB) (p. 859)

6. Tuberculosis, an infectious disease caused by an airborne bacterium, mainly affects the lungs. Although most infected individuals remain asymptomatic by walling off the bacteria in nodules (tubercles), symptoms appear when immunity is depressed. Some patients' failure to complete drug therapy has produced multidrug-resistant TB strains.

Lung Cancer (pp. 859–860)

7. Lung cancer, promoted by free radicals and other carcinogens in tobacco smoke, is extremely aggressive and metastasizes rapidly.

Sleep Apnea (p. 860)

8. Sleep apnea is usually caused by obstruction of the pharynx during sleep.

Developmental Aspects of the Respiratory System
(pp. 860–863)

1. The mucosa of the nasal cavity develops from the invagination of the ectodermal olfactory placodes. The mucosa of the pharynx and lower respiratory passageways develops from an outpocketing of the endodermal foregut lining. Mesoderm forms the walls of the respiratory conduits and the lung stroma.
2. Cystic fibrosis (CF), the most common fatal hereditary disease in North America, results from an abnormal CFTR protein that fails to form a chloride channel. The result is thick mucus, which clogs respiratory passages and invites infection.
3. With age, the thorax becomes more rigid, the lungs become less elastic, and vital capacity declines. In addition, sleep apnea becomes more common, and respiratory system protective mechanisms are less effective.

REVIEW QUESTIONS

To access additional practice questions using your smartphone, tablet, or computer: MasteringA&P® > Study Area > Practice Tests & Quizzes

Level 1 Remember/Understand

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Cutting the phrenic nerves will result in **(a)** air entering the pleural cavity, **(b)** paralysis of the diaphragm, **(c)** stimulation of the diaphragmatic reflex, **(d)** paralysis of the epiglottis.
2. Which of the following laryngeal cartilages is/are not paired? **(a)** epiglottis, **(b)** arytenoid, **(c)** cricoid, **(d)** cuneiform, **(e)** corniculate.
3. Under ordinary circumstances, the inflation reflex is initiated by **(a)** noxious chemicals, **(b)** the ventral respiratory group, **(c)** overinflation of the alveoli and bronchioles, **(d)** the pontine respiratory centers.
4. The detergent-like substance that keeps the alveoli from collapsing between breaths because it reduces the surface tension of the water film in the alveoli is called **(a)** lecithin, **(b)** bile, **(c)** surfactant, **(d)** reluctant.
5. Which of the following determines the direction of gas movement? **(a)** solubility in water, **(b)** partial pressure gradient, **(c)** temperature, **(d)** molecular weight and size of the gas molecule.
6. When the inspiratory muscles contract, **(a)** the size of the thoracic cavity increases in diameter, **(b)** the size of the thoracic cavity increases in length, **(c)** the volume of the thoracic cavity decreases, **(d)** the size of the thoracic cavity increases in both length and diameter.
7. The nutrient blood supply of the lungs is provided by **(a)** the pulmonary arteries, **(b)** the aorta, **(c)** the pulmonary veins, **(d)** the bronchial arteries.
8. Oxygen and carbon dioxide are exchanged in the lungs and through all cell membranes by **(a)** active transport, **(b)** diffusion, **(c)** filtration, **(d)** osmosis.
9. Most oxygen carried in the blood is **(a)** in solution in the plasma, **(b)** combined with plasma proteins, **(c)** chemically combined with the heme in red blood cells, **(d)** in solution in the red blood cells.
10. Which of the following has the greatest stimulating effect on the respiratory centers in the brain? **(a)** oxygen, **(b)** carbon dioxide, **(c)** calcium, **(d)** willpower.

Level 2 Apply/Analyze

11. In mouth-to-mouth artificial respiration, the rescuer blows air from his or her own respiratory system into that of the victim. Which of the following statements are correct?
    (1) Expansion of the victim's lungs is brought about by blowing air in at higher than atmospheric pressure (positive-pressure breathing).
    (2) During inflation of the lungs, the intrapleural pressure increases.
    (3) This technique will not work if the victim has a hole in the chest wall, even if the lungs are intact.
    (4) Expiration during this procedure depends on the elasticity of the alveolar and thoracic walls.
    (a) all of these, **(b)** 1, 2, 4, **(c)** 1, 2, 3, **(d)** 1, 4.
12. A baby holding its breath will **(a)** have brain cells damaged because of low blood oxygen levels, **(b)** automatically start to breathe again when the carbon dioxide levels in the blood reach a high enough value, **(c)** suffer heart damage because of increased pressure in the carotid sinus and aortic arch areas, **(d)** be called a "blue baby."
13. Damage to which of the following would most likely result in cessation of breathing? **(a)** the pontine respiratory group, **(b)** the ventral respiratory group of the medulla, **(c)** the stretch receptors in the lungs, **(d)** the dorsal respiratory group of the medulla.
14. The bulk of carbon dioxide is carried **(a)** chemically combined with the amino acids of hemoglobin as carbaminohemoglobin in the red blood cells, **(b)** as the ion HCO_3^- in the plasma after first entering the red blood cell, **(c)** as carbonic acid in the plasma, **(d)** chemically combined with the heme portion of Hb.
15. Briefly explain the anatomical "reason" why most men have deeper voices than boys or women.
16. **(a)** Differentiate clearly between minute ventilation and alveolar ventilation rate. **(b)** Which provides a more accurate measure of ventilatory efficiency, and why?
17. **(a)** Define hyperventilation. **(b)** If you hyperventilate, do you retain or expel more carbon dioxide? **(c)** What effect does hyperventilation have on blood pH?
18. Describe age-related changes in respiratory function.
19. A member of the "Blues" gang was rushed into an emergency room after receiving a knife wound in the left side of his thorax. The diagnosis was pneumothorax and a collapsed lung. Explain exactly **(a)** why the lung collapsed, and **(b)** why only one lung (not both) collapsed.

Level 3 Evaluate/Synthesize

20. Trace the route of air from the nares to an alveolus. Name subdivisions of organs where applicable, and differentiate between conducting and respiratory zone structures.

21. **(a)** Why is it important that the trachea is reinforced with cartilage rings? **(b)** Why is it advantageous that the rings are incomplete posteriorly?
22. Describe the functional relationships between volume changes and gas flow into and out of the lungs.
23. Daniel, the swimmer with the fastest time on the Springfield College swim team, routinely hyperventilates before a meet, as he says, "to sock some more oxygen into my lungs so I can swim longer without having to breathe." First of all, what basic fact about oxygen loading has Daniel forgotten (a lapse leading to false thinking)? Second, how is Daniel jeopardizing not only his time but his life?
24. A surgeon removed three adjacent bronchopulmonary segments from the left lung of a patient with TB. Almost half of the lung was removed, yet there was no severe bleeding, and relatively few blood vessels had to be cauterized (closed off). Why was the surgery so easy to perform?
25. After a week of scuba diving in the Bahamas, Mary Ann boards an airplane. During her flight home, she develops aching joints, nausea, and dyspnea, which resolve upon landing. During the flight, the cabin pressure was equivalent to an altitude of 8000 feet. Explain her problems.

CLINICAL CASE STUDY

35-Year-Old Female with Chest Trauma

Barbara Joley was in a major car accident. When EMS managed to free her from the wreckage, she was cyanotic and apneic (not breathing). Her heart was still beating, but her pulse was fast and thready. The emergency medical technician reported that when Barbara was found, her head was cocked at a peculiar angle and it looked like she had a fracture at the level of the C_2 vertebra. The following questions refer to these observations.

1. How might the "peculiar" head position explain Barbara's cessation of breathing?
2. + NCLEX-STYLE Barbara's cyanosis can best be explained by which of the following?
   - **a.** Trauma has caused bleeding under the skin, and the accumulated blood is turning black and blue.
   - **b.** Her lungs must be damaged, and as a result, the right side of her heart is sending blood to the body instead of the lungs.
   - **c.** The level of CO_2 in her blood has increased because her breathing has stopped.
   - **d.** The level of O_2 in her blood has decreased because her breathing has stopped.

Barbara is artificially ventilated and survives transport to the hospital. The admission notes include the following observations.

- Right thorax compressed; ribs 7 to 9 fractured
- Right lung pneumothorax; trachea deviation (shift) to the left

Relative to these notes:

3. What is pneumothorax and why would it cause the right lung to collapse? Why hasn't the left lung collapsed?
4. + NCLEX-STYLE How do Barbara's recorded injuries relate to the pneumothorax?
   - **a.** The pain from her broken ribs is causing her to decrease breathing, so the right lung is not inflating.
   - **b.** Barbara's fractured ribs probably punctured her lung tissue and allowed air within the lung to enter the pleural cavity.
   - **c.** When the level of O_2 in the blood decreases, a negative feedback loop involving the central chemoreceptors causes lung inflation to decrease as well.
   - **d.** Her traumatic injury has caused her peripheral chemoreceptors to stop working, so they are not causing her to increase ventilation.
5. The physician inserts a chest tube into the right intrapleural cavity and hooks it up to suction. How might this alleviate the pneumothorax?

23 The Digestive System

In this chapter, you will learn that

The digestive system breaks down food and absorbs the components for use by body cells

by exploring

Part 1 Overview of the Digestive System

by asking

- **23.1 What major processes occur during digestive system activity?**
- **23.2 How is the digestive system organized?**
- **23.3 How is the digestive system controlled?**

Part 2 Functional Anatomy of the Digestive System

looking closer at

- **23.4 The mouth and associated organs**
- **23.5 The pharynx and esophagus**
- **23.6 The stomach**
- **23.7 The liver, gallbladder, and pancreas**
- **23.8 The small intestine**
- **23.9 The large intestine**

Part 3 Physiology of Digestion and Absorption

by first asking

- **23.10 What are the basic mechanisms of digestion and absorption?**

then asking

- **23.11 How is each type of nutrient processed?**

and finally, exploring

- **Developmental Aspects of the Digestive System**

Children are fascinated by the workings of the digestive system. They relish crunching a potato chip, delight in making "mustaches" with milk, and giggle when their stomach "growls." As adults, we know that a healthy digestive system is essential to life, because it converts foods into the raw materials that build and fuel our body's cells. Specifically, the **digestive system** takes in food, breaks it down into nutrient molecules, absorbs these molecules into the bloodstream, and then rids the body of the indigestible remains.

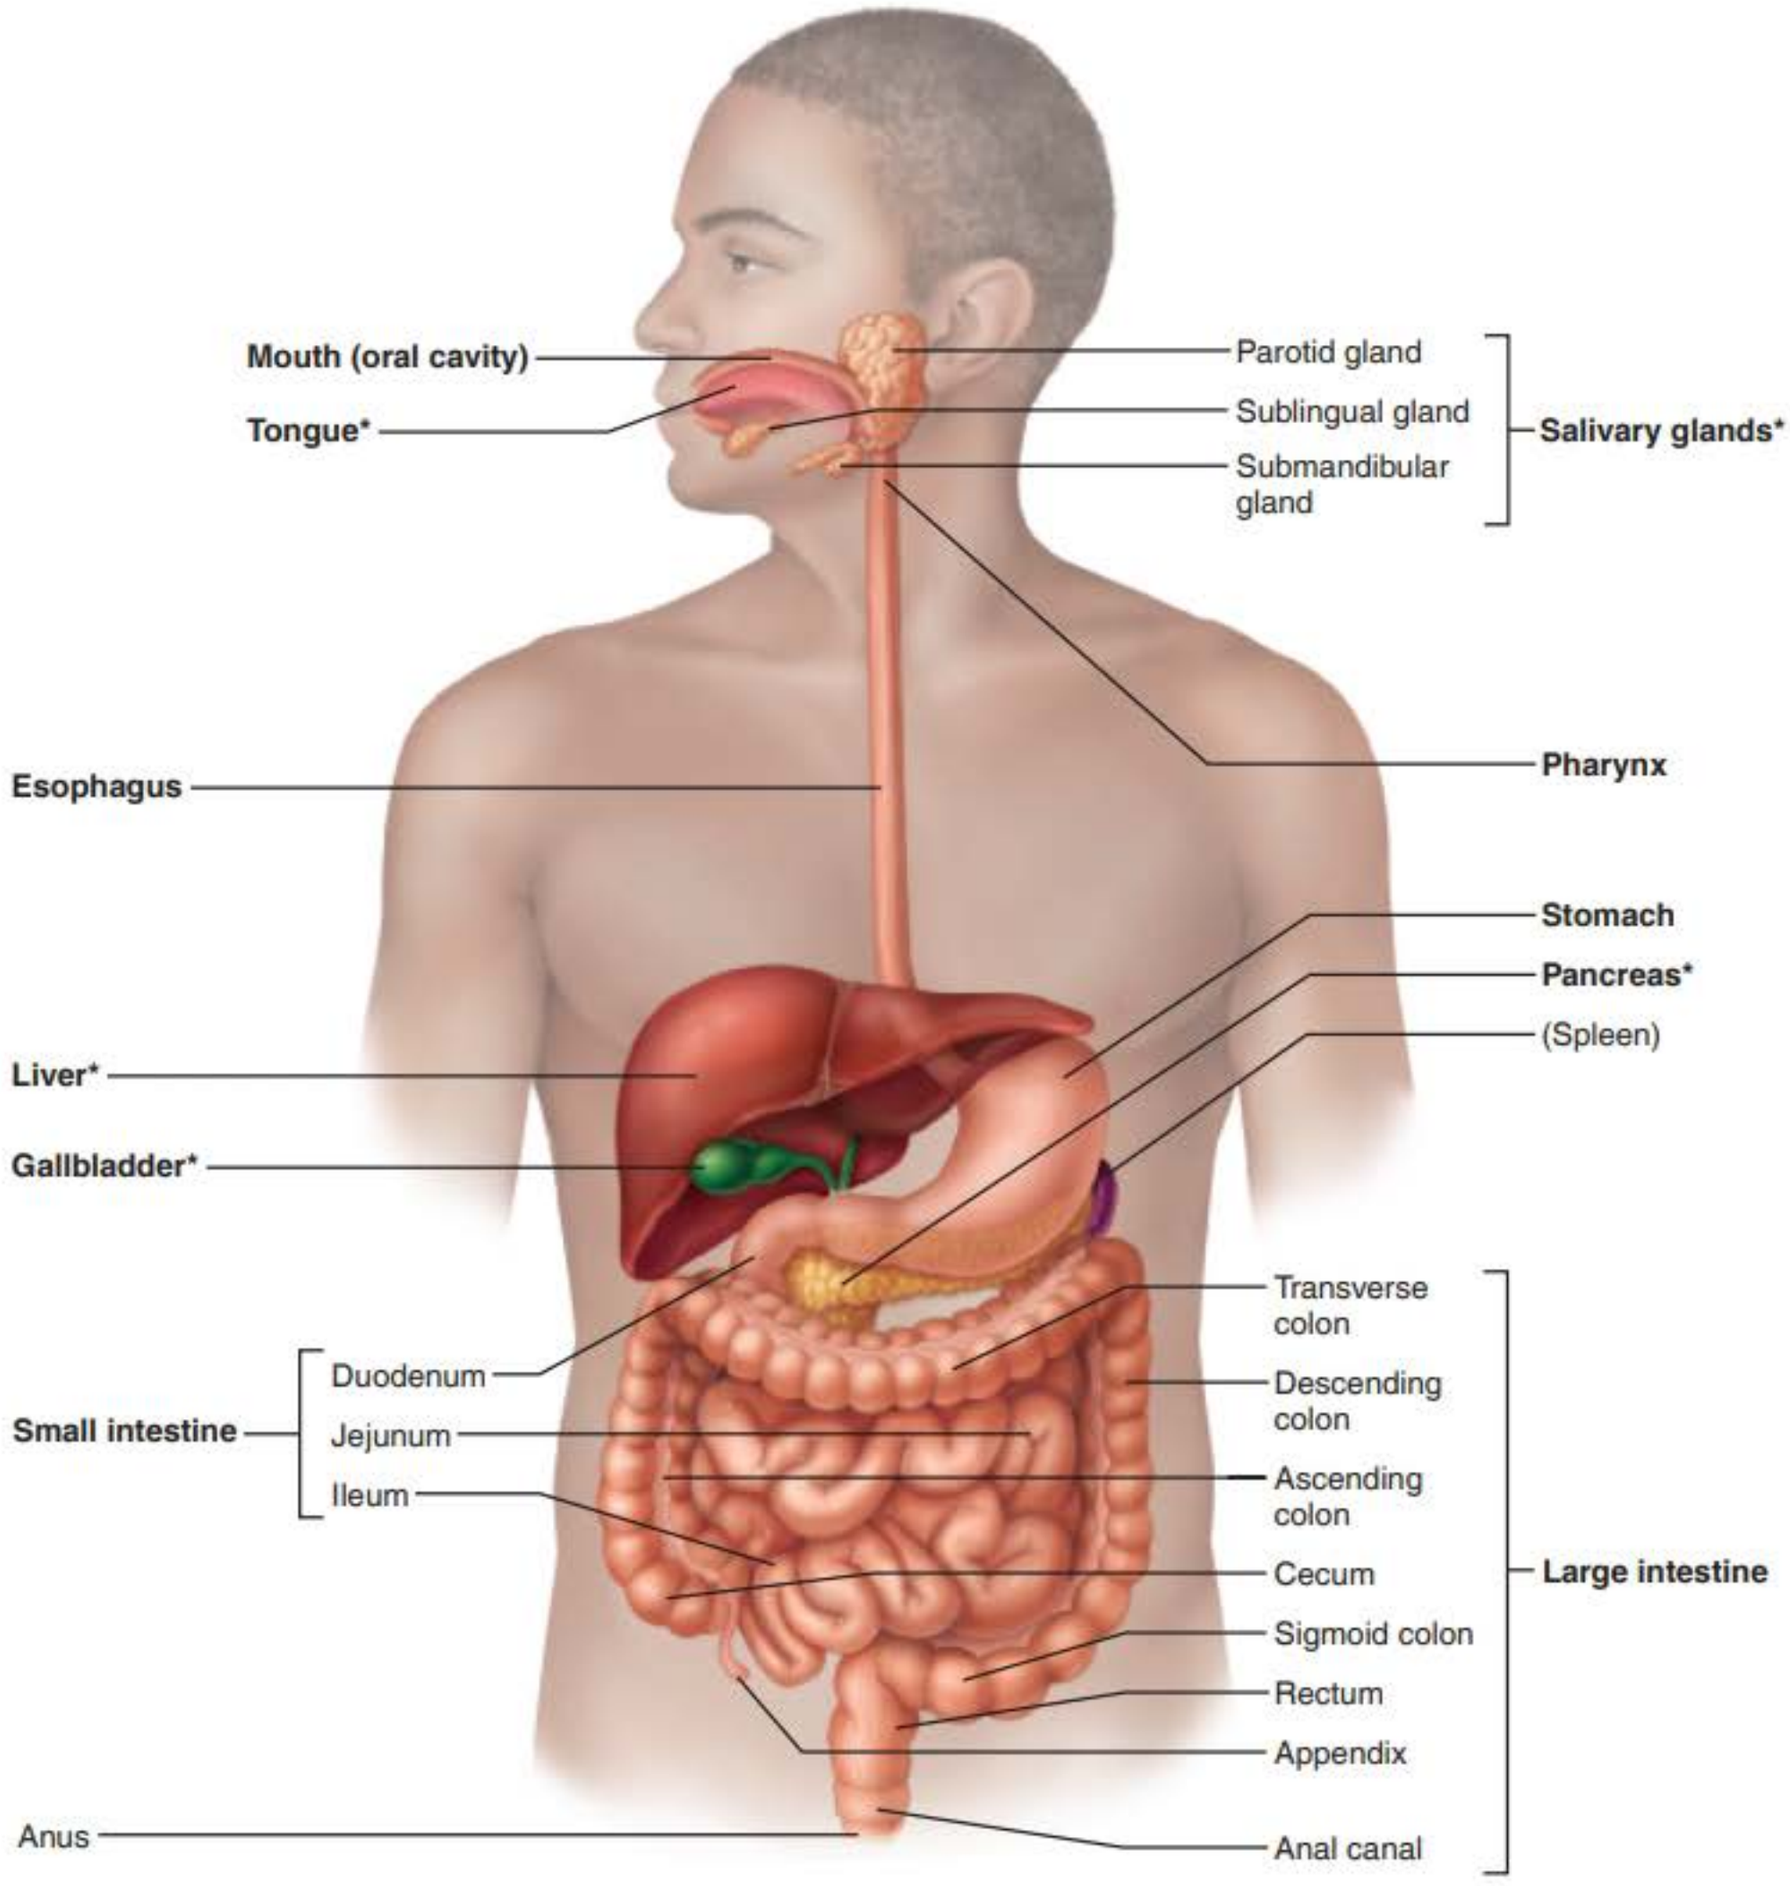

Figure 23.1 Alimentary canal and related accessory digestive organs. Organs with asterisks are accessory organs. Those without asterisks are alimentary canal organs (except the spleen, a lymphoid organ).

PART 1

OVERVIEW OF THE DIGESTIVE SYSTEM

Learning Outcome

- **Describe the functions of the digestive system, and differentiate between organs of the alimentary canal and accessory digestive organs.**

The organs of the digestive system fall into two main groups: (1) those of the *alimentary canal* (al″ĭ-men′tar-e; *aliment* = nourish) and (2) *accessory digestive organs* (**Figure 23.1**).

The **alimentary canal**, also called the **gastrointestinal (GI) tract** or gut, is the continuous muscular tube that winds through the body from the mouth to the anus. It **digests** food—breaks it down into smaller fragments (*digest* = dissolve)—and **absorbs** the digested fragments through its lining into the blood.

The organs of the alimentary canal are the *mouth*, *pharynx*, *esophagus*, *stomach*, *small intestine*, and *large intestine*. The large intestine leads to the terminal opening, or *anus*. In a cadaver, the alimentary canal is approximately 9 m (about 30 ft) long, but in a living person, it is considerably shorter because of its muscle tone. Food material in this tube is technically outside the body because the canal is open to the external environment at both ends.

The **accessory digestive organs** are the *teeth*, *tongue*, *gallbladder*, and a number of large digestive glands—the *salivary glands*, *liver*, and *pancreas*. The teeth and tongue are in the mouth, or oral cavity, while the digestive glands and gallbladder lie outside the GI tract and connect to it by ducts. The accessory digestive glands produce a variety of secretions that help break down foodstuffs.

23.1 What major processes occur during digestive system activity?

Learning Outcome

- **List and define the major processes occurring during digestive system activity.**

We can view the digestive tract as a "disassembly line" in which food becomes less complex at each step of processing and its nutrients become available to the body. The processing of food by the digestive system involves six essential activities (**Figure 23.2**):

- **Ingestion** is taking food into the digestive tract (eating).
- **Propulsion**, which moves food through the alimentary canal, includes *swallowing*, which is initiated voluntarily, and *peristalsis* (per″ĭ-stal′sis), an involuntary process. **Peristalsis** (*peri* = around; *stalsis* = constriction), the major means of propulsion, involves alternating waves of contraction and relaxation of muscles in the organ walls (**Figure 23.3a**). Its main effect is to squeeze food along the tract, but some mixing occurs as well. In fact, peristaltic waves are so powerful that, once swallowed, food and fluids will reach your stomach even if you stand on your head.

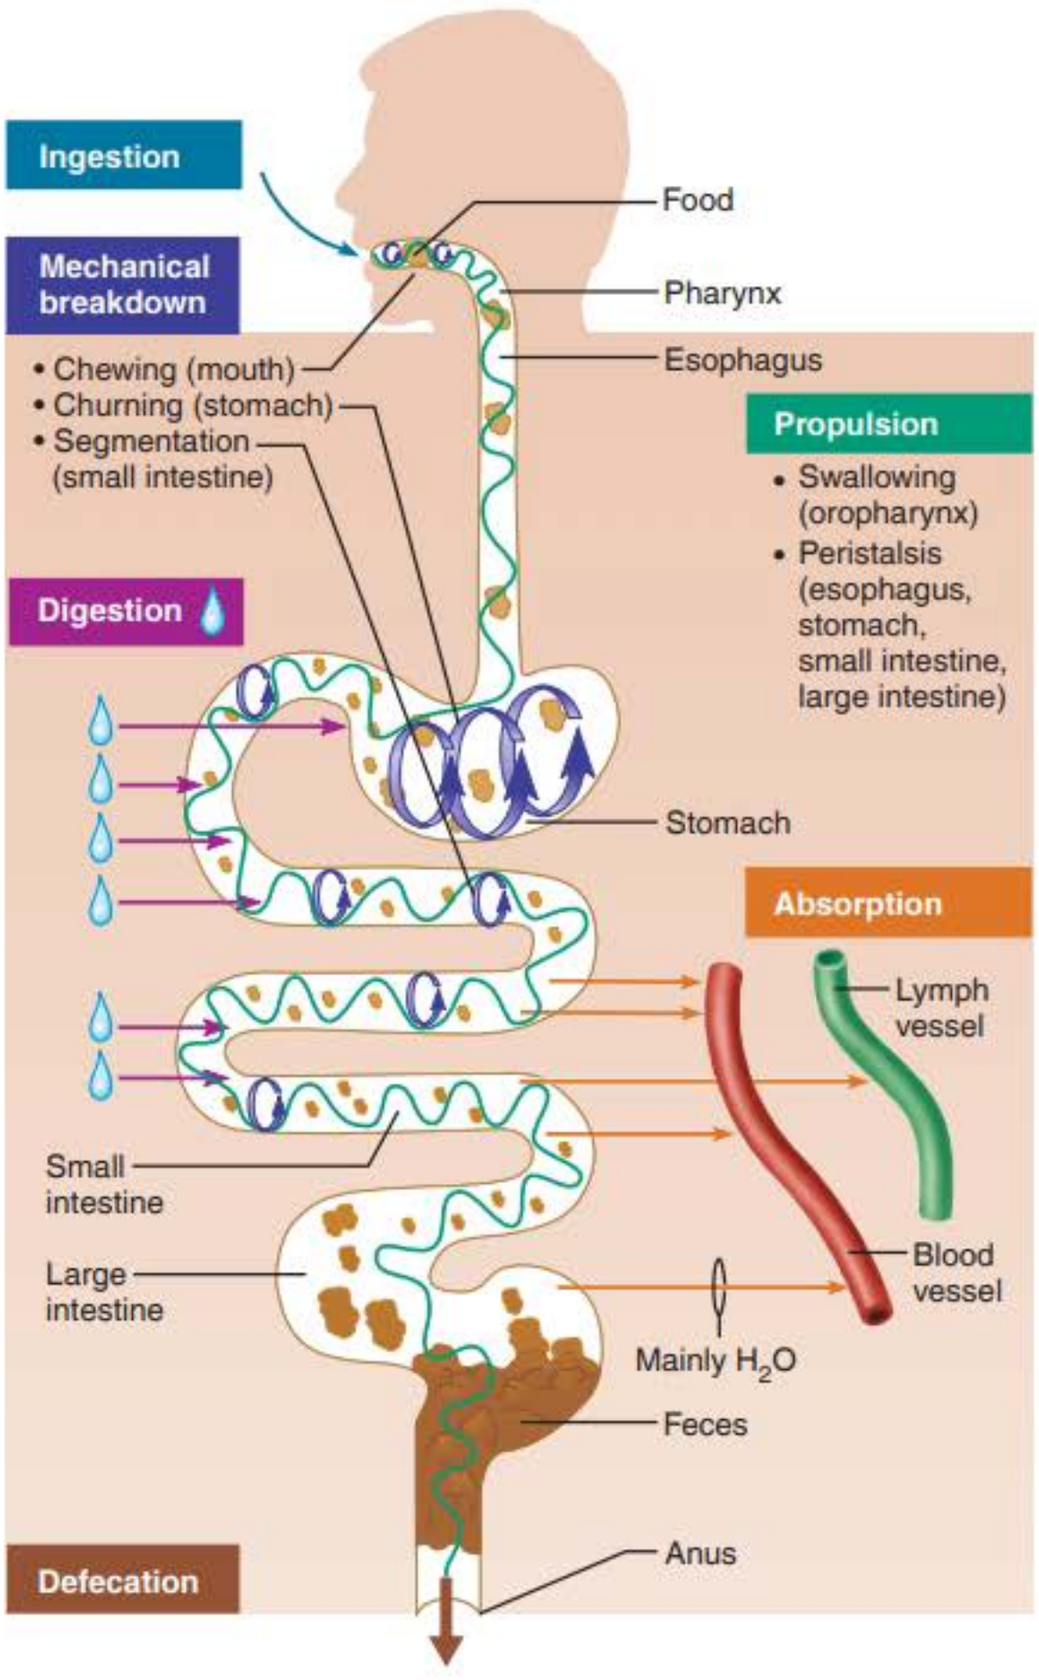

Figure 23.2 Gastrointestinal tract activities. Note that sites of digestion produce enzymes or receive enzymes or other secretions made by accessory organs outside the alimentary canal.

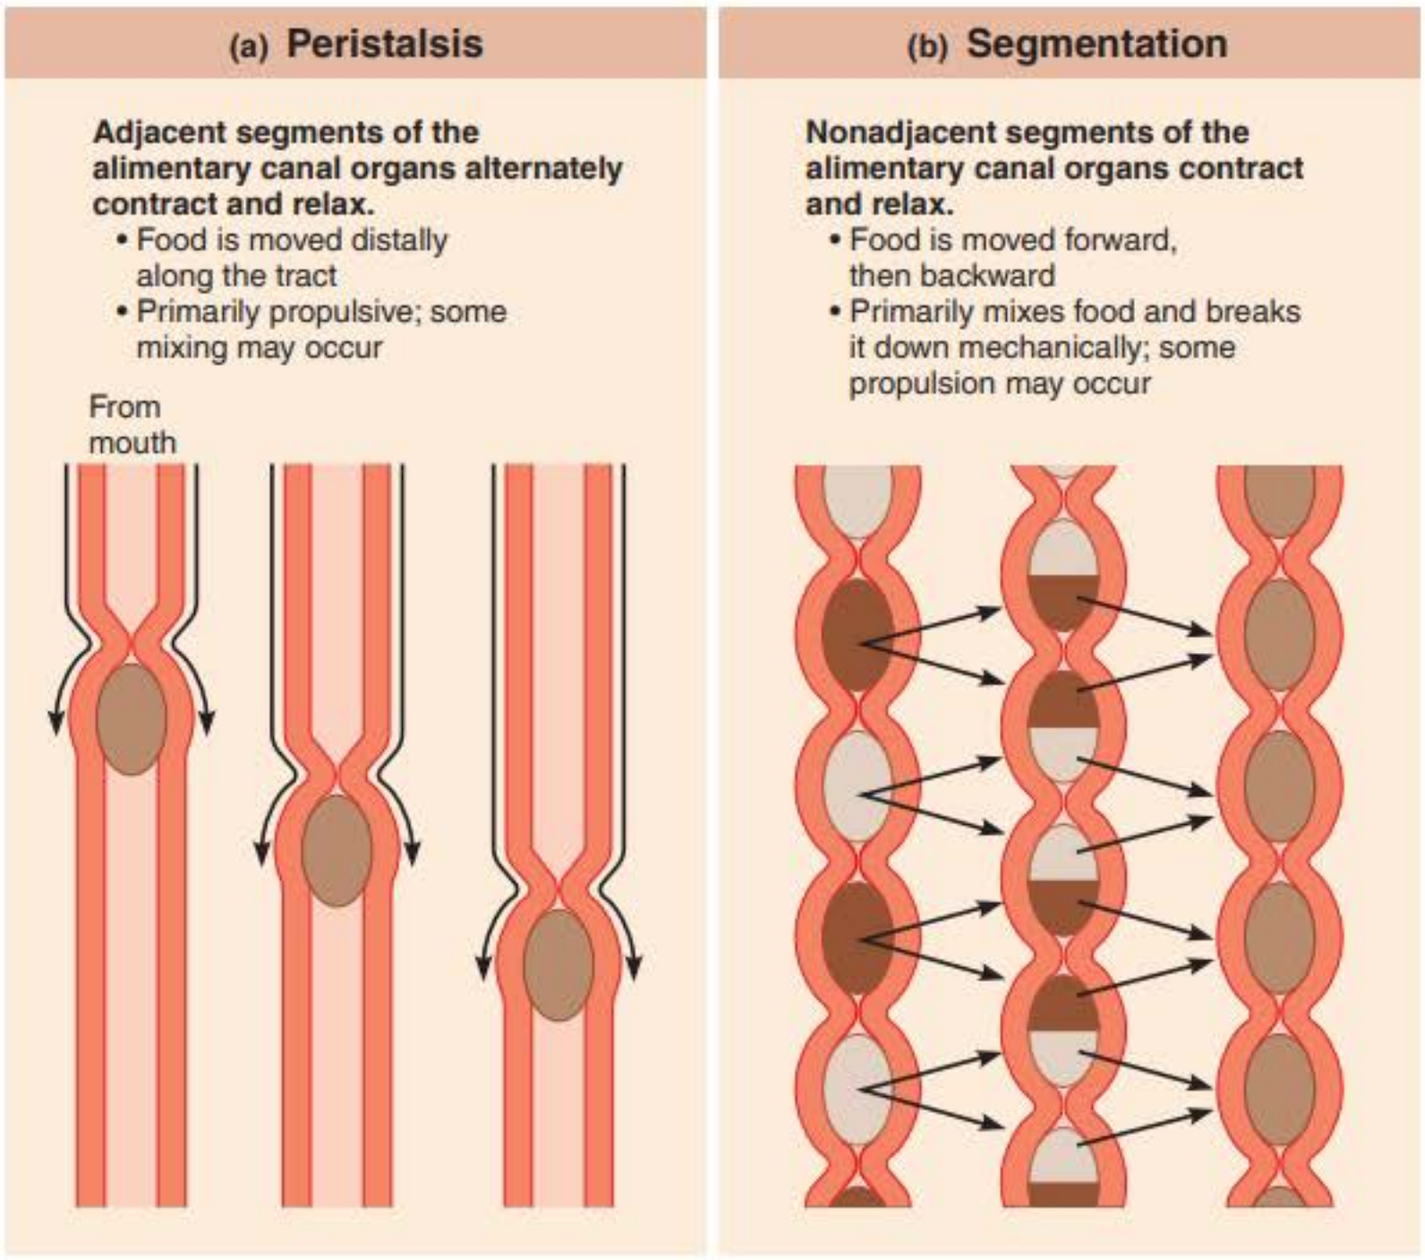

Figure 23.3 Peristalsis and segmentation.

- **Mechanical breakdown** increases the surface area of ingested food, physically preparing it for digestion by enzymes. Mechanical processes include chewing, mixing food with saliva by the tongue, churning food in the stomach, and **segmentation** (rhythmic local constrictions of the small intestine, Figure 23.3b). Segmentation mixes food with digestive juices and makes absorption more efficient by repeatedly moving different parts of the food mass over the intestinal wall.
- **Digestion** involves a series of steps in which enzymes secreted into the lumen (cavity) of the alimentary canal break down complex food molecules to their chemical building blocks. That is, digestion is a catabolic process (◀ p. 36).
- **Absorption** is the passage of digested end products (plus vitamins, minerals, and water) from the lumen of the GI tract through the mucosal cells by active or passive transport into the blood or lymph.
- **Defecation** eliminates indigestible substances from the body via the anus in the form of feces.

Some of these processes are the job of a single organ. For example, only the mouth ingests and only the large intestine defecates. But most digestive system activities require the cooperation of several organs and occur bit by bit as food moves along the tract as described later.

Check Your Understanding

1. Name one organ of the alimentary canal found in the thorax. Name three organs located in the abdominal cavity.
2. What is the usual site of ingestion?
3. Which digestive system activity actually moves nutrients from the outside to the inside of the body?

For answers, see Answers Appendix.

23.2 The GI tract has four layers and is usually surrounded by peritoneum

Learning Outcomes

- **Describe the location and function of the peritoneum.**
- **Define retroperitoneal and name the retroperitoneal organs of the digestive system.**
- **Define splanchnic circulation and indicate the importance of the hepatic portal system.**
- **Describe the tissue composition and general function of each of the four layers of the alimentary canal.**

Relationship of the Digestive Organs to the Peritoneum

Most digestive system organs reside in the abdominopelvic cavity. Recall from Chapter 1 that all ventral body cavities

contain slippery *serous membranes* (◀ pp. 18–19). The **peritoneum** of the abdominopelvic cavity is the most extensive of these membranes (**Figure 23.4**). The **visceral peritoneum** covers the external surfaces of most digestive organs and is continuous with the **parietal peritoneum** that lines the body wall (see Figure 23.34d, p. 908). Between the two peritoneums is the **peritoneal cavity**, a slitlike potential space containing a slippery fluid secreted by the serous membranes. The serous fluid allows the mobile digestive organs to glide easily across one another and along the body wall as they carry out their activities.

A **mesentery** (mes′en-ter″e) is a double layer of peritoneum—a sheet of two serous membranes fused back to back—that extends to the digestive organs from the body wall. Mesenteries have the following functions:

- They provide routes for blood vessels, lymphatics, and nerves to reach the digestive viscera.
- They hold organs in place.
- They store fat.

In most places the mesentery is *dorsal* and attaches to the posterior abdominal wall, but there are *ventral* mesenteries too, such as the one that extends from the liver to the anterior abdominal wall (Figure 23.4, middle). Some digestive organ mesenteries have specific names (such as the *omenta*), or are called "ligaments" (even though these peritoneal folds are nothing like the fibrous ligaments that connect bones).

Not all alimentary canal organs are suspended by a mesentery. For example, during development, some regions of the small intestine adhere to the dorsal abdominal wall (Figure 23.4, bottom). In so doing, they lose their mesentery and come to lie posterior to the peritoneum. These organs, which include most of the pancreas and duodenum (the first part of the small intestine) and parts of the large intestine, are called **retroperitoneal organs** (*retro* = behind). By contrast, digestive organs (like the stomach) that keep their mesentery and remain in the peritoneal cavity are called **intraperitoneal** or **peritoneal organs**.

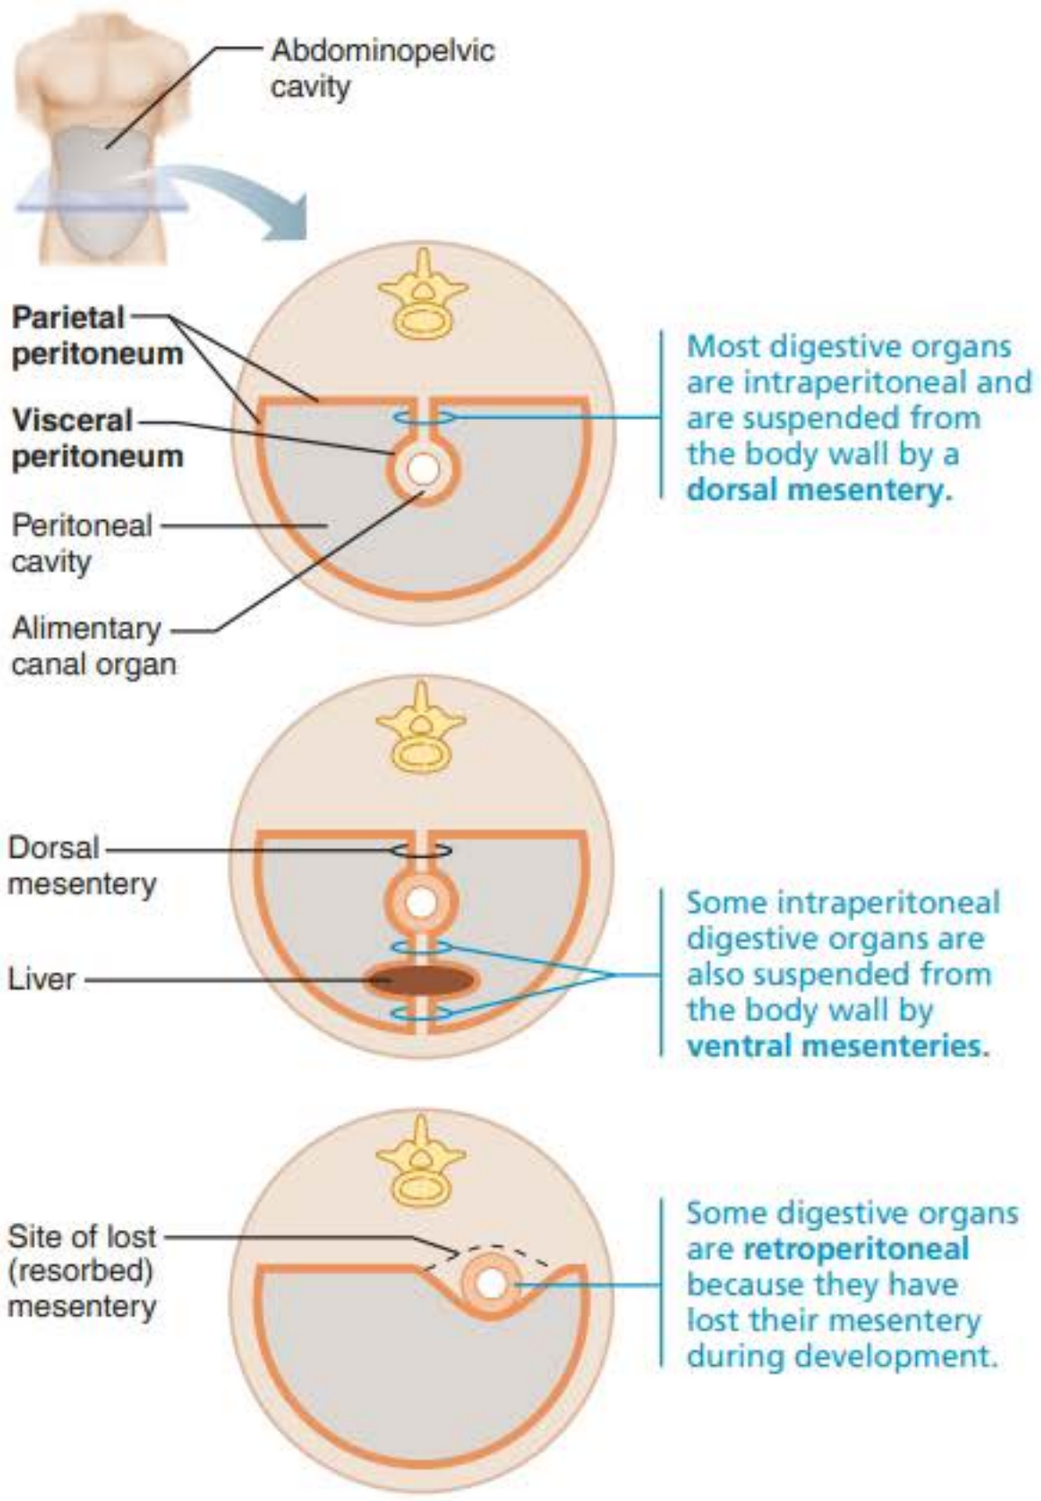

Figure 23.4 The peritoneum and mesenteries. Note that the peritoneal cavity is much smaller than depicted here.

HOMEOSTATIC IMBALANCE 23.1 CLINICAL

Peritonitis is inflammation of the peritoneum. It can arise from a piercing abdominal wound, a perforating ulcer that leaks stomach juices into the peritoneal cavity, or poor sterile technique during abdominal surgery. However, most commonly it results from a burst appendix that sprays bacteria-containing feces all over the peritoneum. In peritonitis, the peritoneal coverings tend to stick together around the infection site. This localizes the infection, providing time for macrophages to prevent the inflammation from spreading.

If peritonitis becomes widespread within the peritoneal cavity, it is dangerous and often lethal. Treatment includes removing as much infectious debris as possible and administering megadoses of antibiotics.

Histology of the Alimentary Canal

Each digestive organ has only a share of the work of digestion. Consequently, it helps to consider structural characteristics that promote similar functions in all parts of the alimentary canal before we consider the functional anatomy of each digestive organ.

From the esophagus to the anal canal, the walls of the alimentary canal have the same four basic layers, or *tunics*—*mucosa, submucosa, muscularis externa*, and *serosa* (**Figure 23.5**). Each layer contains a predominant tissue type that plays a specific role in food breakdown.

The Mucosa

The innermost layer is the **mucosa**, or **mucous membrane**, a moist epithelial membrane that lines the alimentary canal lumen from mouth to anus. Its major functions are to:

- *Secrete* mucus, digestive enzymes, and hormones
- *Absorb* the end products of digestion into the blood
- *Protect* against infectious disease

The mucosa in a particular region of the GI tract may perform one or all three of these functions.

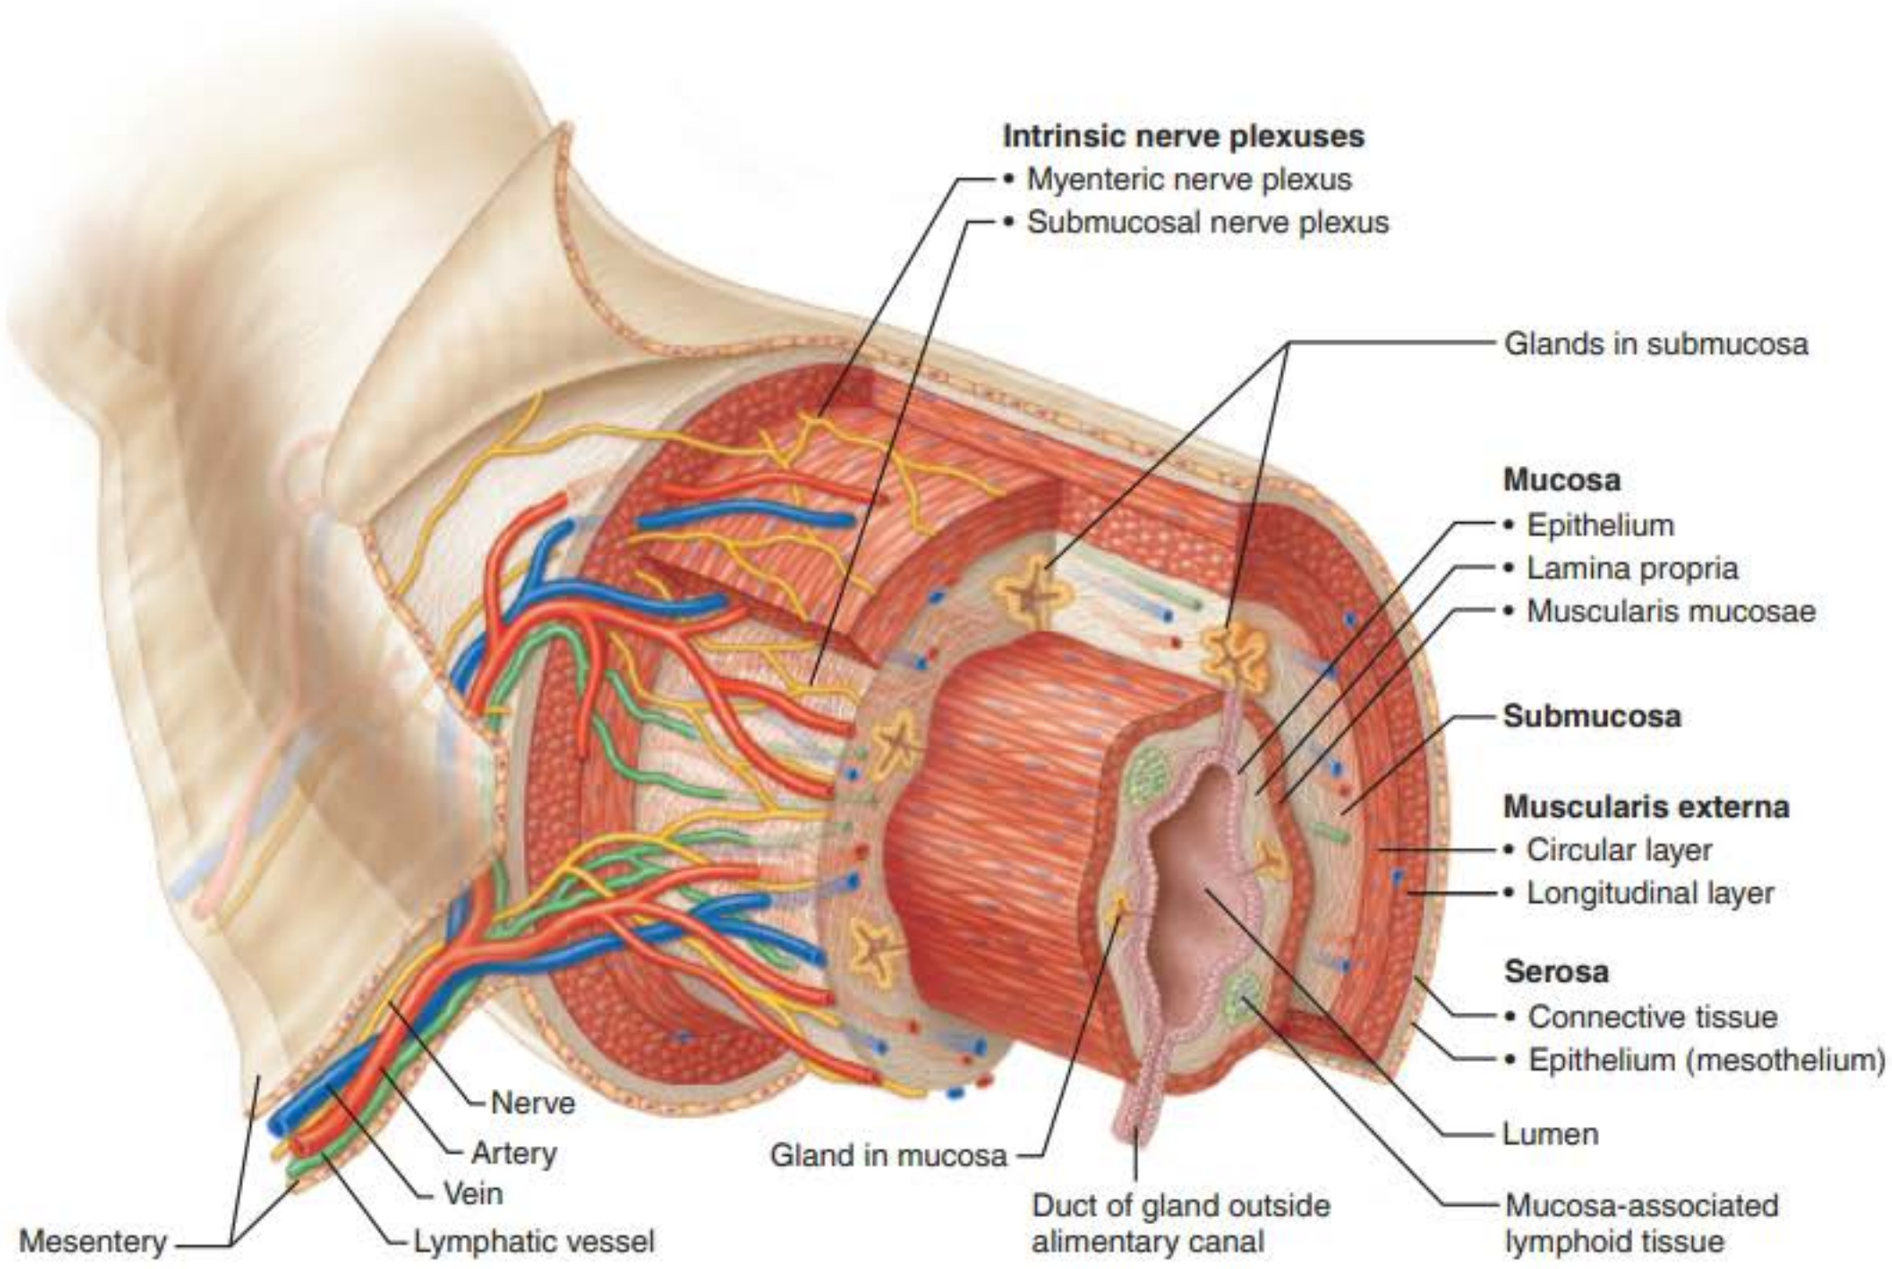

Figure 23.5 Basic structure of the alimentary canal. Its four basic layers are the mucosa, submucosa, muscularis externa, and serosa.

More complex than most other mucosae in the body, the typical digestive mucosa consists of three sublayers: (1) a lining epithelium, (2) a lamina propria, and (3) a muscularis mucosae. Except for that of the mouth, esophagus, and anus where it is stratified squamous, the **epithelium** of the mucosa is a *simple columnar epithelium* rich in mucus-secreting cells (◀ p. 120). The slippery mucus it produces protects certain digestive organs from being digested by enzymes working within their cavities and eases food passage along the tract. In the stomach and small intestine, the mucosa also contains both enzyme-synthesizing and hormone-secreting cells. In such sites, the mucosa is a diffuse endocrine organ as well as part of the digestive organ.

The **lamina propria** (*proprius* = one's own), which underlies the epithelium, is loose areolar connective tissue (◀ p. 130). Its capillaries nourish the epithelium and absorb digested nutrients. Its isolated lymphoid follicles, part of **MALT** (the mucosa-associated lymphoid tissue; ◀ p. 774), help defend us against bacteria and other pathogens, which have rather free access to our digestive tract. Particularly large collections of lymphoid follicles occur within the pharynx (as the tonsils) and in the appendix.

External to the lamina propria is the **muscularis mucosae**, a scant layer of smooth muscle cells that produces local movements of the mucosa that can enhance absorption and secretion.

The Submucosa

The **submucosa**, just external to the mucosa, is areolar connective tissue containing a rich supply of blood and lymphatic vessels, lymphoid follicles, and nerve fibers that supply the surrounding tissues of the GI tract wall. Its abundant elastic fibers enable the stomach, for example, to regain its normal shape after temporarily storing a large meal.

The Muscularis Externa

Surrounding the submucosa is the **muscularis externa**, also simply called the **muscularis**. This layer is responsible for segmentation and peristalsis. It typically has an inner *circular layer* and an outer *longitudinal layer* of smooth muscle cells (◀ Figure 9.22, p. 310, and Figure 23.5). In several places along the tract, the circular layer thickens, forming *sphincters* that act as valves to control food passage from one organ to the next and prevent backflow.

The Serosa

The **serosa**, the outermost layer of the intraperitoneal organs, is the *visceral peritoneum*. In most alimentary canal organs, it is formed of areolar connective tissue covered with *mesothelium*, a single layer of squamous epithelial cells (◀ Figure 4.11a and ◀ Figure 4.4a, respectively).

In the esophagus, which is located in the thoracic instead of the abdominopelvic cavity, the serosa is replaced by an **adventitia** (ad″ven-tish′e-ah), ordinary dense connective tissue that binds the esophagus to surrounding structures. Retroperitoneal organs have *both* an adventitia (on the side facing the dorsal body wall) and a serosa (on the side facing the peritoneal cavity).

Blood Supply: The Splanchnic Circulation

The **splanchnic circulation** includes those arteries that branch off the abdominal aorta to serve the digestive organs and the *hepatic portal circulation*. The arterial supply—the branches of the celiac trunk that serve the spleen, liver, and stomach, and the mesenteric arteries that serve the small and large intestines (◀ pp. 745–747)—normally receives one-quarter of the cardiac output. This percentage increases after a meal. The hepatic portal circulation (◀ pp. 756–757) collects nutrient-rich venous blood draining from the digestive viscera and delivers it to the liver.

Check Your Understanding

4. How does the location of the visceral peritoneum differ from that of the parietal peritoneum?
5. Of the following organs, which is/are retroperitoneal? Stomach, pancreas, liver.
6. What name is given to the venous portion of the splanchnic circulation?
7. DRAW Sketch a cross section of the alimentary canal and label the four major tissue layers and the three parts of the innermost layer.
8. MAKE CONNECTIONS The two types of smooth muscle are unitary and multi unit (see Chapter 9). Which type would you expect to find in the muscularis externa, and what characteristics make it well suited for this location?

For answers, see Answers Appendix.

23.3 The GI tract has its own nervous system called the enteric nervous system

Learning Outcome

- **Describe stimuli and controls of digestive activity.**

A theme we have stressed in this book is the body's efforts to maintain a constant internal environment. Most organ systems respond to changes in that environment either by attempting to restore some plasma variable to its former levels or by changing their own function.

The digestive system, however, must create the optimal environment for its functioning within the lumen of the GI tract, an area that is actually *outside* the body. Essentially all digestive tract regulatory mechanisms control luminal conditions so that food breakdown and absorption can occur there as effectively as possible.

In order to accomplish this, the GI tract has its own *enteric nervous system* (sometimes also called the *gut brain*), which consists of over 100 million neurons. You could truly say that the gut, with more neurons than the entire spinal cord, has a mind of its own! We will describe the enteric nervous system next, and then outline key concepts that govern regulation of digestive activity.

Enteric Nervous System

The **enteric nervous system** (*enter* = gut) is the in-house nerve supply of the alimentary canal. It is staffed by **enteric neurons** that communicate widely with one another to regulate digestive system activity. These semiautonomous enteric neurons constitute the bulk of the two major *intrinsic nerve plexuses* (ganglia interconnected by unmyelinated fiber tracts) found in the walls of the alimentary canal: the submucosal and myenteric nerve plexuses (Figure 23.5). These plexuses interconnect like chicken wire all along the GI tract and regulate digestive activity throughout its length (**Figure 23.6**).

The **submucosal nerve plexus** occupies the submucosa, and the large **myenteric nerve plexus** (mi-en-ter′ik; "intestinal muscle") lies between the circular and longitudinal muscle layers of the muscularis externa. Enteric neurons of these plexuses provide the major nerve supply to the GI tract wall and control GI tract motility (motion).

The enteric nervous system participates in both short and long reflex arcs (**Figure 23.7**).

- **Short reflexes** are mediated entirely by enteric nervous system plexuses in response to stimuli within the GI tract.

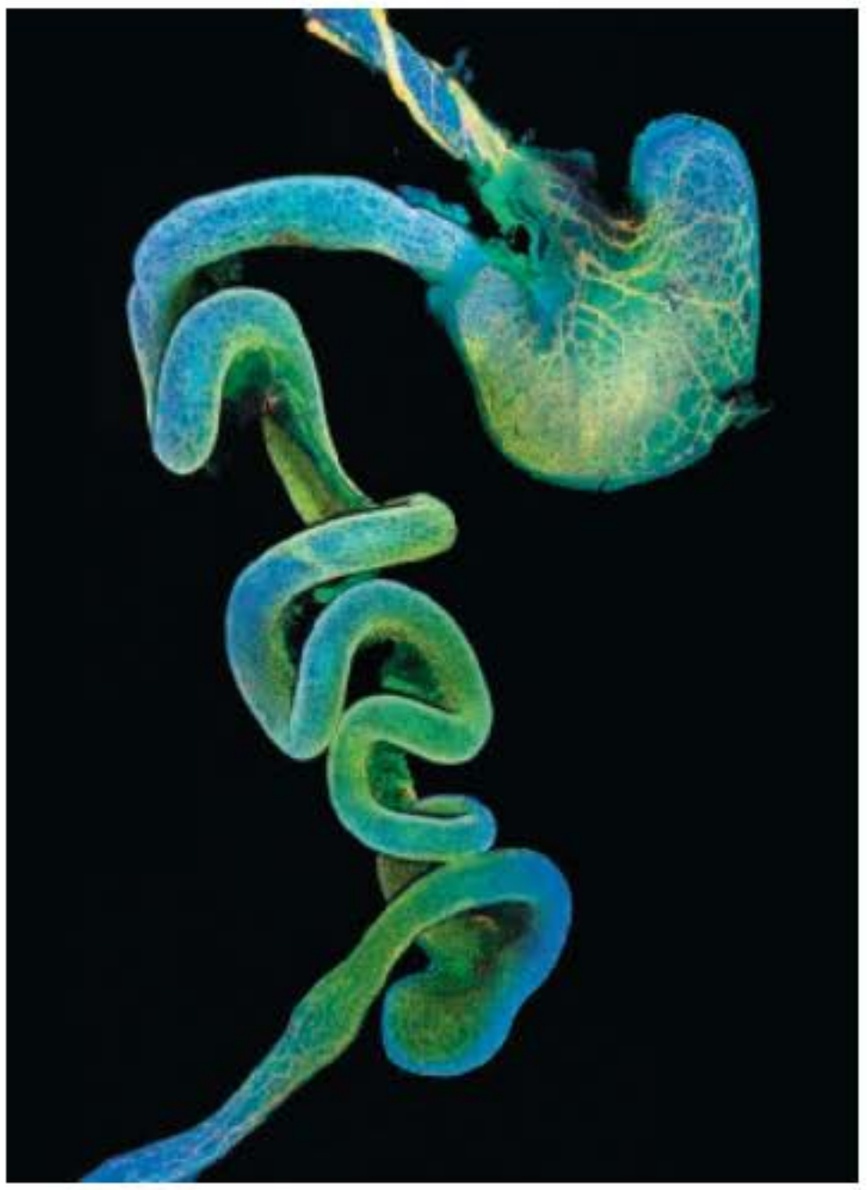

Figure 23.6 The enteric nervous system. The nerves of the enteric nervous sytem (yellow) extend throughout the alimentary canal. (Photo of immature mouse gut.)

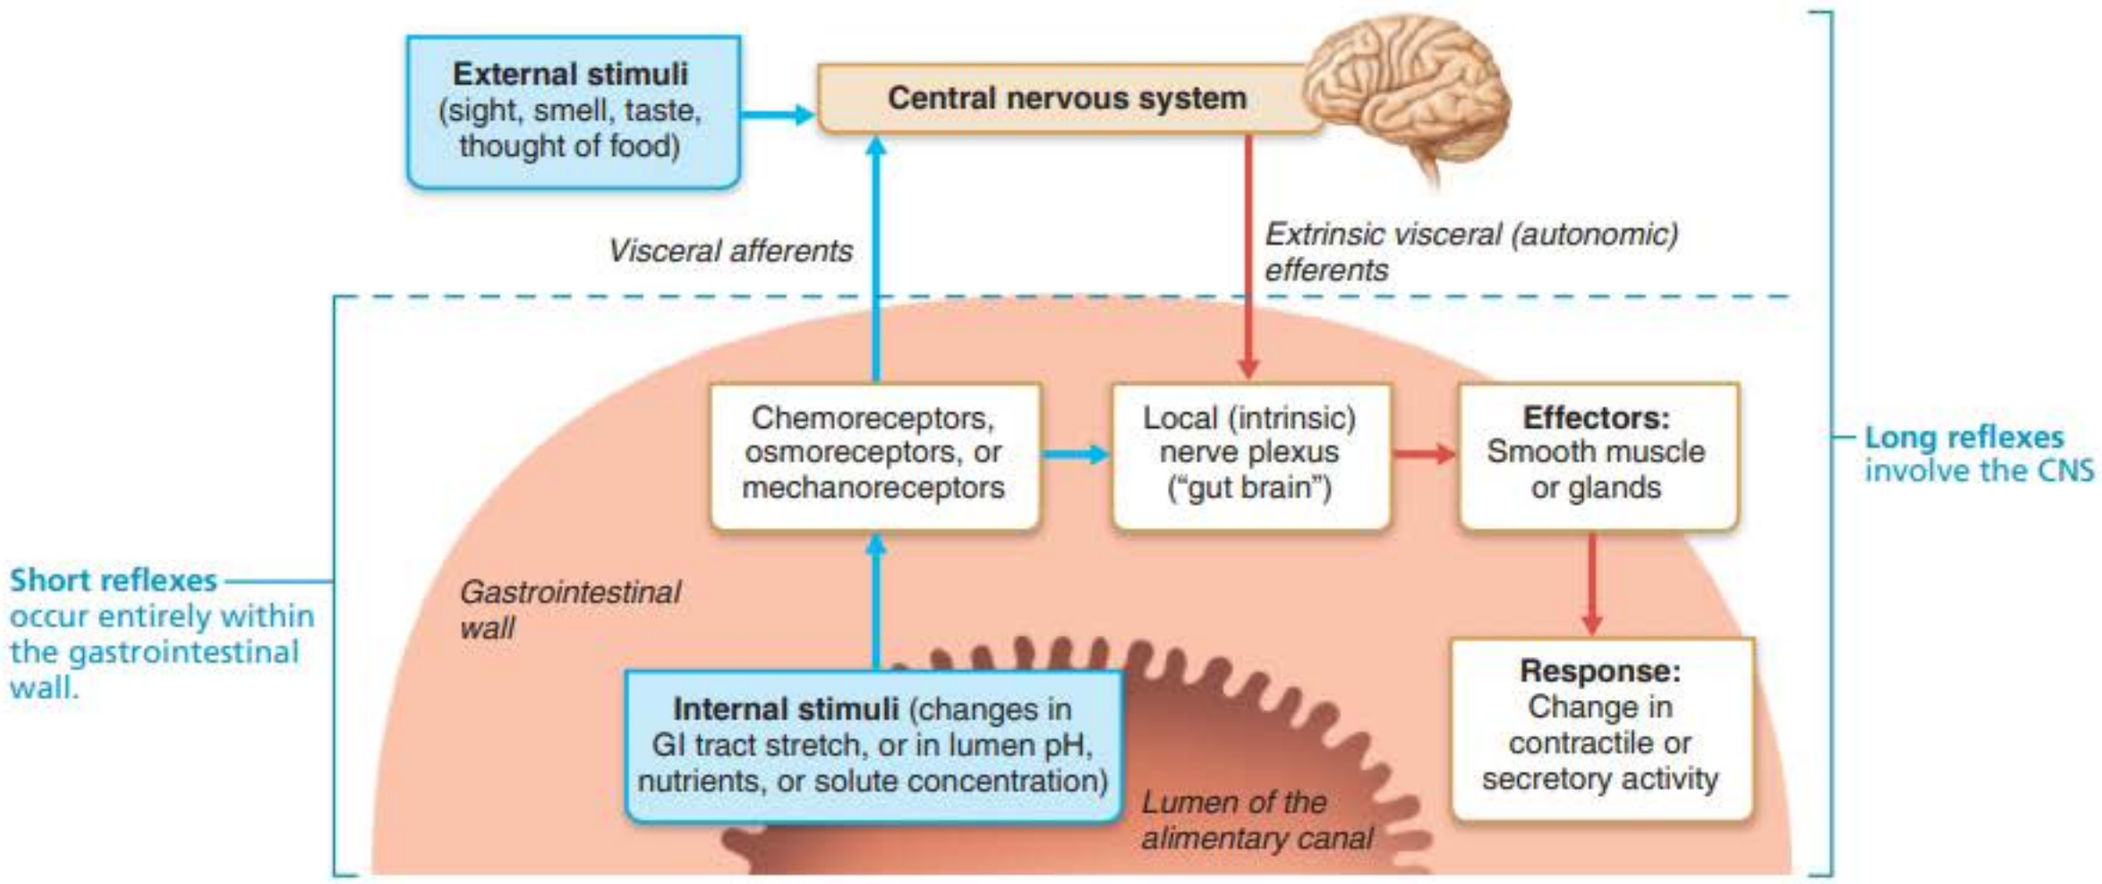

Figure 23.7 Neural reflex pathways initiated by stimuli inside or outside the gastrointestinal tract.

Control of the patterns of segmentation and peristalsis is largely automatic, involving pacemaker cells and reflex arcs between enteric neurons in the same or different organs.

- **Long reflexes** involve CNS integration centers and extrinsic autonomic nerves. The enteric nervous system sends information to the central nervous system via visceral sensory fibers. It receives sympathetic and parasympathetic motor fibers from the autonomic nervous system. These enter the intestinal wall to synapse with neurons in the intrinsic plexuses. Long reflexes can be initiated by stimuli arising inside or outside of the GI tract. In these reflexes, the enteric nervous system acts as a way station for the autonomic nervous system, allowing extrinsic controls to influence digestive activity (Figure 23.7). Generally speaking, parasympathetic inputs enhance digestive activity and sympathetic inpulses inhibit them.

Basic Concepts of Regulating Digestive Activity

Three key concepts govern regulation of digestive activity:

- **Digestive activity is provoked by a range of mechanical and chemical stimuli.** Receptors involved in controlling GI tract activity are located in the walls of the tract's organs. These receptors respond to several stimuli, most importantly stretching of the organ by food in the lumen, changes in osmolarity (solute concentration) and pH of the contents, and the presence of substrates and end products of digestion.
- **Effectors of digestive activity are smooth muscle and glands.** When stimulated, receptors in the GI tract initiate reflexes that stimulate smooth muscle of the GI tract walls to mix lumen contents and move them along the tract. Reflexes can also activate or inhibit glands that secrete digestive juices into the lumen or hormones into the blood.
- **Neurons (intrinsic and extrinsic) and hormones control digestive activity.** The nervous system controls digestive activity via both *intrinsic controls* (involving short reflexes entirely within the enteric nervous system as described above) and *extrinsic controls* (involving long reflexes).

  The stomach and small intestine also contain hormone-producing cells. When stimulated, these cells release their products to the interstitial fluid in the extracellular space. Blood and interstitial fluid distribute these hormones to their target cells in the same or different digestive tract organs, where they affect secretion or contraction.

Check Your Understanding

9. When sensors in the GI tract are stimulated, they trigger reflexes. What types of digestive activity may be put into motion via those reflexes?
10. The term "gut brain" does not really mean there is a brain in the digestive system. What does it refer to?
11. Jerry has been given a drug that inhibits parasympathetic stimulation of his digestive tract. Should he "eat hearty" or temporarily refrain from eating, and why?

For answers, see Answers Appendix.

PART 2

FUNCTIONAL ANATOMY OF THE DIGESTIVE SYSTEM

Now that we have summarized some points that unify the digestive system organs, let's take a tour down the alimentary canal and examine the special structural and functional capabilities of each organ of this system. Figure 23.1 shows most of these organs in their normal body positions, so you may find it helpful to refer back to that illustration from time to time as you read the following modules.

As we tour the digestive system organs, we will examine how each participates in the six basic digestive processes. (This information was introduced on pp. 870–871 and is summarized in Table 23.2 on p. 904.) Since we cover digestion and absorption in a special physiology section later in the chapter, we will focus on the other digestive processes on our tour.

23.4 Ingestion occurs only at the mouth

Learning Outcomes

- **Describe the gross and microscopic anatomy and the basic functions of the mouth and its associated organs.**
- **Describe the composition and functions of saliva, and explain how salivation is regulated.**
- **Explain the dental formula and differentiate clearly between deciduous and permanent teeth.**

Aside from ingestion, the digestive functions associated with the mouth mostly reflect the activity of the related accessory organs, such as teeth, salivary glands, and tongue. In the mouth we chew food and mix it with saliva containing enzymes that begin the process of digestion. The mouth also begins the propulsive process of swallowing, which carries food through the pharynx and esophagus to the stomach.

The Mouth

The **mouth** is also called the **oral cavity**, or *buccal cavity* (buk′al). Its boundaries are the lips anteriorly, cheeks laterally, palate superiorly, and tongue inferiorly (**Figure 23.8**). Its anterior opening is the **oral orifice**. Posteriorly, the oral cavity is continuous with the *oropharynx*.

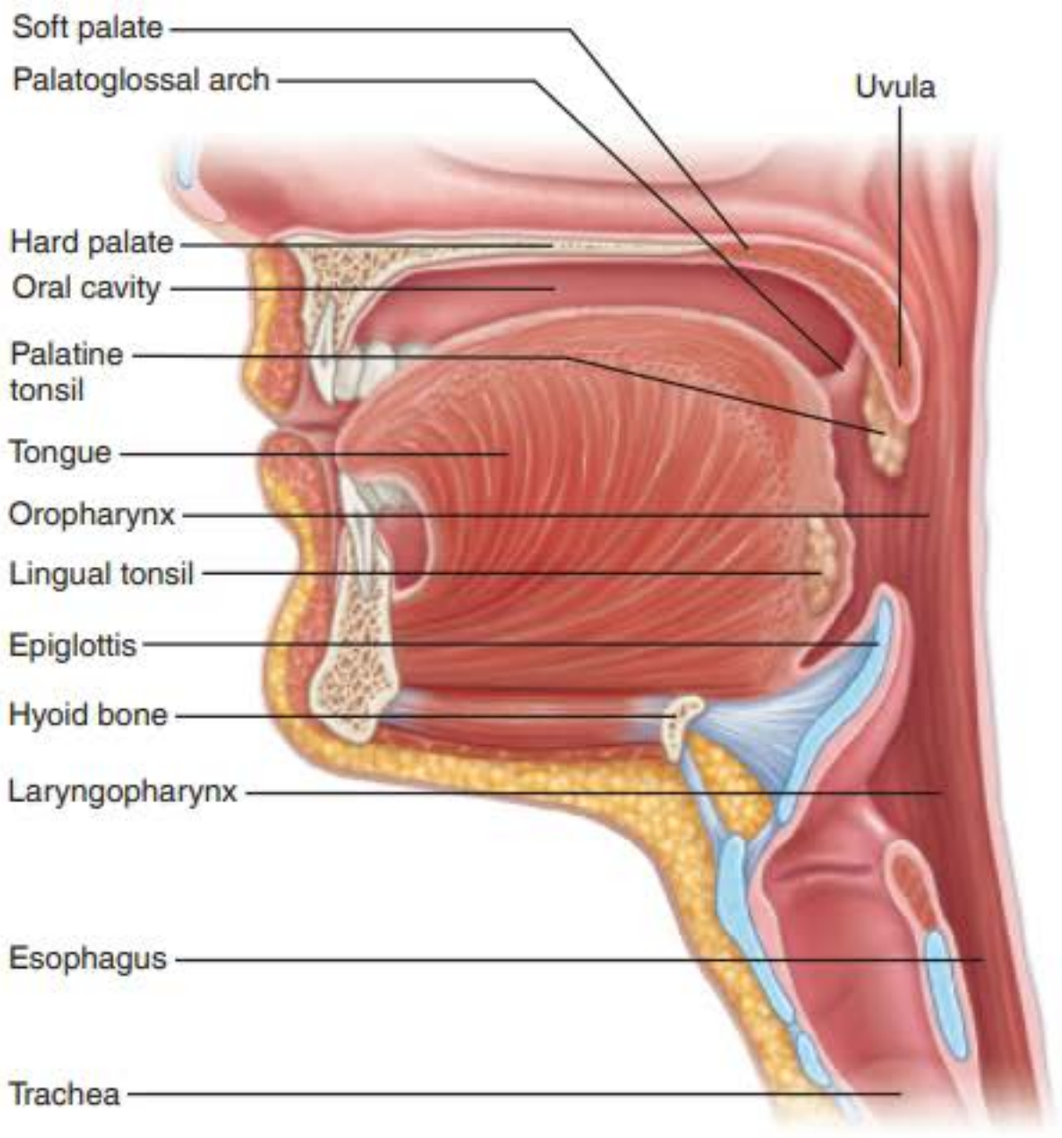
The walls of the mouth are lined with a thick stratified squamous epithelium (◀ Figure 4.4e, p. 122), which withstands considerable friction. The epithelium on the gums, hard palate, and dorsum of the tongue is slightly keratinized for extra protection against abrasion during eating.

The Lips and Cheeks

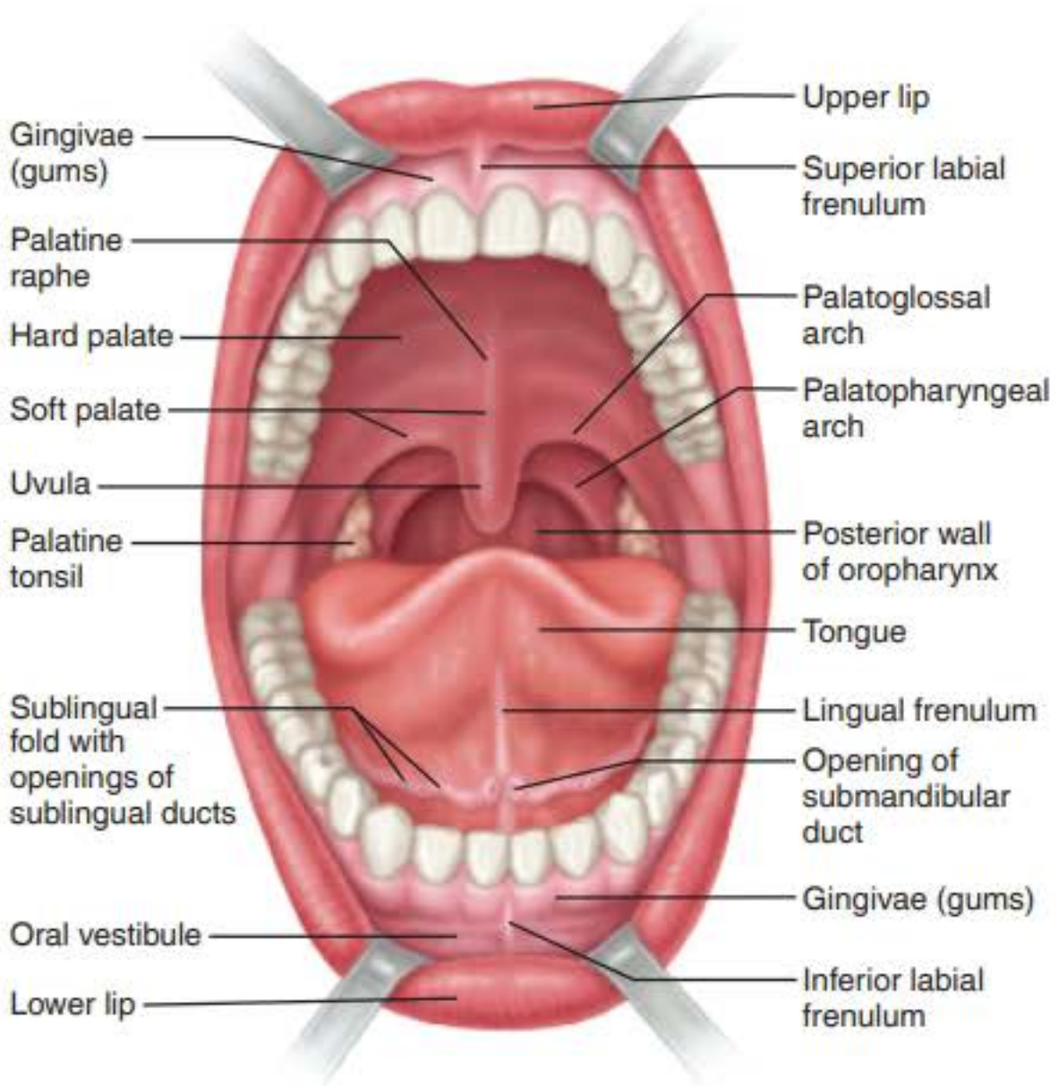
The **lips (labia)** and the **cheeks**, which help keep food between the teeth when we chew, are composed of a core of skeletal muscle covered externally by skin. The *orbicularis oris muscle* forms the fleshy lips; the cheeks are formed largely by the *buccinators*. The recess bounded externally by the lips and cheeks and internally by the gums and teeth is the **oral vestibule** (“porch”). The area that lies within the teeth and gums is the **oral cavity proper**. The **labial frenulum** (fren′u-lum) is a median fold that joins the internal aspect of each lip to the gum (Figure 23.8b).

The Palate

The **palate**, forming the roof of the mouth, has two distinct parts: the hard palate anteriorly and the soft palate posteriorly (Figure 23.8). The **hard palate** is underlain by the palatine bones



(a) Sagittal section of the oral cavity and pharynx



(b) Anterior view

Figure 23.8 Anatomy of the oral cavity (mouth).

and the palatine processes of the maxillae, and it forms a rigid surface against which the tongue forces food during chewing. The mucosa on either side of its *raphe* (ra′fe), a midline ridge, is slightly corrugated, which helps create friction.

The **soft palate** is a mobile fold formed mostly of skeletal muscle that rises reflexively to close off the nasopharynx when we swallow.

- To demonstrate this action, try to breathe and swallow at the same time.

Laterally, the soft palate is anchored to the tongue by the **palatoglossal arches** and to the wall of the oropharynx by the more posterior **palatopharyngeal arches**. These two paired folds form the boundaries of the **fauces** (faw′sēz; *fauc* = throat), the arched area of the oropharynx that contains the palatine tonsils. Projecting downward from the free edge of the soft palate is the fingerlike **uvula** (u′vu-lah).

The Tongue

The **tongue** occupies the floor of the mouth (Figure 23.8). It is composed of interlacing bundles of skeletal muscle fibers. During chewing, the tongue grips the food and constantly repositions it between the teeth. The tongue also mixes food with saliva, forming it into a compact mass called a **bolus** (bo′lus; "a lump"), and then initiates swallowing by pushing the bolus posteriorly into the pharynx. The versatile tongue also helps us form consonants (k, d, t, and so on) when we speak.

The tongue has both intrinsic and extrinsic skeletal muscle fibers. The **intrinsic muscles** are confined in the tongue and are not attached to bone. Their muscle fibers, which run in several different planes, allow the tongue to change its shape (but not its position), becoming thicker, thinner, longer, or shorter as needed for speech and swallowing.

The **extrinsic muscles** extend to the tongue from their points of origin on bones of the skull or the soft palate, as described in Chapter 10 (◀ Table 10.2 and Figure 10.8). The extrinsic muscles alter the tongue's position. They protrude it, retract it, and move it from side to side. The tongue has a median septum of connective tissue, and each half contains identical muscle groups. A fold of mucosa called the **lingual frenulum** secures the tongue to the floor of the mouth and limits its posterior movements.

HOMEOSTATIC IMBALANCE 23.2 CLINICAL

Children born with an extremely short lingual frenulum are sometimes referred to as "tongue-tied." Restricted tongue movement may interfere with breast-feeding. This congenital condition, called *ankyloglossia* ("fused tongue"), is sometimes corrected surgically by snipping the frenulum.

The superior tongue surface bears papillae, peglike projections of the underlying mucosa (**Figure 23.9**).

- The conical **filiform papillae** roughen the tongue surface, helping us lick semisolid foods (such as ice cream) and providing friction for manipulating foods. These papillae, the smallest and most numerous type, align in parallel rows on the tongue dorsum. They contain keratin, which stiffens them and gives the tongue its whitish appearance.
- The mushroom-shaped **fungiform papillae** are scattered widely over the tongue surface. Each has a vascular core that gives it a reddish hue.
- Eight to twelve large **vallate papillae** are located in a V-shaped row at the back of the tongue. They resemble the fungiform papillae but have an additional surrounding furrow.
- Pleatlike **foliate papillae** are located on the lateral aspects of the posterior tongue.

The fungiform, vallate, and foliate papillae house taste buds (◀ pp. 578–579).

Immediately posterior to the vallate papillae is the **terminal sulcus**, a groove that distinguishes the portion of the tongue that lies in the oral cavity (its body) from its posterior portion in the oropharynx (its root). The mucosa covering the root of the tongue lacks papillae, but it is still bumpy because of the nodular *lingual tonsil*, which lies just deep to its mucosa (Figure 23.9).

The Salivary Glands

A number of glands associated with the oral cavity secrete **saliva**. Saliva:

- Cleanses the mouth
- Dissolves food chemicals so they can be tasted
- Moistens food and helps compact it into a bolus
- Contains the enzyme **amylase** that begins the digestion of starchy foods

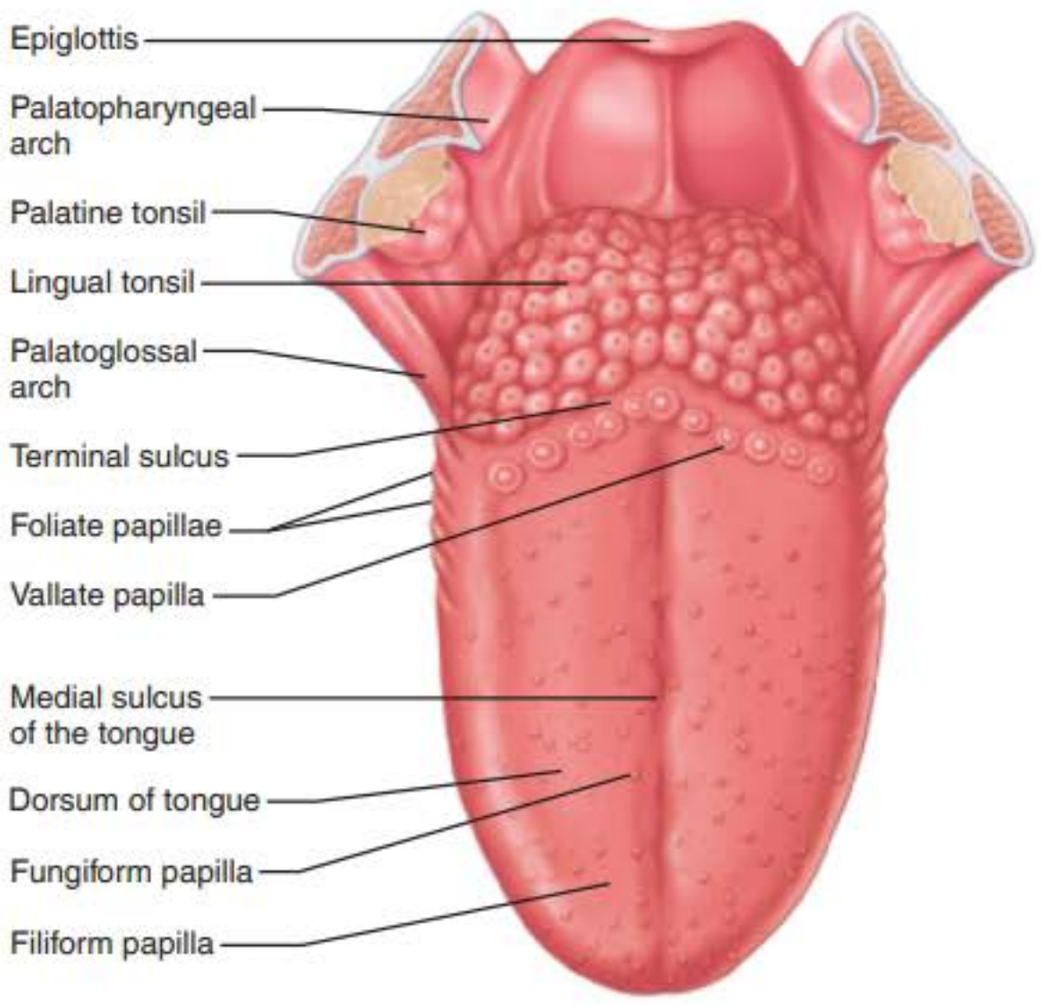


Figure 23.9 Dorsal surface of the tongue, and the tonsils.

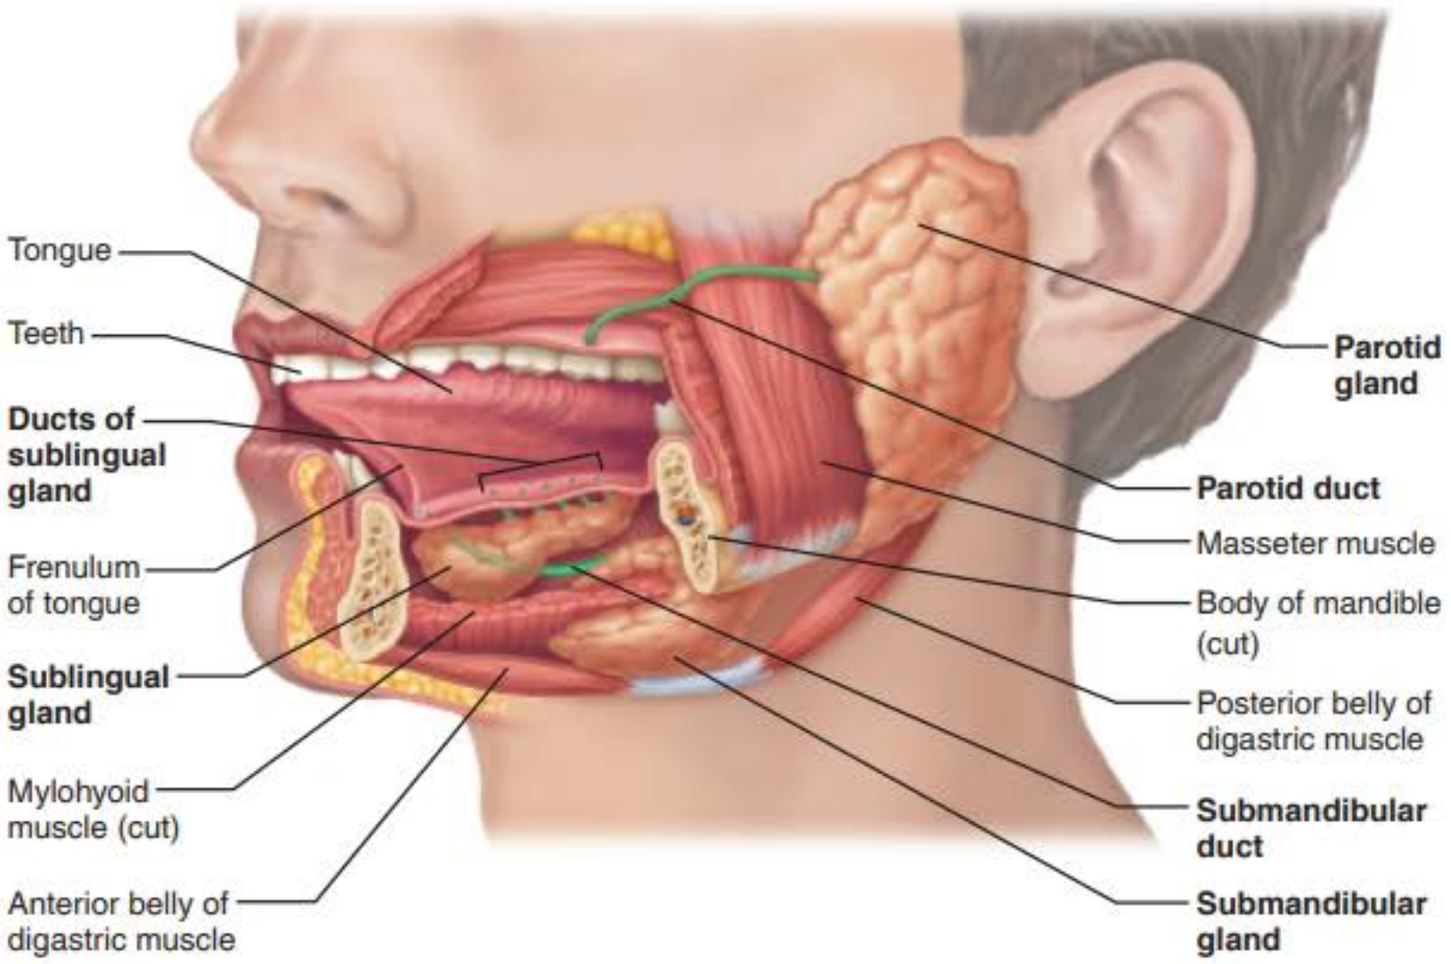

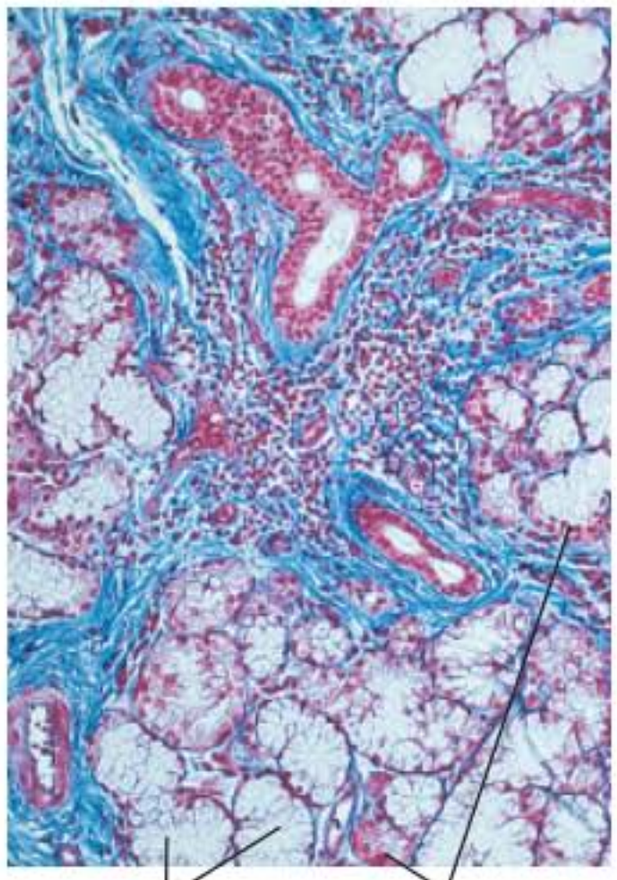

Figure 23.10 The salivary glands. (a) The parotid, submandibular, and sublingual glands and their ducts. **(b)** Photomicrograph of the sublingual gland (150×), a mixed salivary gland containing mostly mucous cells (light blue) with a few serous cells (purple).

Practice Histology questions:
MasteringA&P® > Study Area > Lab Tools > PAL

Most saliva is produced by the **major** or **extrinsic salivary glands** that lie outside the oral cavity and empty their secretions into it. **Minor** or **intrinsic salivary glands** (buccal glands and others) scattered throughout the oral cavity mucosa augment the output slightly.

The major salivary glands are paired compound alveolar or tubuloalveolar glands that develop from the oral mucosa and remain connected to it by ducts (**Figure 23.10a**). The large, roughly triangular **parotid gland** (pah-rot′id; *par* = near, *oto* = the ear) lies anterior to the ear between the masseter muscle and the skin. Its prominent duct parallels the zygomatic arch, pierces the buccinator muscle, and opens into the vestibule next to the second upper molar.

Branches of the facial nerve run through the parotid gland on their way to the muscles of facial expression (◀ p. 503). For this reason, surgery on this gland can result in facial paralysis.

HOMEOSTATIC IMBALANCE 23.3 CLINICAL

Normal salivary gland function is vital for oral health. If too little saliva is made, an uncomfortably dry mouth results, a condition called *xerostomia* (ze-ro-sto′me-ah; *zer* = dry, *stom* = mouth). This lack of moisture may lead to difficulty with chewing and swallowing, and oral infections. Xerostomia can be caused by certain medications, diabetes, HIV/AIDS, and Sjögren's syndrome (an autoimmune disease that affects moisture-producing glands throughout the body).

About the size of a walnut, the **submandibular gland** lies along the medial aspect of the mandibular body. Its duct runs beneath the mucosa of the oral cavity floor and opens at the base of the lingual frenulum (see Figure 23.8b). The small, almond-shaped **sublingual gland** lies anterior to the submandibular gland under the tongue and opens via 10–20 ducts into the floor of the mouth (Figure 23.10a).

The salivary glands are composed of two types of secretory cells: serous and mucous (Figure 23.10b). **Serous cells** produce a watery secretion containing enzymes, ions, and a tiny bit of mucin, whereas **mucous cells** produce **mucus**, a stringy, viscous solution. The parotid and submandibular glands contain mostly serous cells. Buccal glands have approximately equal numbers of serous and mucous cells. The sublingual glands contain mostly mucous cells.

Composition of Saliva

Saliva is largely water—97 to 99.5%—and therefore is hypoosmotic. Its osmolarity depends on the specific glands that are active and the stimulus for salivation. As a rule, saliva is slightly acidic (pH 6.75 to 7.00), but its pH may vary. Its solutes include:

- Electrolytes (Na^+, K^+, Cl^-, PO_4^{3-}, and HCO_3^-)
- The digestive enzymes salivary amylase and lingual lipase (lingual lipase makes only a minor contribution to overall fat digestion)
- The proteins mucin, lysozyme, and IgA
- Metabolic wastes (urea and uric acid)

When dissolved in water, the glycoprotein *mucin* forms thick mucus that lubricates the oral cavity and hydrates foodstuffs (◀ p. 783).

Saliva protects against microorganisms because it contains:

- *IgA antibodies* (◀ Table 21.5, p. 799).
- *Lysozyme*, a bactericidal enzyme that inhibits bacterial growth in the mouth and may help prevent tooth decay.
- *Defensins* (◀ p. 783). Besides acting as a local antibiotic, defensins function as cytokines to call defensive cells (lymphocytes, neutrophils, etc.) into the mouth for battle.

Control of Salivation

The minor salivary glands secrete saliva continuously in amounts just sufficient to keep the mouth moist. But when food enters the mouth, the major glands are activated and large amounts of saliva pour out. The average output of saliva is about 1500 ml per day, but can be much higher when salivary glands are appropriately stimulated.

Salivation is controlled primarily by the parasympathetic division of the autonomic nervous system. When we ingest food, chemoreceptors and mechanoreceptors in the mouth send signals to the **salivatory nuclei** in the brain stem (pons and medulla). As a result, parasympathetic nervous system activity increases. Impulses sent via motor fibers in the *facial* (VII) and *glossopharyngeal* (IX) *nerves* dramatically increase the output of watery (serous), enzyme-rich saliva.

The chemoreceptors are activated most strongly by acidic substances. The mechanoreceptors are activated by virtually any mechanical stimulus in the mouth—even chewing rubber bands.

Sometimes just the sight or smell of food is enough to get the juices flowing. The mere thought of hot fudge sauce on peppermint ice cream will make many a mouth water! Irritation of the lower GI tract by bacterial toxins, spicy foods, or hyperacidity also increases salivation. This response may help wash away or neutralize the irritants.

In contrast to parasympathetic controls, the sympathetic division (specifically fibers in T_1–T_3) causes release of a thick, mucin-rich saliva. Strong activation of the sympathetic division constricts blood vessels serving the salivary glands and almost completely inhibits saliva release, causing a dry mouth. Dehydration also inhibits salivation because low blood volume reduces filtration pressure at capillary beds.

The Teeth

The **teeth** lie in sockets (alveoli) in the gum-covered margins of the mandible and maxilla. We *masticate*, or chew, by opening and closing our jaws and moving them from side to side while using our tongue to move the food between our teeth. In the process, the teeth tear and grind the food, physically breaking it down into smaller fragments.

Dentition and the Dental Formula

Ordinarily by age 21, two sets of teeth, the **primary** and **permanent dentitions**, have formed (**Figure 23.11**). The primary dentition consists of the **deciduous teeth** (de-sid′u-us; *decid* = falling off), also called **milk** or **baby teeth**. The first teeth to appear, at about age 6 months, are the lower central incisors. Additional pairs of teeth erupt at one- to two-month intervals until about 24 months, when all 20 milk teeth have emerged.

HOMEOSTATIC IMBALANCE 23.4 CLINICAL

Although primary teeth will eventually be replaced by permanent teeth, these first teeth nevertheless deserve careful attention. *Decaying primary teeth* can be painful and may lead to serious infection. Primary teeth also serve as important "place holders" for developing permanent teeth. Primary teeth can be kept healthy by brushing and by limiting exposure to sugary liquids, especially from prolonged bottle feeding.

As the deep-lying **permanent teeth** enlarge and develop, the roots of the milk teeth are resorbed from below, causing them to loosen and fall out between ages 6 and 12. Generally, all the permanent teeth but the third molars have erupted by the end of adolescence. The third molars, also called *wisdom teeth*, emerge

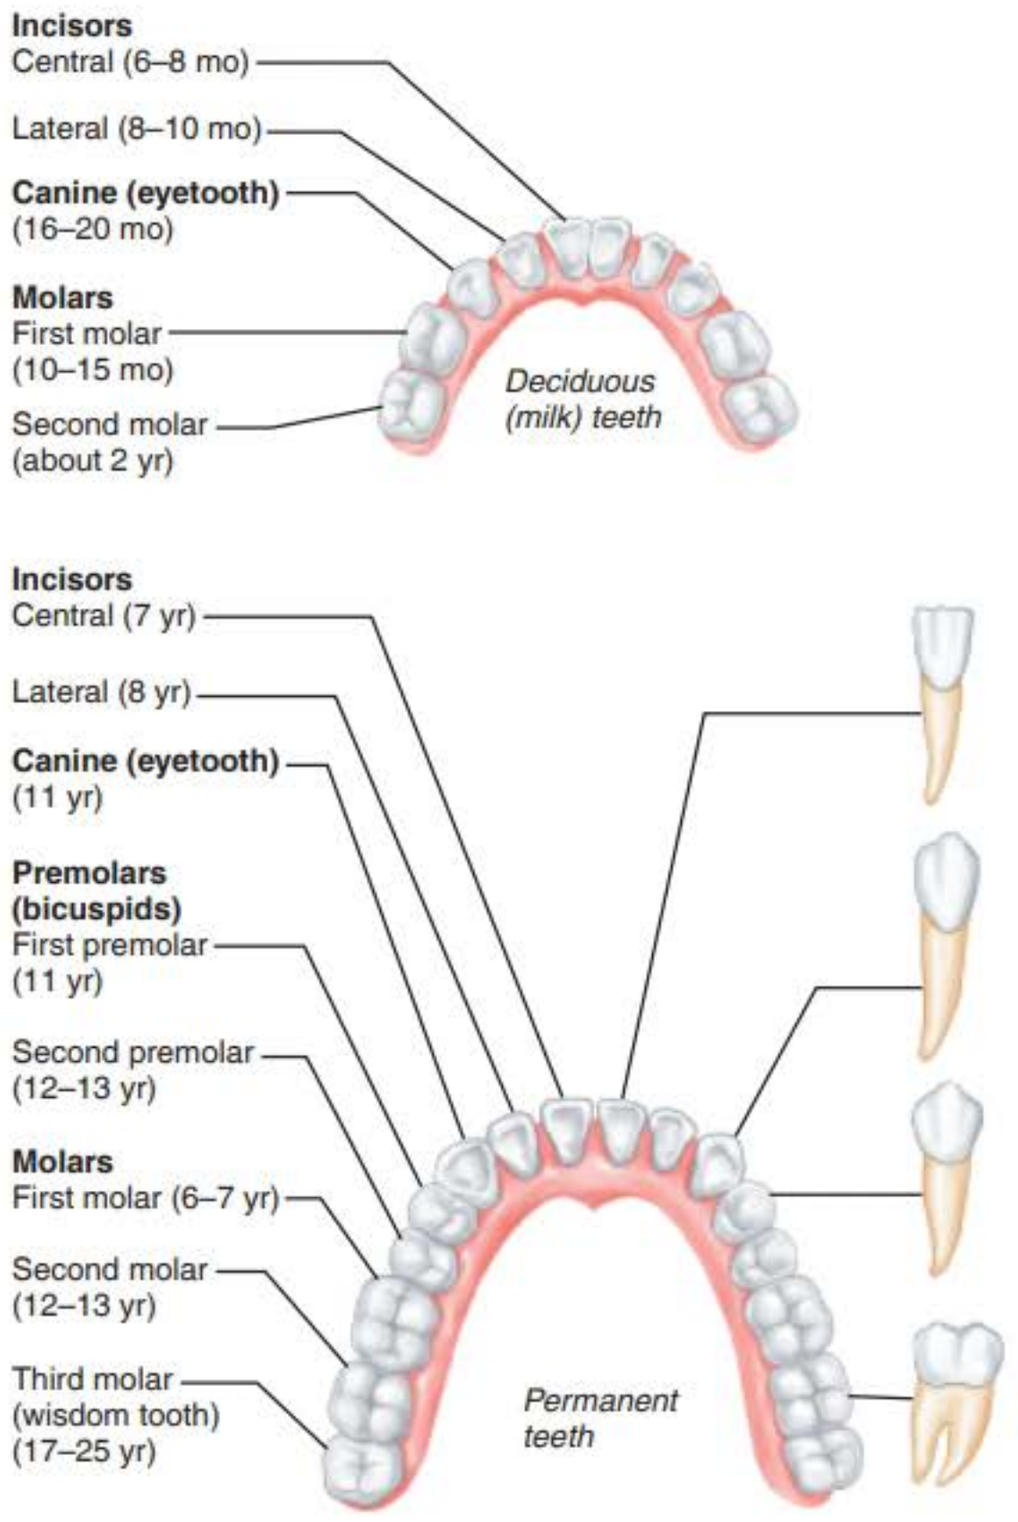

Figure 23.11 Human dentition. Teeth of the lower jaw: the deciduous and permanent sets. Approximate age at which tooth erupts is shown in parentheses. The shapes of individual teeth are shown on the right.

between ages 17 and 25. There are usually 32 permanent teeth in a full set, but sometimes the wisdom teeth never erupt or are completely absent.

HOMEOSTATIC IMBALANCE 23.5 CLINICAL

When a tooth remains trapped in the jawbone, it is said to be *impacted*. Impacted teeth can cause a good deal of pressure and pain and must be removed surgically. Wisdom teeth are most commonly involved.

Teeth are classified according to their shape and function as incisors, canines, premolars, and molars (Figure 23.11). The chisel-shaped **incisors** are adapted for cutting or nipping off pieces of food. The conical or fanglike **canines** (cuspids or eyeteeth) tear and pierce. The **premolars** (bicuspids) and **molars** have broad crowns with rounded cusps (tips) best suited for grinding or crushing. The molars, with four or five cusps, are the best grinders. During chewing, the upper and lower molars repeatedly lock together, an action that generates tremendous crushing forces.

The **dental formula** is a shorthand way of indicating the numbers and relative positions of the different types of teeth. This formula is written as a ratio, uppers over lowers, for *one-half* of the mouth. Since the other side is a mirror image, we obtain total dentition by multiplying the dental formula by 2.

The primary dentition consists of two incisors (I), one canine (C), and two molars (M) on each side of each jaw, and its dental formula is written as

$$\frac{2\text{I, } 1\text{C, } 2\text{M (upper jaw)}}{2\text{I, } 1\text{C, } 2\text{M (lower jaw)}} \times 2 \quad (20 \text{ teeth})$$

Similarly, the permanent dentition [two incisors, one canine, two premolars (PM), and three molars] is

$$\frac{2\text{I, } 1\text{C, } 2\text{PM, } 3\text{M}}{2\text{I, } 1\text{C, } 2\text{PM, } 3\text{M}} \times 2 \quad (32 \text{ teeth})$$

23

Tooth Structure

Each tooth has two major regions: the crown and the root (**Figure 23.12**). The enamel-covered **crown** is the exposed part of the tooth above the **gingiva** (jin′jĭ-vah), or **gum**, which surrounds the tooth like a tight collar. **Enamel**, a brittle ceramic-like material thick as a dime, directly bears the force of chewing. Enamel is heavily mineralized with calcium salts, and its densely packed hydroxyapatite (mineral) crystals are oriented in force-resisting columns perpendicular to the tooth's surface. This makes it the hardest substance in the body. The cells that produce enamel degenerate when the tooth erupts; consequently, decayed or cracked areas of enamel will not heal and must be artificially filled.

The **root** is the portion of the tooth embedded in the jawbone. Canine teeth, incisors, and premolars have one root, although the first upper premolars commonly have two. The first two upper molars have three roots, while the corresponding lower molars have two. The root pattern of the third molar varies, but a fused single root is most common.

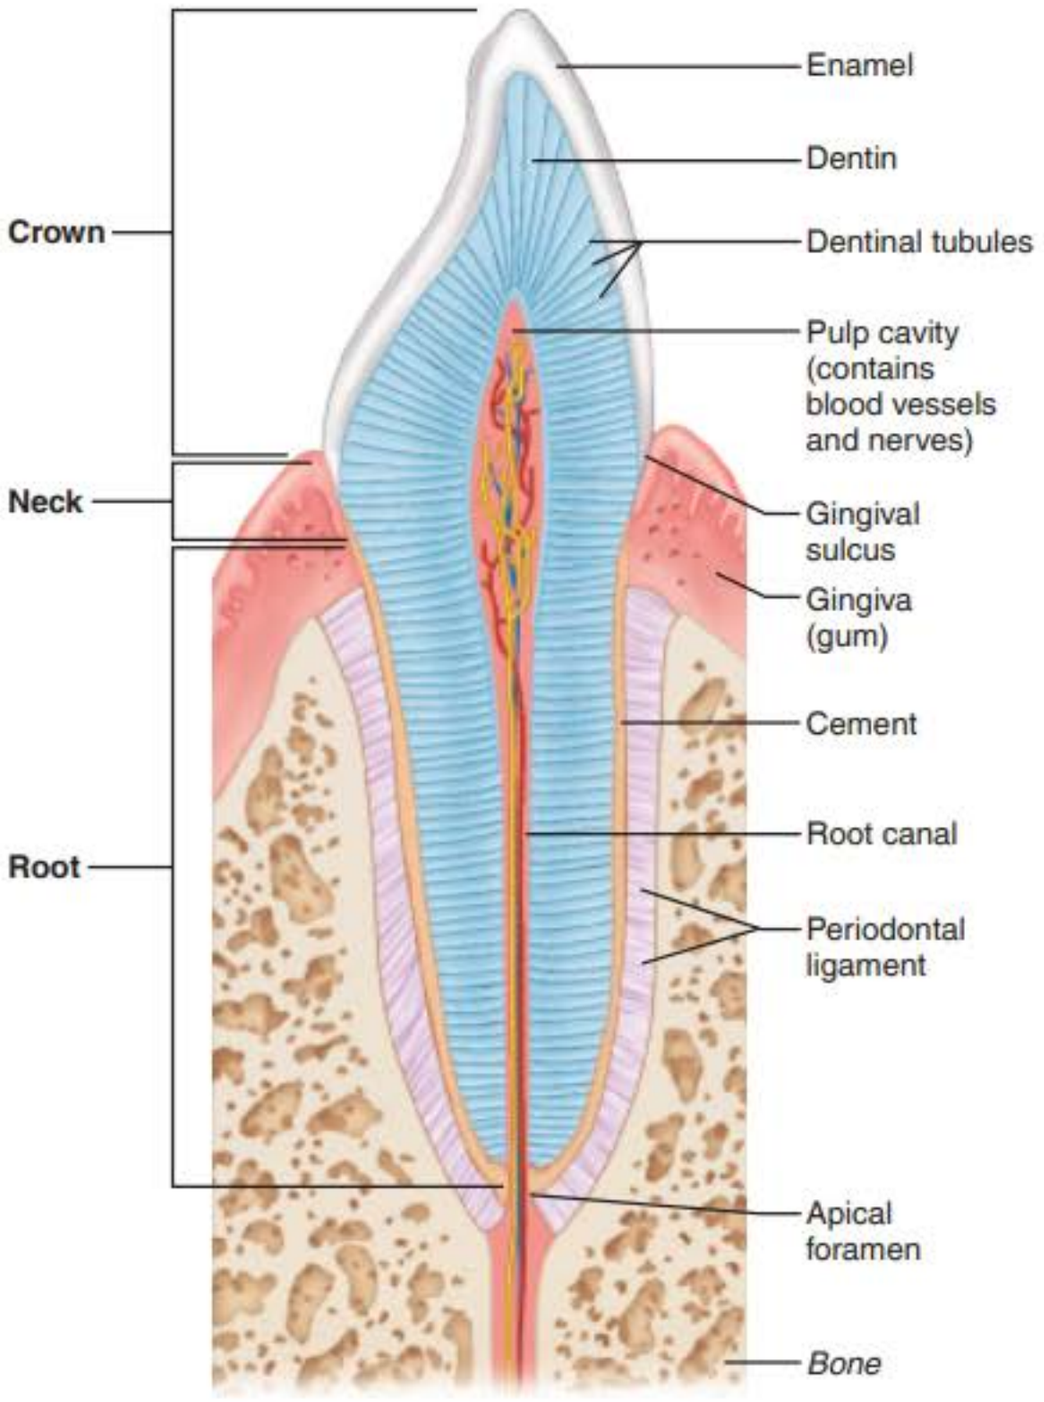

Figure 23.12 Longitudinal section of a canine tooth within its bony socket (alveolus).

A constricted tooth region called the **neck** connects the crown and root. **Cement**, a calcified connective tissue, covers the outer surface of the root and attaches the tooth to the thin **periodontal ligament** (per″e-o-don′tal; "around the tooth"). This ligament anchors the tooth in the bony socket (alveolus) of the jaw, forming a fibrous joint called a *gomphosis*. Where the gingiva borders on a tooth, it dips downward to form a shallow groove called the *gingival sulcus*.

Dentin, a protein-rich bonelike material, underlies the enamel cap and forms the bulk of a tooth. More resilient (flexible) than enamel, dentin acts as a shock absorber during biting and chewing. Dentin surrounds a central **pulp cavity** containing a number of soft tissue structures (connective tissue, blood vessels, and nerve fibers) collectively called **pulp**. Pulp supplies nutrients to the tooth tissues and provides tooth sensation. Where the pulp cavity extends into the root, it becomes the **root canal**. At the proximal end of each root canal is an **apical foramen** that allows blood vessels, nerves, and other structures to enter the pulp cavity.

The teeth are served by the superior and inferior alveolar nerves, branches of the trigeminal nerve (◀ Table 13.2, p. 502). The superior and inferior alveolar arteries, branches of the maxillary artery (◀ Figure 19.24b, p. 741), supply blood.

Dentin contains unique radial striations called *dentinal tubules* (Figure 23.12). Each tubule contains an elongated process of an **odontoblast** (o-don′to-blast; "tooth former"), the cell type that secretes and maintains the dentin. The odontoblasts line the pulp cavity just deep to the dentin. Dentin forms throughout adult life and gradually encroaches on the pulp cavity. New dentin can also be laid down fairly rapidly to compensate for tooth damage or decay.

Enamel, dentin, and cement are all calcified and resemble bone (to differing extents), but they differ from bone because they are avascular. Enamel differs from cement and dentin because it lacks collagen and is almost entirely mineral.

Tooth and Gum Disease CLINICAL

Dental caries (kār′ēz; "rottenness"), or **cavities**, result from bacterial action that gradually demineralizes enamel and underlying dentin. Decay begins when **dental plaque** (a film of sugar, bacteria, and other mouth debris) adheres to the teeth. Bacterial metabolism of the trapped sugars produces acids, which dissolve the calcium salts of the teeth. Once the salts are leached out, enzymes released by the bacteria readily digest the remaining organic matrix of the tooth. Frequent brushing helps prevent caries by removing plaque.

More serious than tooth decay is the effect of unremoved plaque on the gums. As dental plaque accumulates, it calcifies, forming **calculus** (kal′ku-lus; "stone") or tartar. These stony-hard deposits disrupt the seal between gingivae and teeth, deepening the sulcus and putting the gums at risk for infection by pathogenic anaerobic bacteria. In the early stages of such an infection, called **gingivitis** (jin″jĭ-vi′tis), the gums are red, sore, swollen, and may bleed.

Gingivitis is reversible if the calculus is removed, but if it is neglected the bacteria eventually form pockets of infection which become inflamed. Neutrophils and other immune cells attack not only the intruders but also body tissues, carving deep pockets around the teeth, destroying the periodontal ligament, and activating osteoclasts which dissolve the bone. This serious condition, **periodontal disease** or **periodontitis**, affects up to 95% of all people over age 35 and accounts for 80–90% of tooth loss in adults.

Tooth loss from periodontitis is not inevitable. Various treatments can alleviate the bacterial infestations and encourage the surrounding tissues to reattach to the teeth and bone.

Periodontal disease may jeopardize more than just teeth. Some contend that it increases the risk of heart disease and stroke in at least two ways: (1) the chronic inflammation promotes atherosclerotic plaque, and (2) bacteria entering the blood from infected gums stimulate the formation of clots that clog coronary and cerebral arteries. Risk factors for periodontal disease include smoking, diabetes mellitus, and oral (tongue or lip) piercing.

Digestive Processes of the Mouth

The mouth and its accessory digestive organs are involved in four of the six digestive processes described earlier. The mouth (1) ingests, (2) begins mechanical breakdown by chewing, (3) initiates propulsion by swallowing, and (4) starts the digestion of polysaccharides. Absorption does not occur in the mouth except for a few drugs that are absorbed through the oral mucosa (for example, nitroglycerine used to alleviate the pain of angina, ◀ p. 683).

Chewing and swallowing are the processes that promote mechanical breakdown and propulsion, respectively. We describe chewing next, but because the mouth participates in only the first phase of swallowing, we will postpone its discussion until the end of the next module.

Mastication (Chewing)

As food enters the mouth, its mechanical breakdown begins with **mastication**, or chewing. The cheeks and closed lips hold food between the teeth, the tongue mixes food with saliva to soften it, and the teeth cut and grind solid foods into smaller morsels.

Mastication is partly voluntary and partly reflexive. We voluntarily put food into our mouths and contract the muscles that close our jaws. The pattern and rhythm of continued jaw movements are controlled mainly by stretch reflexes and in response to pressure inputs from receptors in the cheeks, gums, and tongue, but they can also be voluntary if desired.

Check Your Understanding

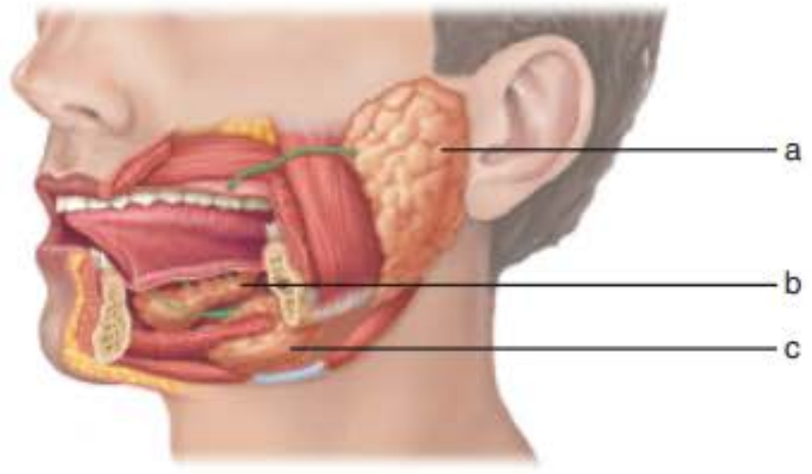
12. Which structure forms the roof of the mouth?

13. Besides preparing food for swallowing, the tongue has another role. What is it?

14. Name three antimicrobial substances found in saliva.

15. Which tooth substance is harder than bone? Which tooth region includes nervous tissue and blood vessels?

16. Identify each of the glands a–c. Which has a duct that opens at the base of the lingual frenulum? Which has a duct that pierces the buccinator muscle?



For answers, see Answers Appendix.

23.5 The pharynx and esophagus move food from the mouth to the stomach

Learning Outcomes

- **Describe the anatomy and basic functions of the pharynx and esophagus.**
- **Describe the mechanism of swallowing.**

The Pharynx

From the mouth, food passes posteriorly into the **oropharynx** and then the **laryngopharynx** (◀ Figure 22.5 and Figure 23.8a), both common passageways for food, fluids, and air. (The nasopharynx has no digestive role.)

The histology of the pharyngeal wall resembles that of the oral cavity. The mucosa contains a friction-resistant stratified squamous epithelium well supplied with mucus-producing glands. The external muscle layer consists of two *skeletal muscle* layers. The cells of the inner layer run longitudinally. Those of the outer layer, the *pharyngeal constrictor* muscles, encircle the wall like three stacked fists (◀ Figure 10.9c, p. 339). Contractions of these muscles propel food into the esophagus below.

The Esophagus

The **esophagus** (ĕ-sof′ah-gus; "carry food") is a muscular tube about 25 cm (10 inches) long and is collapsed when not involved in food propulsion (**Figure 23.13**). As food moves through the laryngopharynx, the epiglottis closes off the larynx and incoming food is routed posteriorly into the esophagus.

As shown in Figure 23.1, the esophagus takes a fairly straight course through the mediastinum of the thorax. It pierces the diaphragm at the **esophageal hiatus** (hi-a′tus; "gap") to enter the abdomen. It joins the stomach at the **cardial orifice** within the abdominal cavity. The cardial orifice is surrounded by the **gastroesophageal** or **cardiac sphincter** (gas″tro-ĕ-sof″ah-je′al), which is a *physiological* sphincter (see Figure 23.14). That is, it acts as a sphincter, but the only structural evidence of this sphincter is a slight thickening of the circular smooth muscle at that point. The muscular diaphragm, which surrounds this

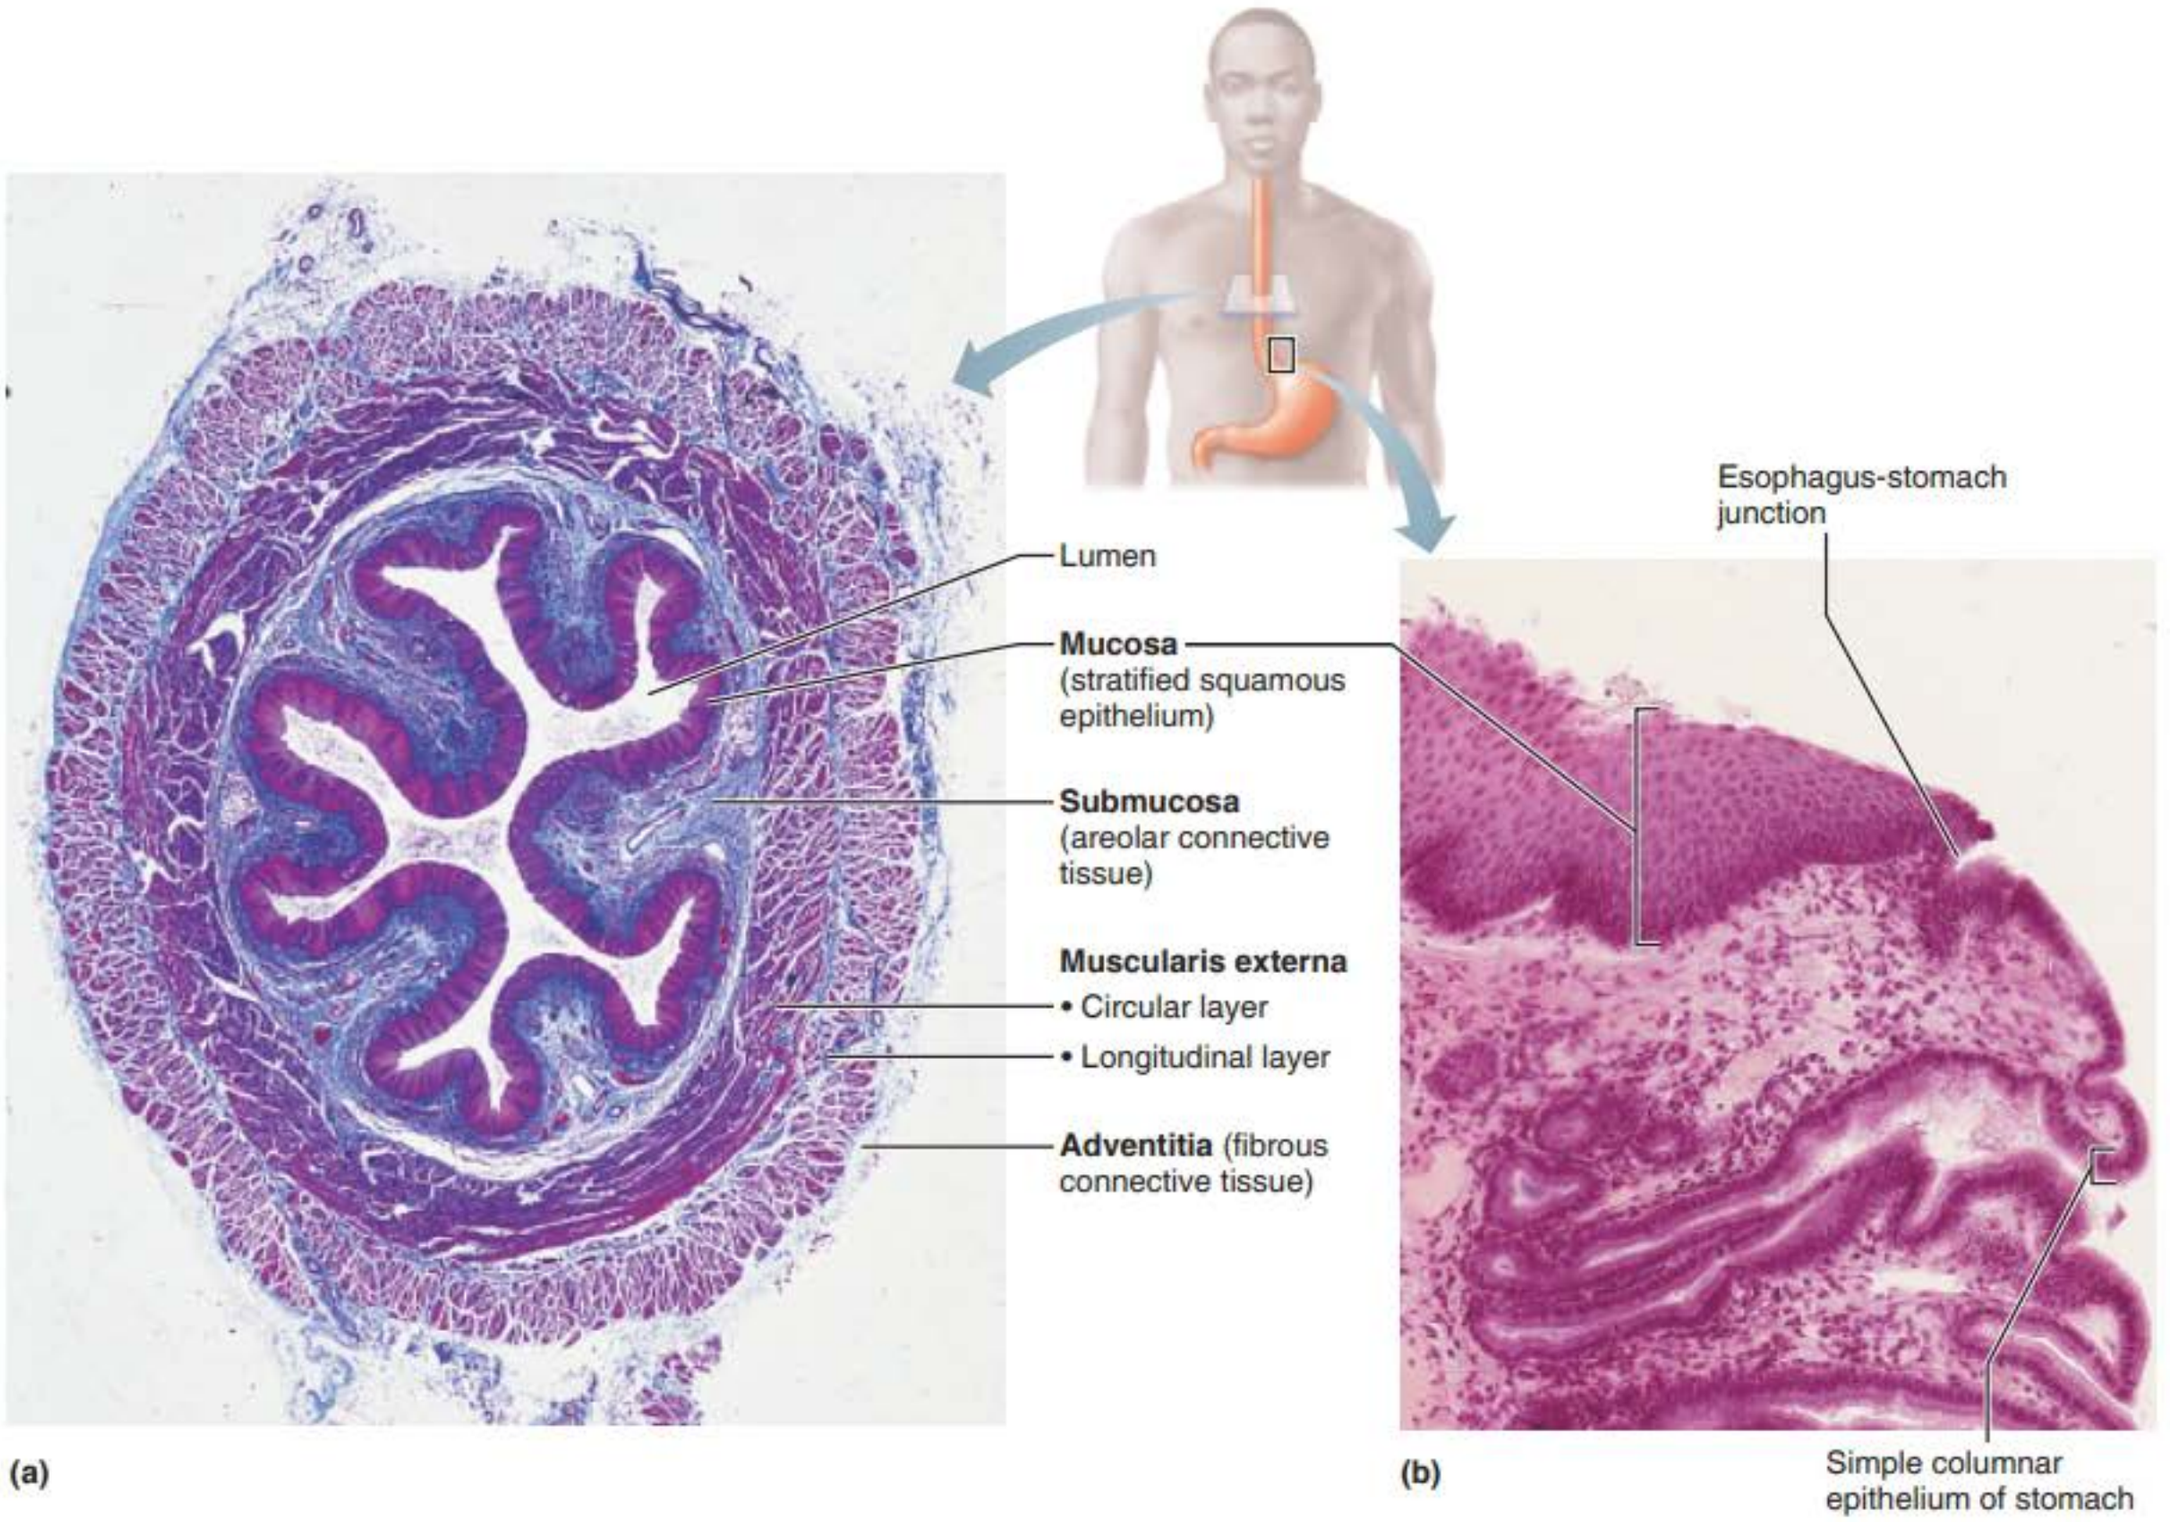


Figure 23.13 Microscopic structure of the esophagus. (a) Cross-sectional view of the esophagus taken from the region close to the stomach junction (10×). Here, the muscularis is composed of smooth muscle. **(b)** Longitudinal section through the esophagus-stomach junction (130×). MasteringA&P® > Study Area > Lab Tools > PAL

sphincter, helps keep it closed when food is not being swallowed. Mucous cells on both sides of the sphincter help protect the esophagus from reflux of stomach acid.

HOMEOSTATIC IMBALANCE 23.6 CLINICAL

Heartburn, the first symptom of *gastroesophageal reflux disease* (*GERD*), is the burning, radiating substernal pain that occurs when stomach acid regurgitates into the esophagus. Symptoms are so similar to those of a heart attack that many first-time sufferers of heartburn are rushed to the emergency room. Heartburn is most likely when a person has eaten or drunk to excess, and in conditions that force abdominal contents superiorly, such as extreme obesity, pregnancy, and running, which splashes stomach contents upward with each step.

Heartburn is also common in those with a **hiatal hernia**, a structural abnormality (most often due to abnormal relaxation or weakening of the gastroesophageal sphincter) in which the superior part of the stomach protrudes slightly above the diaphragm. Since the diaphragm no longer reinforces the sphincter, gastric juice may enter the esophagus, particularly when lying down. If the episodes are frequent and prolonged, *esophagitis* (inflammation of the esophagus) and *esophageal ulcers* may result. An even more threatening sequel is esophageal cancer. Treatment varies, but GERD is usually addressed with lifestyle and dietary modifications, along with antacids and certain prescription drugs.

Unlike the mouth and pharynx, the esophagus wall has all four of the basic alimentary canal layers described earlier. Some features of interest:

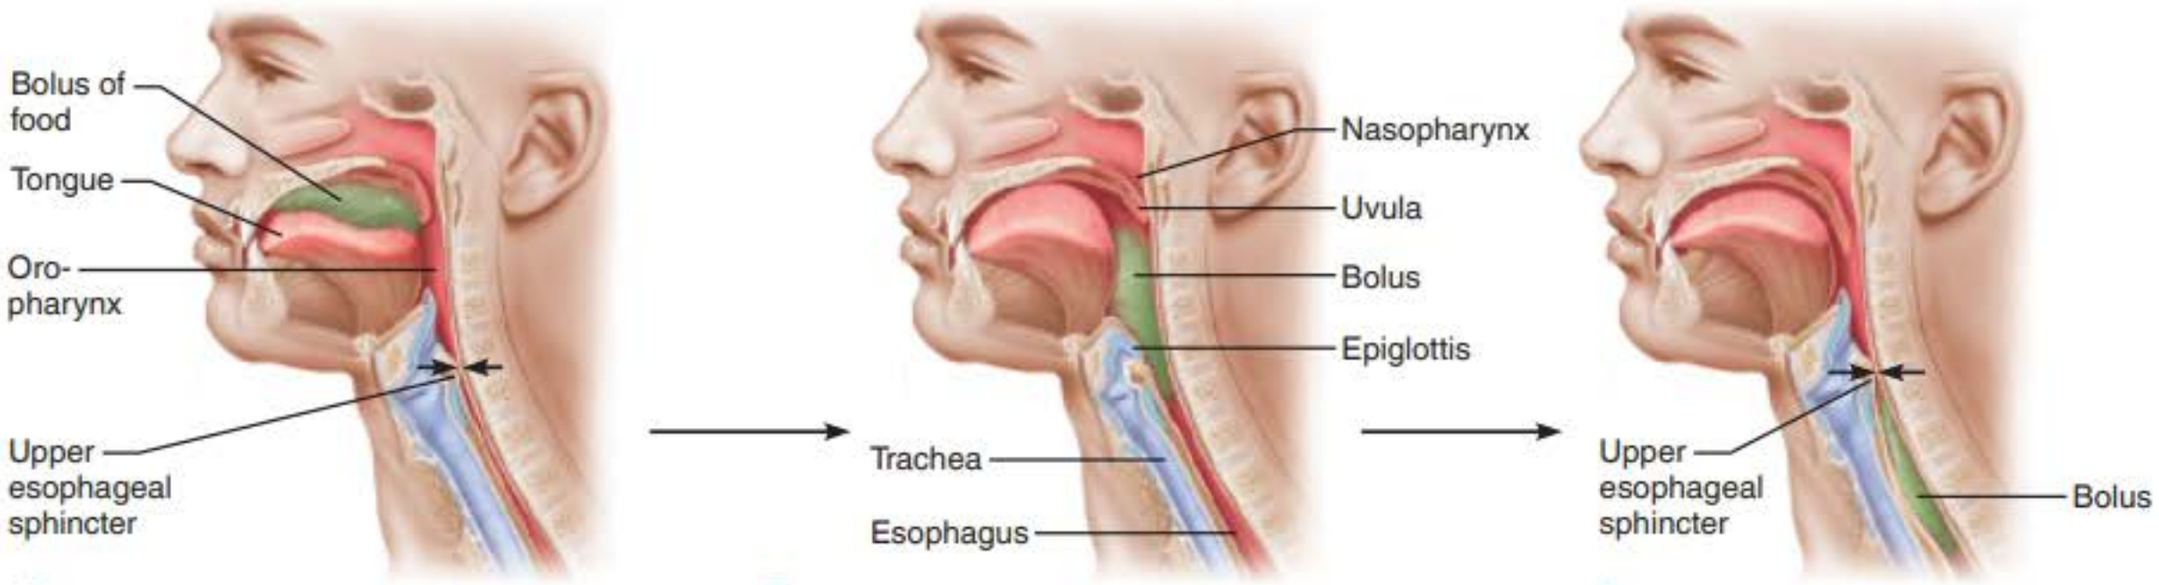
- The esophageal mucosa contains a *nonkeratinized* stratified squamous epithelium. At the esophagus-stomach junction, that abrasion-resistant epithelium changes abruptly to the simple columnar epithelium of the stomach, which is specialized for secretion (Figure 23.13b).
- The submucosa contains mucus-secreting *esophageal glands*. As a bolus moves through the esophagus, it compresses these glands, causing them to secrete mucus that "greases" the esophageal walls and aids food passage.
- The muscularis externa is skeletal muscle in its superior third, a mixture of skeletal and smooth muscle in its middle third, and entirely smooth muscle in its inferior third.
- Instead of a serosa, the esophagus has a fibrous adventitia composed entirely of connective tissue, which blends with surrounding structures along its route.

Digestive Processes: Swallowing

The pharynx and esophagus merely serve as conduits to pass food from the mouth to the stomach. Their single digestive system function is food propulsion, accomplished by **deglutition** (deg″loo-tish′un), or swallowing.

To send food on its way from the mouth, it is first compacted by the tongue into a bolus and is then swallowed. This complicated process involves the coordinated activity of over 22 separate muscle groups. Before we examine the steps of this process in detail, let's outline the two major phases involved in deglutition.

- The **buccal phase** occurs in the mouth and is voluntary. It ends when a food bolus or a "bit of saliva" leaves the mouth and stimulates tactile receptors in the posterior pharynx, initiating the next phase.
- The **pharyngeal-esophageal phase** is involuntary and is controlled by the swallowing center in the brain stem (medulla and lower pons). Various cranial nerves, most importantly the vagus nerves, transmit motor impulses from the swallowing center to the muscles of the pharynx and esophagus. Once food enters the pharynx, respiration is momentarily inhibited and all routes except the desired one into the digestive tract are blocked off. Solid foods pass from the oropharynx to the stomach in about 8 seconds, and fluids, aided by gravity, pass in 1 to 2 seconds.



(1) Buccal phase:
- The upper esophageal sphincter is contracted (closed).
- The tongue presses against the hard palate, forcing the food bolus into the oropharynx.

(2) Pharyngeal-esophageal phase begins:
- The tongue blocks the mouth.
- The soft palate and its uvula rise, closing off the nasopharynx.
- The larynx rises so that the epiglottis blocks the trachea.
- The upper esophageal sphincter relaxes; food enters the esophagus.

(3) Pharyngeal-esophageal phase continues (steps (3)–(5)):
- The constrictor muscles of the pharynx contract, forcing food into the esophagus inferiorly.
- The upper esophageal sphincter contracts after food enters.

(4) Peristalsis moves food through the esophagus to the stomach.

(5) The gastroesophageal sphincter surrounding the cardial orifice opens. After food enters the stomach, the sphincter closes, preventing regurgitation.

Figure 23.14 Deglutition (swallowing). The process of swallowing consists of a buccal (voluntary) phase (step (1)) and a pharyngeal-esophageal (involuntary) phase (steps (2)–(5)).

Figure 23.14 illustrates each phase of deglutition and the protective mechanisms that prevent food from being inhaled. If we talk or inhale while swallowing, these protective mechanisms may be short-circuited and food may enter the respiratory passageways instead. This typically triggers the cough reflex.

Check Your Understanding

17. To which two organ systems does the pharynx belong?
18. How is the muscularis externa of the esophagus unique in the body?
19. What is the functional significance of the epithelial change seen at the esophagus-stomach junction?
20. How are the respiratory passages blocked during swallowing?

For answers, see Answers Appendix.

23.6 The stomach temporarily stores food and begins protein digestion

Learning Outcomes

- **Describe stomach structure and indicate changes in the basic alimentary canal structure that aid its digestive function.**
- **Name the cell types responsible for secreting the various components of gastric juice and indicate the importance of each component in stomach activity.**
- **Explain how gastric secretion and stomach motility are regulated.**
- **Define and account for the alkaline tide.**

Below the esophagus, the GI tract expands to form the **stomach** (see Figure 23.1), a temporary "storage tank." Besides serving as a holding area for ingested food, the stomach continues the demolition job begun in the oral cavity by further degrading food both physically and chemically. As a result, food is converted into a slurry called **chyme** (kīm; "juice"). It then delivers chyme into the small intestine.

Gross Anatomy of the Stomach

The stomach lies in the upper left quadrant of the peritoneal cavity, nearly hidden by the liver and diaphragm. The adult stomach varies from 15 to 25 cm (6 to 10 inches) long, but its diameter and volume depend on how much food it contains. An empty stomach has a volume of about 50 ml and a cross-sectional diameter only slightly larger than the large intestine, but when it is really distended it can hold about 4 L (1 gallon) of food and may extend nearly to the pelvis! When empty, the stomach collapses inward, throwing its mucosa (and submucosa) into large, longitudinal folds called **rugae** (roo′ge; *ruga* = wrinkle, fold).

Figure 23.15a shows the major regions of the stomach. The small **cardial part**, or **cardia** ("near the heart"), surrounds the cardial orifice through which food enters the stomach from the esophagus. The **fundus** is the stomach's dome-shaped part, tucked beneath the diaphragm, that bulges superolaterally to the cardia. The **body**, or the midportion of the stomach, is continuous inferiorly with the funnel-shaped **pyloric part**. The wider and more superior area of the pyloric part, the **pyloric antrum** (*antrum* = cave), narrows to form the **pyloric canal**, which terminates at the **pylorus**. The pylorus is continuous with the duodenum through the **pyloric sphincter** or **valve**, which controls stomach emptying (*pylorus* = gatekeeper).

The convex lateral surface of the stomach is its **greater curvature**, and its concave medial surface is the **lesser curvature**. Extending from these curvatures are two mesenteries, called *omenta* (o-men′tah), that help tether the stomach to other digestive organs and the body wall (see Figure 23.34, p. 908). The **lesser omentum** runs from the liver to the lesser curvature of the stomach, where it becomes continuous with the visceral peritoneum covering the stomach. The **greater omentum** drapes inferiorly from the greater curvature of the stomach to cover the coils of the small intestine. It then runs dorsally and superiorly, wrapping the spleen and the transverse portion of the large intestine before blending with the *mesocolon*, a dorsal mesentery that secures the large intestine to the parietal peritoneum of the posterior abdominal wall.

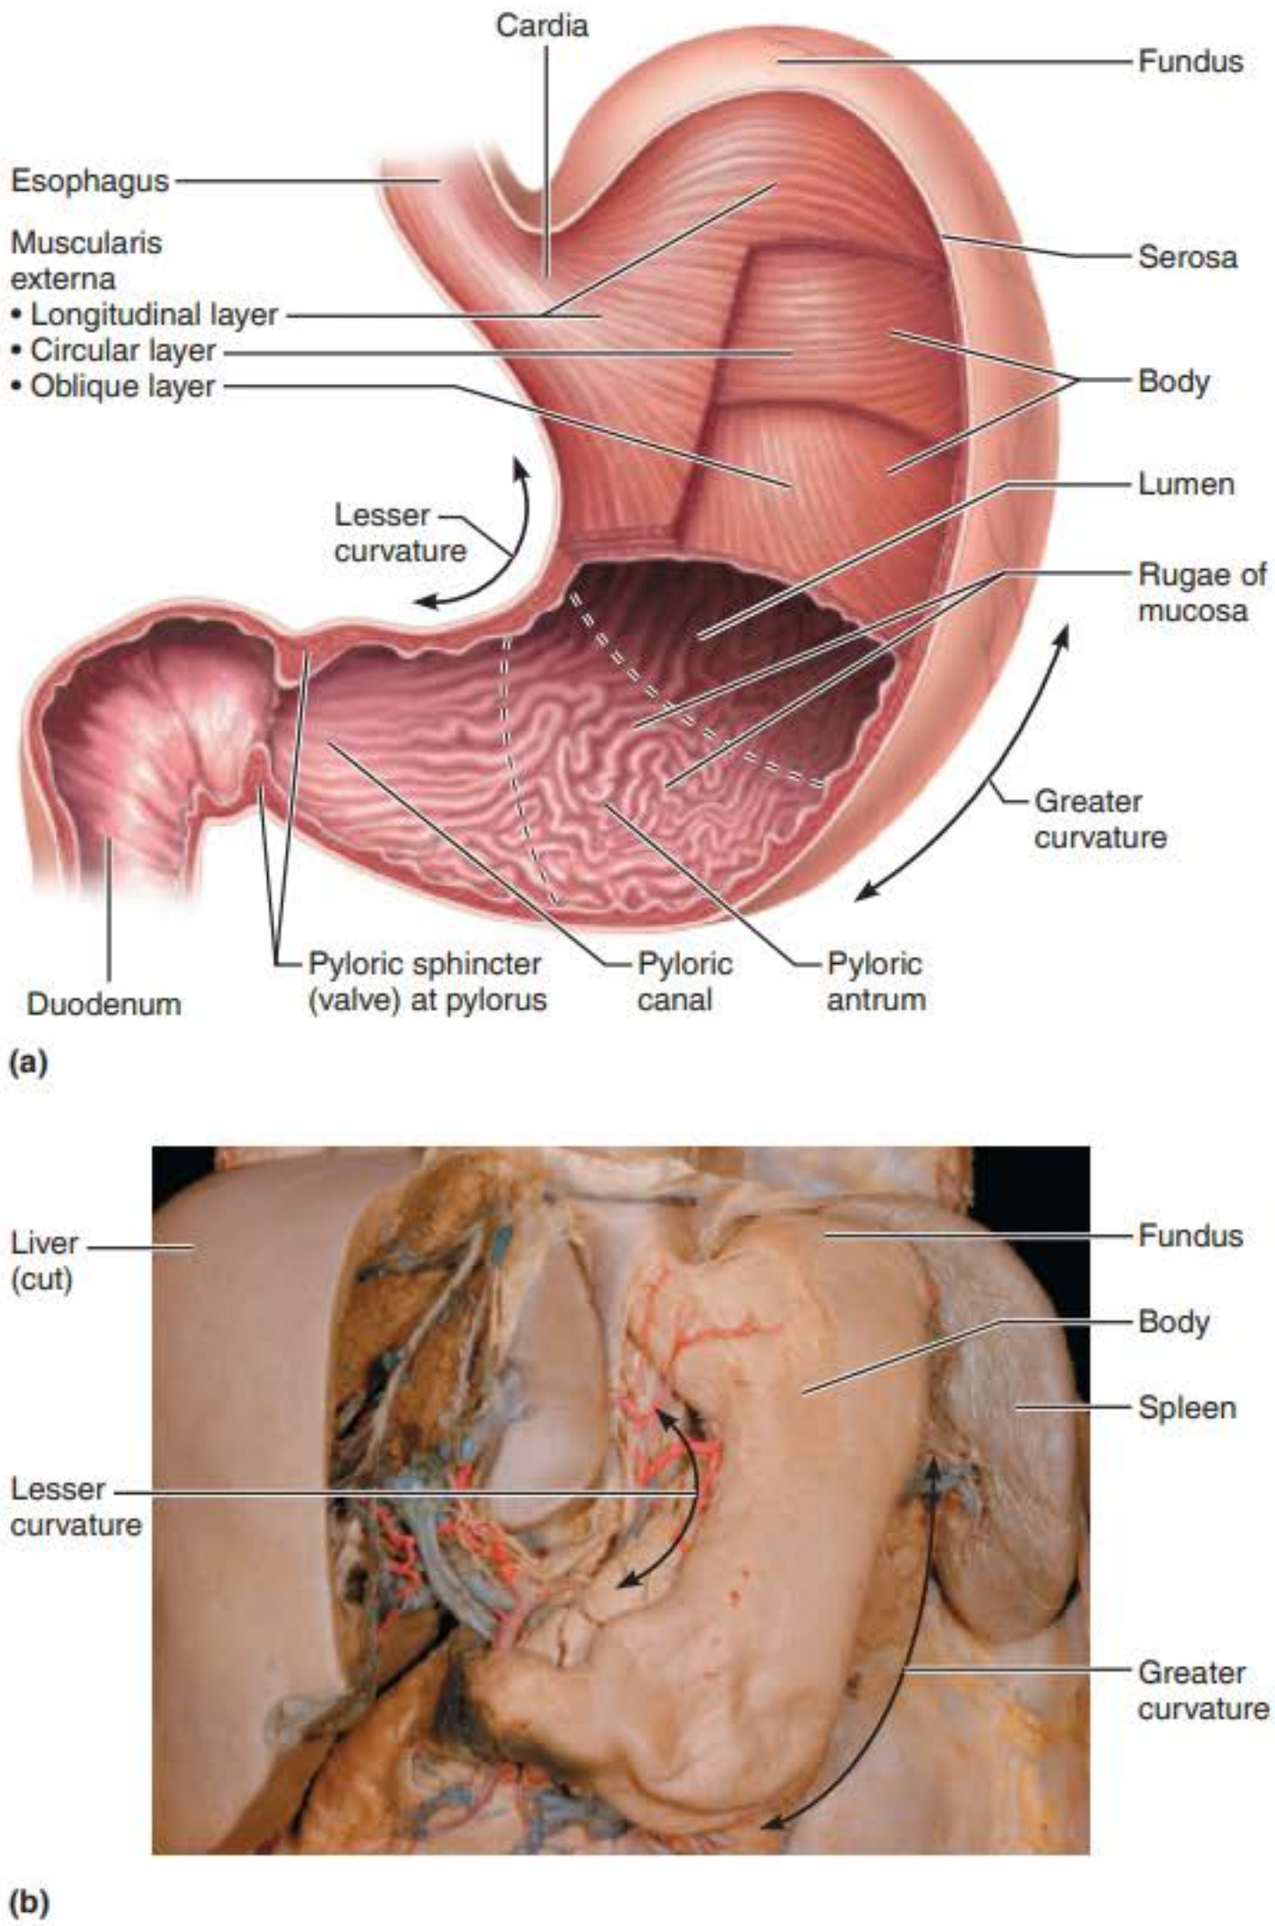


Figure 23.15 Anatomy of the stomach. (a) Gross internal anatomy (frontal section). **(b)** Photograph of external aspect of stomach.

The greater omentum is riddled with fat deposits (*ament* = fatty skin) that give it the appearance of a lacy apron. It also contains large collections of lymph nodes. The immune cells and macrophages in these nodes "police" the peritoneal cavity and intraperitoneal organs.

The stomach is served by the autonomic nervous system. Sympathetic fibers from thoracic splanchnic nerves are relayed through the celiac ganglion (◀ pp. 540–541). Parasympathetic fibers are supplied by the vagus nerve. The arterial supply of the stomach is provided by branches (gastric and splenic) of the celiac trunk (◀ Figure 19.26, p. 745). The

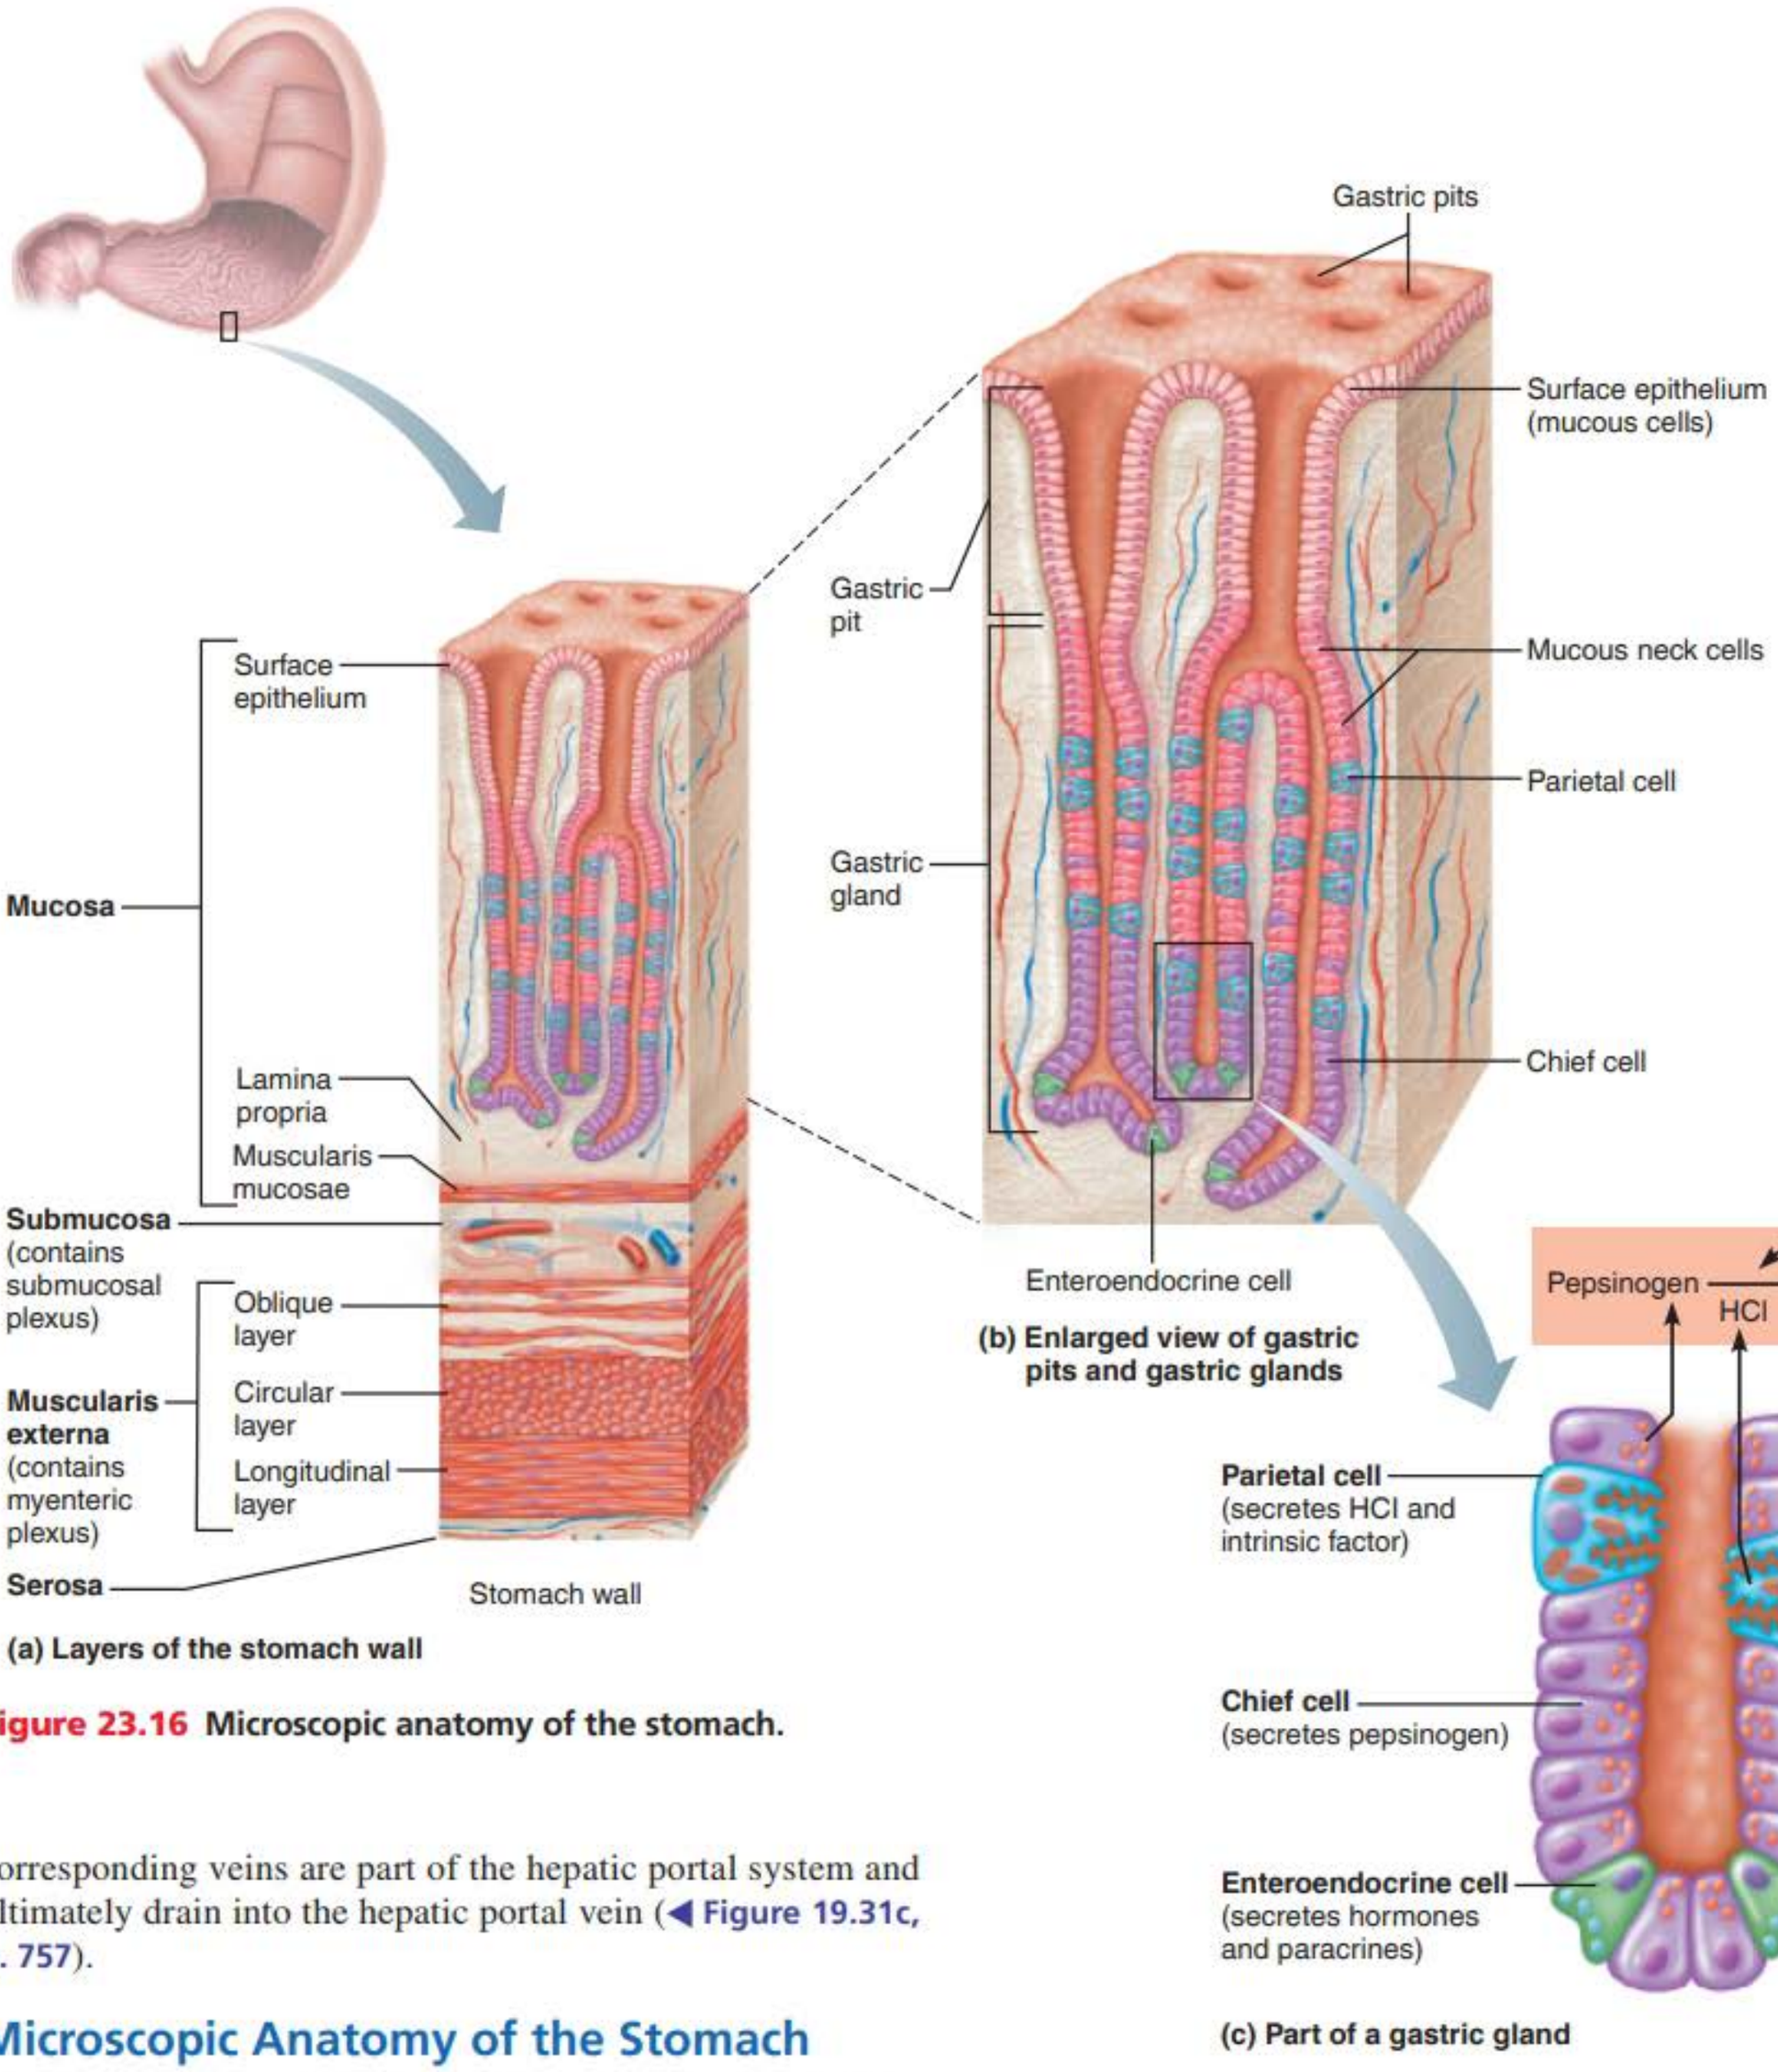

Figure 23.16 Microscopic anatomy of the stomach.

corresponding veins are part of the hepatic portal system and ultimately drain into the hepatic portal vein (◀ **Figure 19.31c, p. 757**).

Microscopic Anatomy of the Stomach

The stomach wall contains the four layers typical of most of the alimentary canal, but its muscularis and mucosa are modified for the special roles of the stomach. Besides the usual circular and longitudinal layers of smooth muscle, the muscularis externa has an incomplete innermost layer of smooth muscle fibrils that runs *obliquely* (Figure 23.15a and **Figure 23.16a**). Together, the smooth muscles of the stomach allow the stomach not only to mix, churn, and move food along the tract, but also to pummel the food, physically breaking it down into smaller fragments and ramming it into the small intestine.

The lining epithelium of the stomach mucosa is a simple columnar epithelium composed entirely of mucous cells. They produce a cloudy, protective two-layer coat of alkaline mucus in which the surface layer consists of viscous, insoluble mucus that traps a layer of bicarbonate-rich fluid beneath it. This otherwise smooth lining is dotted with millions of deep **gastric pits**, which

lead into tubular **gastric glands** that produce the stomach secretion called **gastric juice** (Figure 23.16).

The cells forming the walls of the gastric pits are primarily mucous cells, but those composing the gastric glands vary in different stomach regions. For example, the cells in the glands of the cardia and pylorus primarily secrete mucus, whereas cells of the pyloric antrum produce mucus and several hormones including most of the stimulatory hormone called gastrin.

Types of Gland Cells

Glands of the stomach fundus and body, where most digestion occurs, are substantially larger and produce the majority of the stomach secretions. The glands in these regions contain a variety of secretory cells, including mucous neck, parietal, chief, and enteroendocrine cells.

Mucous Neck Cells **Mucous neck cells** are found primarily in the "neck," but are also scattered deeper within the glands. They produce a thin, soluble mucus quite different from that secreted by the mucous cells of the surface epithelium (Figure 23.16b). It is not yet understood what special function this *acidic* mucus performs.

Parietal Cells **Parietal cells** are scattered among the chief cells (described next), mainly in the more apical (closer to the lumen) region of the glands. Parietal cells simultaneously secrete *hydrochloric acid* (*HCl*) and *intrinsic factor* (Figure 23.16b, c). Although they appear oval when viewed with a light microscope, parietal cells actually have three prongs that bear dense microvilli (they look like fuzzy pitchforks!). This structure provides a huge surface area for secreting H^+ and Cl^- into the stomach lumen.

HCl makes the stomach contents extremely acidic (pH 1.5–3.5), a condition necessary for activation and optimal activity of the protein-digesting enzyme *pepsin*. The acidity also helps digest food by denaturing proteins and breaking down cell walls of plant foods, and is harsh enough to kill many of the bacteria ingested with foods. Intrinsic factor is a glycoprotein required for vitamin B_{12} absorption in the small intestine.

Chief Cells **Chief cells** occur mainly in the basal regions of the gastric glands. The cuboidal chief cells produce *pepsinogen* (pep-sin′o-jen), the inactive form of the **pepsin**. When these cells are stimulated, the first pepsinogen molecules they release are activated by HCl encountered in the apical region of the gland (Figure 23.16c). But once pepsin is present, it also catalyzes the conversion of pepsinogen to pepsin. The activation process involves removing a small peptide fragment from pepsinogen, causing it to change shape and expose its active site. This positive feedback process is limited only by the amount of pepsinogen present.

Chief cells also secrete lipases (fat-digesting enzymes) that account for about 15% of overall GI lipolysis.

Enteroendocrine Cells **Enteroendocrine cells** (en″ter-o-en′do-krin; "gut endocrine"), typically located deep in the gastric glands (Figure 23.16b, c), release a variety of chemical messengers directly into the interstitial fluid of the lamina propria. Some of these, for example **histamine** and **serotonin**, act locally as paracrines. Others, such as **somatostatin**, act both as paracrines locally and as hormones that diffuse into the blood capillaries to influence several digestive system target organs (**Table 23.1**, p. 888). **Gastrin**, a hormone, plays essential roles in regulating stomach secretion and motility, as we will describe shortly.

The Mucosal Barrier

The stomach mucosa is exposed to some of the harshest conditions in the entire digestive tract. Gastric juice is corrosively acidic (the H^+ concentration in the stomach can be 100,000 times that found in blood), and its protein-digesting enzymes can digest the stomach itself.

However, the stomach protects itself by producing the **mucosal barrier**. Three factors create this barrier:

- *A thick coating of bicarbonate-rich mucus* builds up on the stomach wall.
- *The epithelial cells of the mucosa are joined together by tight junctions* (◀ p. 67) that prevent gastric juice from leaking into underlying tissue layers.
- *Damaged epithelial mucosal cells are shed and quickly replaced* by division of undifferentiated *stem cells* that reside where the gastric pits join the gastric glands. The stomach surface epithelium of mucous cells is completely renewed every three to six days, but the more sheltered glandular cells deep within the gastric glands have a much longer life span.

HOMEOSTATIC IMBALANCE 23.7 CLINICAL

Anything that breaches the gel-like mucosal barrier causes inflammation of the stomach wall, a condition called *gastritis*. Persistent damage to the underlying tissues can promote **peptic ulcers**, specifically called **gastric ulcers** when they are erosions of the stomach wall (**Figure 23.17**). The most distressing symptom of gastric ulcers is gnawing epigastric pain that seems to bore through to your back. The pain typically occurs 1–3 hours after eating and is often relieved by eating again. The danger posed by ulcers is perforation of the stomach wall, leading to peritonitis and, perhaps, massive hemorrhage.

For years, ulcers were blamed on factors that increased HCl production or reduced mucus secretion, including aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs such as ibuprofen), smoking, spicy food, alcohol, coffee, and stress. Although acidic conditions *are* necessary for ulcers to form, acidity in itself is not sufficient to cause them. Ninety percent of recurrent ulcers are the

Figure 23.17 A gastric ulcer.

Table 23.1 Hormones and Paracrines That Act in Digestion*

HORMONE	SITE OF PRODUCTION	STIMULUS FOR PRODUCTION	TARGET ORGAN	ACTIVITY
Cholecystokinin (CCK)†	Duodenal mucosa	Fatty chyme (also partially digested proteins)	Stomach	• Inhibits stomach's secretory activity
			Liver/pancreas	• Potentiates secretin's actions on these organs
			Pancreas	• Increases output of enzyme-rich pancreatic juice
			Gallbladder	• Stimulates organ to contract and expel stored bile
			Hepatopancreatic sphincter	• Relaxes sphincter to allow entry of bile and pancreatic juice into duodenum
Glucose-dependent insulinotropic peptide (GIP) (or gastric inhibitory peptide)†	Duodenal mucosa	Fatty chyme	Stomach	• Inhibits HCl production (minor effect)
			Pancreas (beta cells)	• Stimulates insulin release
Gastrin	Stomach mucosa (G cells)	Food (particularly partially digested proteins) in stomach (chemical stimulation); acetylcholine released by nerve fibers	Stomach (parietal cells)	• Increases HCl secretion • Stimulates gastric emptying (minor effect)
			Small intestine	• Stimulates contraction of intestinal muscle
			Ileocecal valve	• Relaxes ileocecal valve
			Large intestine	• Stimulates mass movements
Histamine	Stomach mucosa	Food in stomach	Stomach	• Activates parietal cells to release HCl
Intestinal gastrin	Duodenal mucosa	Acidic and partially digested foods in duodenum	Stomach	• Stimulates gastric glands and motility
Motilin	Duodenal mucosa	Fasting; periodic release every 1½–2 hours by neural stimuli	Proximal duodenum	• Stimulates migrating motor complex
Secretin†	Duodenal mucosa	Acidic chyme (also partially digested proteins and fats)	Stomach	• Inhibits gastric gland secretion and gastric motility
			Pancreas	• Increases output of pancreatic juice rich in bicarbonate ions; potentiates CCK's action
			Liver	• Increases bile output
Serotonin	Stomach mucosa	Food in stomach	Stomach	• Causes contraction of stomach muscle
Somatostatin	Stomach mucosa; duodenal mucosa	Food in stomach; stimulation by sympathetic nerve fibers	Stomach	• Inhibits gastric secretion of all products
			Pancreas	• Inhibits secretion
			Small intestine	• Inhibits GI blood flow; thus inhibits intestinal absorption
			Gallbladder and liver	• Inhibits contraction and bile release
Vasoactive intestinal peptide (VIP)	Enteric neurons	Chyme containing partially digested foods	Small intestine	• Stimulates buffer secretion • Increases blood flow through intestinal capillaries • Relaxes intestinal smooth muscle
			Pancreas	• Increases secretion
			Stomach	• Inhibits acid secretion

*Except for somatostatin, all of these polypeptides also stimulate the growth (particularly of the mucosa) of the organs they affect.
†Secretin, cholecystokinin, and GIP are enterogastrones (p. 891). VIP may also play this role.

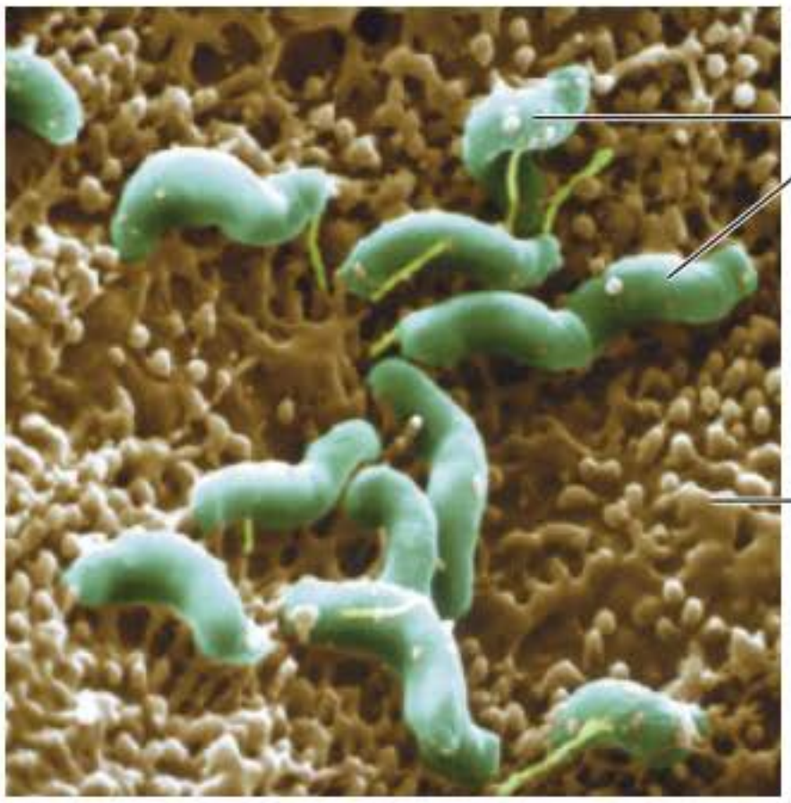

Figure 23.18 Photomicrograph of *H. pylori*, the bacteria that most commonly cause gastric ulcers.

work of a strain of acid-resistant, corkscrew-shaped *Helicobacter pylori* bacteria (**Figure 23.18**), which burrow like a drill bit through the mucus and destroy the protective mucosal layer. Even more troubling are studies that link this bacterium to some stomach cancers.

More than half of the population harbors *H. pylori*, but these pathological effects occur in only 10–20% of infected individuals. The antimicrobial activity of gastric mucin appears to protect most of us from *H. pylori*'s invasive attacks.

A breath test can easily detect the presence of *H. pylori*. A two-week-long course of antibiotics kills the bacteria, promotes healing of the ulcers, and prevents recurrence. For active ulcers, a blocker for H_2 (histamine) receptors may also help because it inhibits HCl secretion by blocking histamine's effects.

The relatively few peptic ulcers not caused by *H. pylori* generally result from long-term use of NSAIDs. In such noninfectious cases, blocking HCl secretion either directly (with pump inhibitors) or indirectly [with H_2 (histamine) receptor blockers] is the therapy of choice.

Digestive Processes in the Stomach

Except for ingestion and defecation, the stomach is involved in the whole "menu" of digestive activities. We will briefly outline the digestive activities here, and these are summarized in **Table 23.2** (p. 904).

- **Propulsion.** Like the esophagus, the stomach exhibits peristalsis.
- **Mechanical breakdown.** The churning action provided by the stomach's smooth muscle during peristalsis causes mechanical breakdown of stomach contents. We discuss stomach contractions further on p. 892.
- **Digestion.** Protein digestion begins in the stomach and is the main type of enzymatic breakdown that occurs there. HCl produced by stomach glands denatures dietary proteins in preparation for enzymatic digestion. (The unfolded amino acid chain is more accessible to the enzymes.) The most important protein-digesting enzyme produced by the gastric mucosa is pepsin. In infants, however, the stomach glands also secrete *rennin*, an enzyme that acts on milk protein (casein), converting it to a curdy substance that looks like soured milk.

  Fat digestion occurs primarily in the small intestine, but gastric and lingual lipases acting in the acidic pH of the stomach also contribute.
- **Absorption.** Not much is absorbed in the stomach, but two common lipid-soluble substances—alcohol and aspirin—pass easily through the stomach mucosa into the blood.

Despite the obvious benefits of preparing food to enter the intestine, the only stomach function essential to life is secretion of intrinsic factor. **Intrinsic factor** is required for intestinal absorption of vitamin B_{12}, needed to produce mature erythrocytes. In its absence, *pernicious anemia* results. However, if vitamin B_{12} is administered by injection, individuals can survive with minimal digestive problems even after total gastrectomy (stomach removal).

In the sections that follow, we will examine (1) the regulation of secretion by gastric glands, (2) the mechanism of HCl secretion, and (3) stomach motility and emptying.

Regulation of Gastric Secretion

Under normal conditions the gastric mucosa pours out as much as 3 L of gastric juice—an acid brew so potent it can dissolve nails—every day. Both neural and hormonal mechanisms control gastric secretion.

- Neural controls consist of both long (vagus nerve–mediated) and short (local enteric) nerve reflexes (see Figure 23.7, p. 875). In each case, acetylcholine (ACh) is released, stimulating the output of gastric juice. When the stomach is stimulated by the vagus nerves (which are parasympathetic, ◀ p. 537), secretory activity of virtually all of its glands increases. (In contrast, activation of sympathetic nerves depresses secretory activity.)
- Hormonal control of gastric secretion is largely the province of *gastrin*. It stimulates secretion of HCl by the stomach, and of hormones (mostly gastrin antagonists) by the small intestine.

Control of HCl-secreting parietal cells is multifaceted. It is stimulated by three chemicals: ACh, gastrin, and histamine. When only one of the three chemicals binds to parietal cell receptors, HCl secretion is scanty, but when all three bind, HCl pours forth. As we noted earlier, antihistamines that bind to and block the H_2 (histamine) receptors of parietal cells are used to treat gastric ulcers caused by hyperacidity. So, as you might guess, histamine (acting as a paracrine) is a key player here.

Stimuli acting at three distinct sites—the head, stomach, and small intestine—provoke or inhibit gastric secretions. Accordingly, the three phases of gastric secretion are called the *cephalic, gastric*, and *intestinal phases*. One or more phases may occur at the same time.

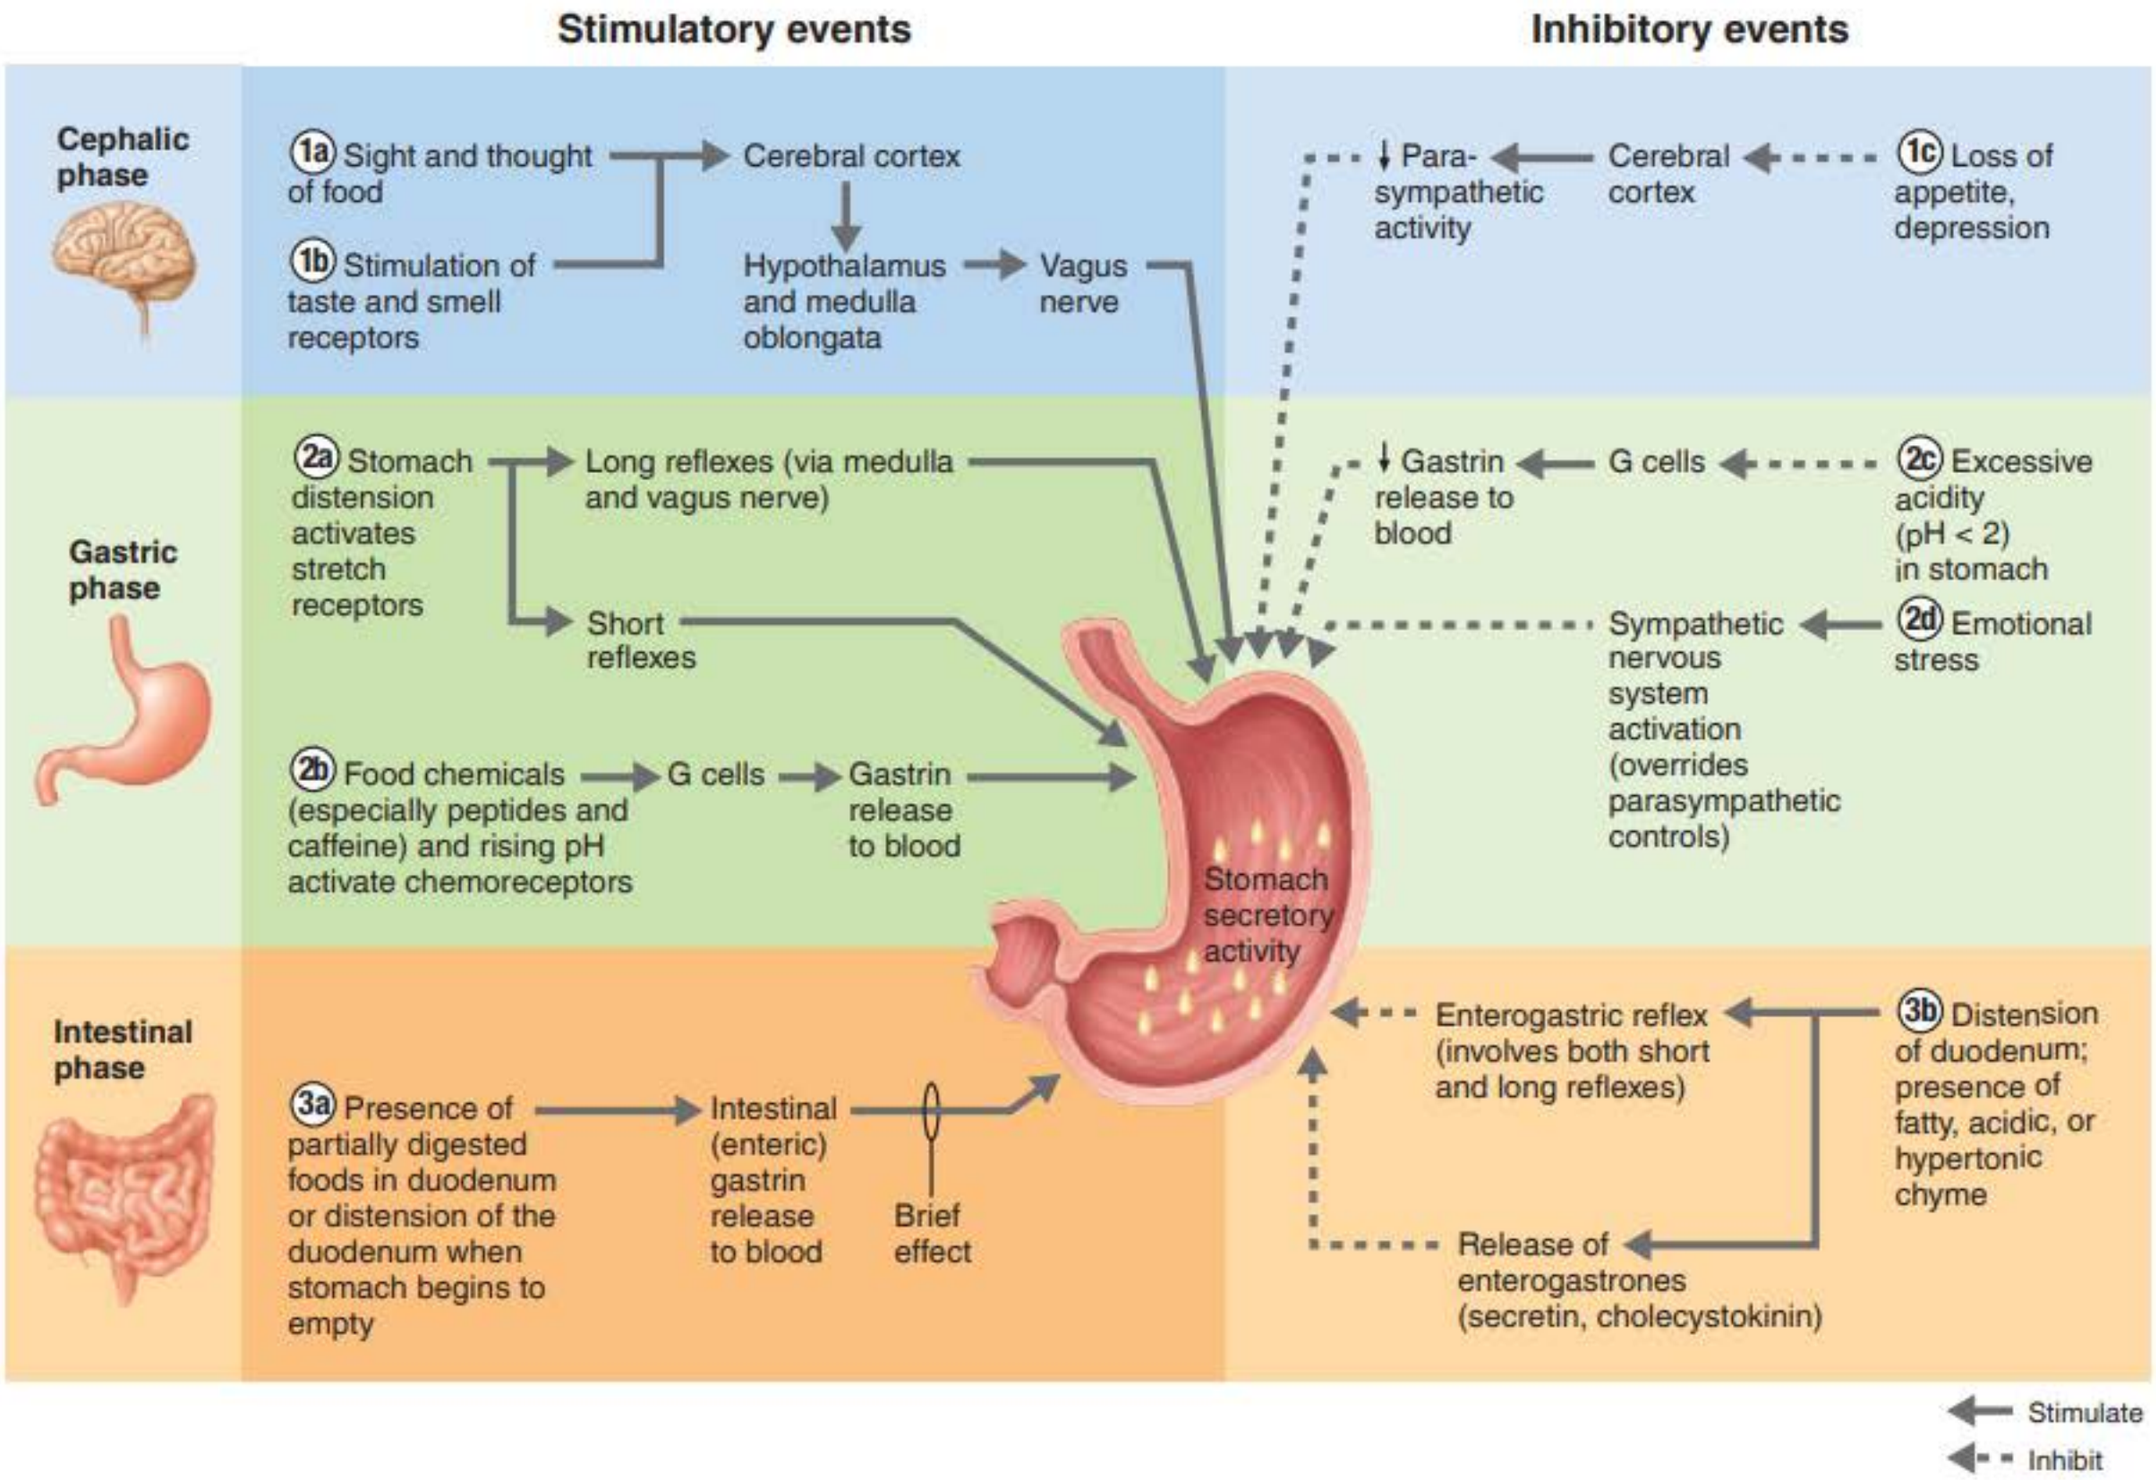

Figure 23.19 Neural and hormonal mechanisms that regulate release of gastric juice.
Stimulatory factors are shown on the left; inhibitory factors are shown on the right.

Cephalic (Reflex) Phase

The **cephalic**, or **reflex**, **phase** of gastric secretion occurs *before* food enters the stomach (**Figure 23.19**). Only a few minutes long, this phase is triggered by the aroma, taste, sight, or thought of food. These triggers act via the vagus nerve to stimulate gastric glands, getting the stomach ready for its digestive chore.

Gastric Phase

Once food reaches the stomach, local neural and hormonal mechanisms initiate the **gastric phase**. This phase lasts three to four hours and provides about two-thirds of the gastric juice released.

Stimulation The most important secretory stimuli are distension, peptides, and low acidity. As shown in Figure 23.19:

- (2a) Stomach distension activates stretch receptors and initiates both short and long reflexes. In the long reflexes, impulses travel to the medulla and then back to the stomach via vagal fibers.
- (2b) Chemical stimuli provided by partially digested proteins, caffeine, and rising pH directly activate gastrin-secreting enteroendocrine cells called **G cells** in the stomach antrum.

During this phase, gastrin plays a major role in stimulating parietal cells to secrete HCl. It prods parietal cells to spew out HCl (1) by acting directly on receptors on these cells, and (2) by stimulating enteroendocrine cells to release histamine.

When protein foods are in the stomach, the pH of the gastric contents generally rises because proteins act as buffers to tie up H^+. The rise in pH stimulates gastrin secretion and subsequently HCl release, which in turn provides the acidic conditions needed to digest proteins. The more protein in the meal, the greater the amount of gastrin and HCl released. As proteins are digested, the gastric contents gradually become more acidic, which again inhibits the gastrin-secreting cells. This negative feedback mechanism helps maintain optimal pH and working conditions for gastric enzymes.

Inhibition As shown in Figure 23.19 (2c), highly acidic (pH below 2) gastric contents *inhibit* gastrin secretion—a situation that commonly occurs between meals. Stress, fear, anxiety, or anything that triggers the fight-or-flight response inhibits gastric secretion because the sympathetic division overrides parasympathetic (vagal) controls of digestion (Figure 23.19 (2d)).

Intestinal Phase

The **intestinal phase** of gastric secretion begins with a brief stimulatory component followed by inhibition (Figure 23.19 ③).

Stimulation The initial stimulatory part of the intestinal phase is set into motion as partially digested food fills the first part (duodenum) of the small intestine. This stimulates intestinal mucosal cells to release **intestinal (enteric) gastrin**, a hormone that encourages the gastric glands to continue their secretory activity. This stimulatory effect is brief because it is overridden by inhibitory stimuli as the intestine fills.

Inhibition Four main factors in the duodenum cause it to put the "brakes" on gastric secretion. *Distension* of the duodenum or the presence of *acidic*, *fatty*, or *hypertonic chyme* all trigger both neuronal and hormonal signals to tell the stomach "whoa, enough already!" As we will see on p. 893, these same four factors also decrease gastric emptying. These brakes on gastric activity protect the small intestine from excessive acidity. They also prevent a massive influx of chyme from overwhelming the digestive and absorptive capacities of the duodenum by matching the amount of entering chyme to the processing abilities of the small intestine. Inhibition is achieved in two ways:

- **Enterogastric reflex:** The duodenum inhibits acid secretion in the stomach by short reflexes through the enteric nervous system and by long reflexes involving sympathetic and vagus nerves.
- **Enterogastrones:** The enterogastrone hormones are released by a scattering of enteroendocrine cells in the duodenal mucosal epithelium. The two most important enterogastrones are **secretin** (se-kre′tin) and **cholecystokinin (CCK)** (ko″le-sis″to-ki′nin). The enterogastrones inhibit gastric secretion and also play other roles (see Table 23.1, p. 888).

Mechanism of HCl Secretion

The process of HCl formation within the parietal cells is shown in **Figure 23.20**. When parietal cells are appropriately stimulated, H^+ is actively pumped into the stomach lumen by H^+-K^+ ATPases (*proton pumps*). As acid is pumped into the stomach, base (HCO_3^-) is exported into the blood. This flow of base is called the **alkaline tide**.

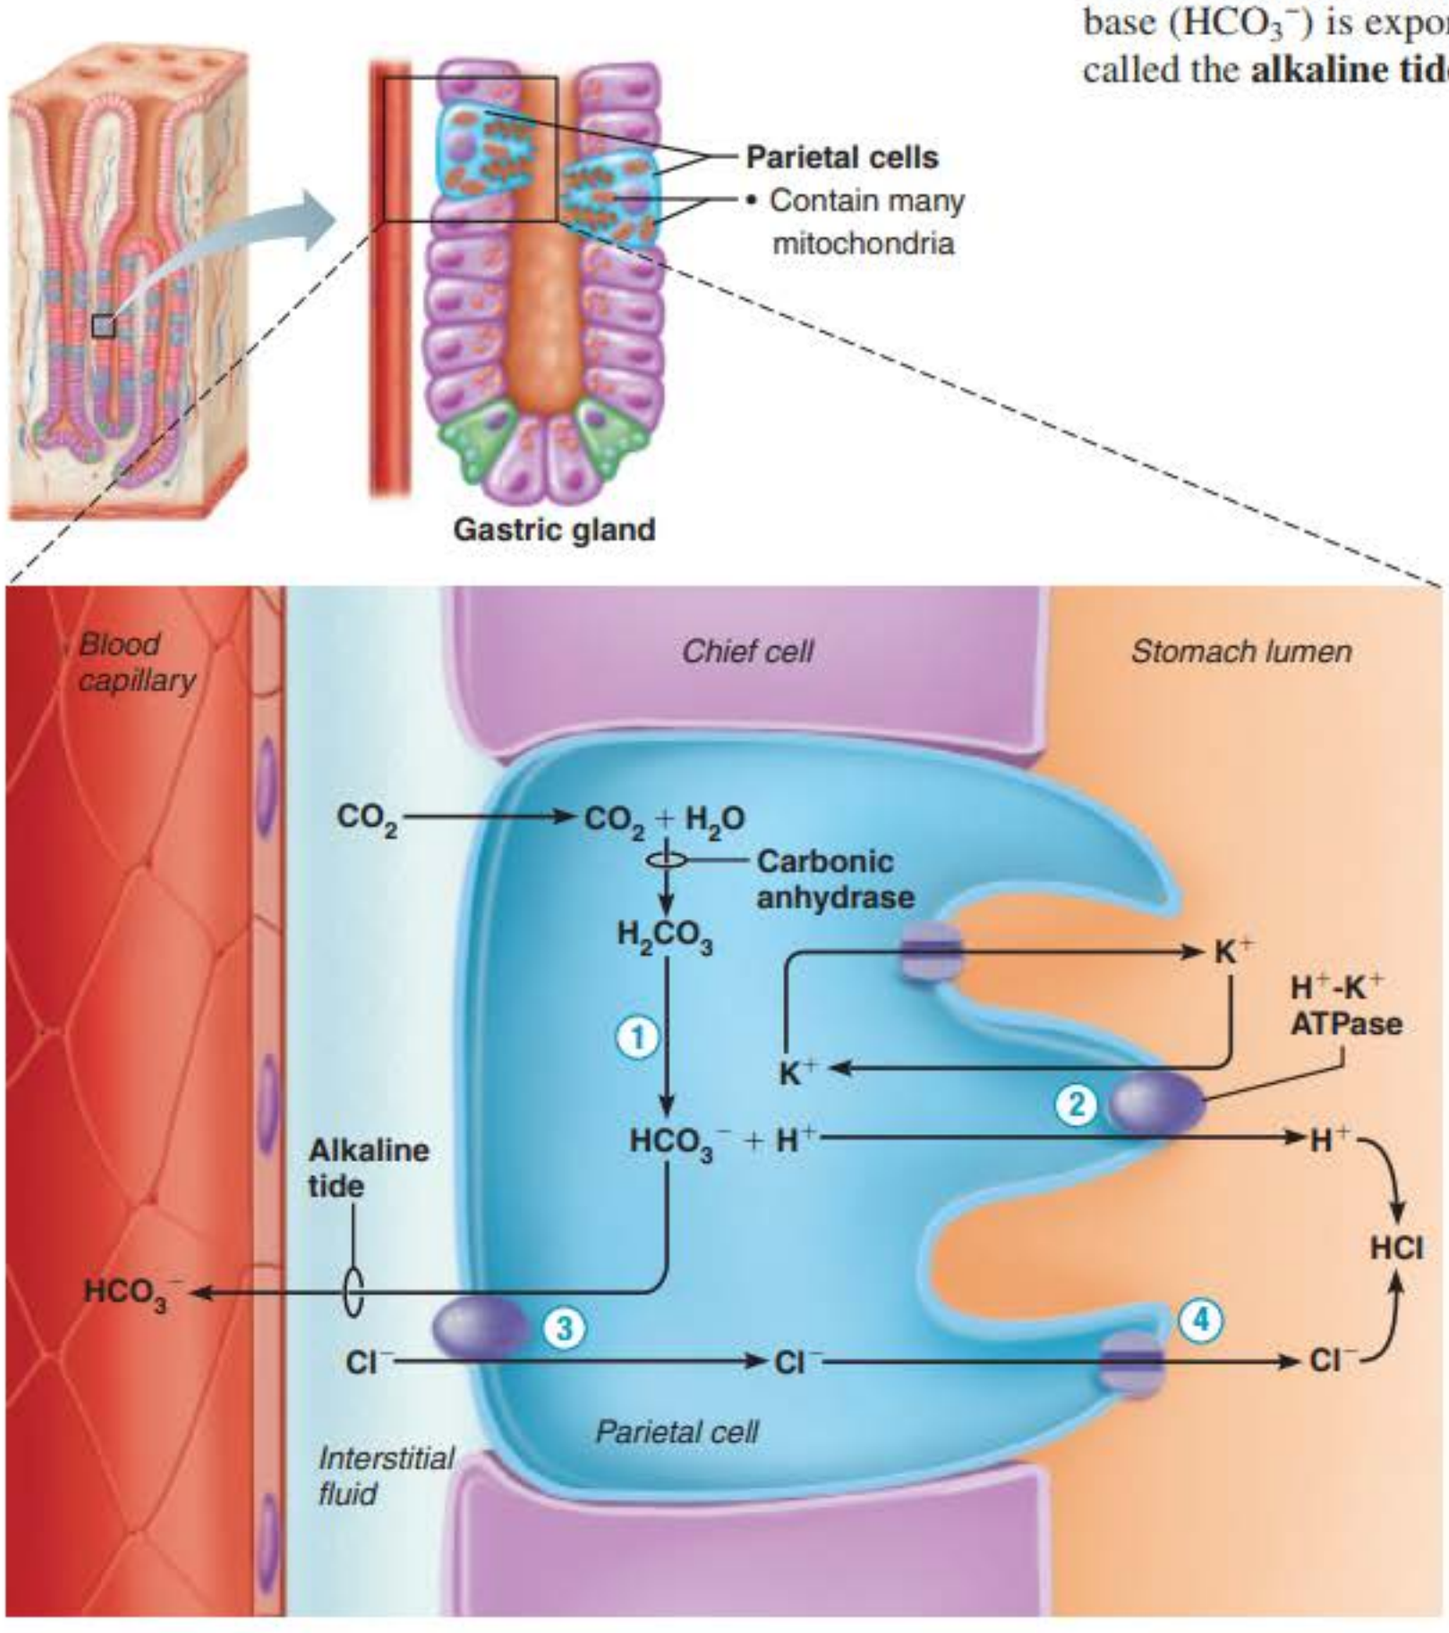

Figure 23.20 Mechanism of HCl secretion by parietal cells.

Regulation of Gastric Motility and Emptying

Stomach contractions not only accommodate its filling and cause its emptying, but they also compress, knead, and mix the food with gastric juice to produce chyme. The processes of mechanical breakdown and propulsion are inseparable in the stomach due to a unique type of peristalsis.

Response of the Stomach to Filling

The stomach stretches to accommodate incoming food, but internal stomach pressure remains constant until about 1.5 L of food have been ingested. Thereafter, the pressure rises. The relatively unchanging pressure in a filling stomach is due to two factors:

- **Receptive relaxation** of smooth muscle in the stomach fundus and body occurs both in anticipation of and in response to food moving through the esophagus and into the stomach. The swallowing center of the brain stem coordinates this process, which is mediated by the vagus nerves.
- **Gastric accommodation** is the intrinsic ability of visceral smooth muscle to exhibit the *stress-relaxation response*. In other words, the stomach can stretch without greatly increasing its tension and contracting expulsively. As we described in Chapter 9 (◀ pp. 315–316), this capability is very important in hollow organs, like the stomach, that must serve as temporary reservoirs.

Gastric Contractile Activity

Like the esophagus, the stomach exhibits peristalsis. After a meal, peristalsis begins near the gastroesophageal sphincter, where it produces gentle rippling movements of the thin stomach wall. But as the contractions approach the pylorus, where the stomach musculature is thicker, they become much more powerful. Consequently, the contents of the fundus and body (food storage area) remain relatively undisturbed, while foodstuffs in and around the pyloric antrum receive a lively pummeling and mixing.

The pyloric part of the stomach, which holds about 30 ml of chyme, acts as a dynamic filter that allows only liquids and small particles to pass through the barely open pyloric valve. Normally, each peristaltic wave reaching the pyloric muscle squirts 3 ml or less of chyme into the small intestine. Because the contraction also *closes* the valve, the rest (about 27 ml) is propelled backward into the stomach, where it is mixed further (**Figure 23.21**). This back-and-forth pumping action (retropulsion) effectively breaks up solids.

Although the strength of the stomach's peristaltic waves can be modified, their rate is constant—always around three per minute. This contractile rhythm is set by *enteric pacemaker cells*, muscle-like noncontractile cells formerly called *interstitial cells of Cajal* (kă-hal′). Located in the myenteric plexus (◀ p. 874), the pacemaker cells depolarize and repolarize spontaneously three times each minute, establishing the so-called *cyclic slow waves* of the stomach, or its **basic electrical rhythm (BER)**. Since gap junctions (◀ p. 68) couple the pacemakers electrically to the rest of the smooth muscle sheet, their "beat" is transmitted efficiently and quickly to the entire muscularis.

The pacemakers set the maximum frequency of contraction, but they do not initiate the contractions or regulate their force. Instead, they generate subthreshold depolarization waves, which are then "ignited" (enhanced by further depolarization and brought to threshold) by neural and hormonal factors.

The same factors that increase gastric secretions also enhance the strength of stomach contractions. Distension of the stomach wall by food activates stretch receptors and gastrin-secreting cells, both of which ultimately stimulate gastric smooth muscle

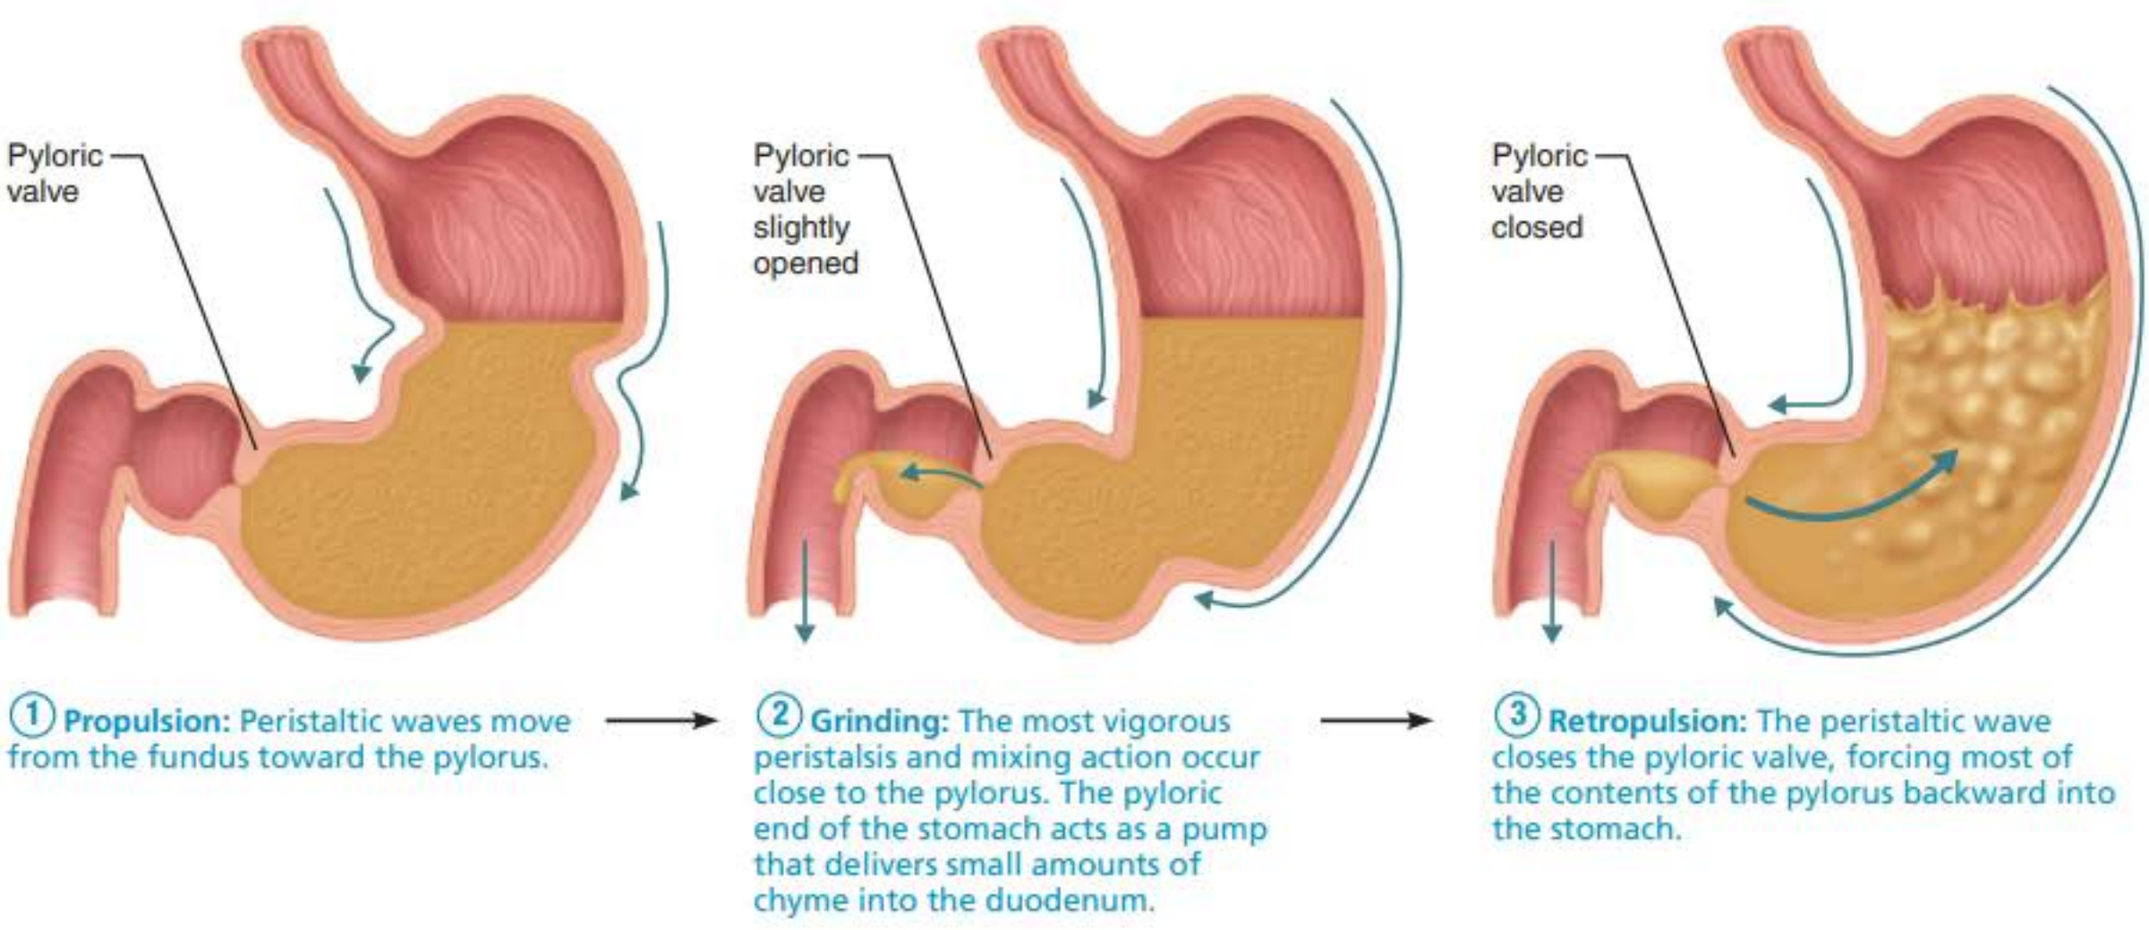

Figure 23.21 **Peristaltic waves in the stomach.**

and increase gastric motility. For this reason, the more food there is in the stomach, the more vigorous the stomach mixing and emptying movements will be—within certain limits—as we describe next.

Regulation of Gastric Emptying

The stomach usually empties completely within four hours after a meal. However, the larger the meal (the greater the stomach distension) and the more liquid its contents, the faster the stomach empties. Fluids pass quickly through the stomach. Solids linger, remaining until they are well mixed with gastric juice and converted to the liquid state.

The rate of gastric emptying also depends as much—and perhaps more—on the contents of the duodenum as on what is happening in the stomach. The stomach and duodenum act in tandem. As chyme enters the duodenum, receptors in its wall respond to chemical signals and to stretch. This initiates the enterogastric reflex and the hormonal (enterogastrone) mechanisms that inhibit gastric secretion as we described earlier. These mechanisms also prevent further duodenal filling by reducing the force of pyloric contractions (**Figure 23.22**).

A carbohydrate-rich meal moves through the duodenum rapidly, but fats form an oily layer at the top of the chyme and are digested more slowly by enzymes acting in the intestine. For this reason, when chyme entering the duodenum is fatty, reflexes slow stomach emptying, and food may remain in the stomach six hours or more.

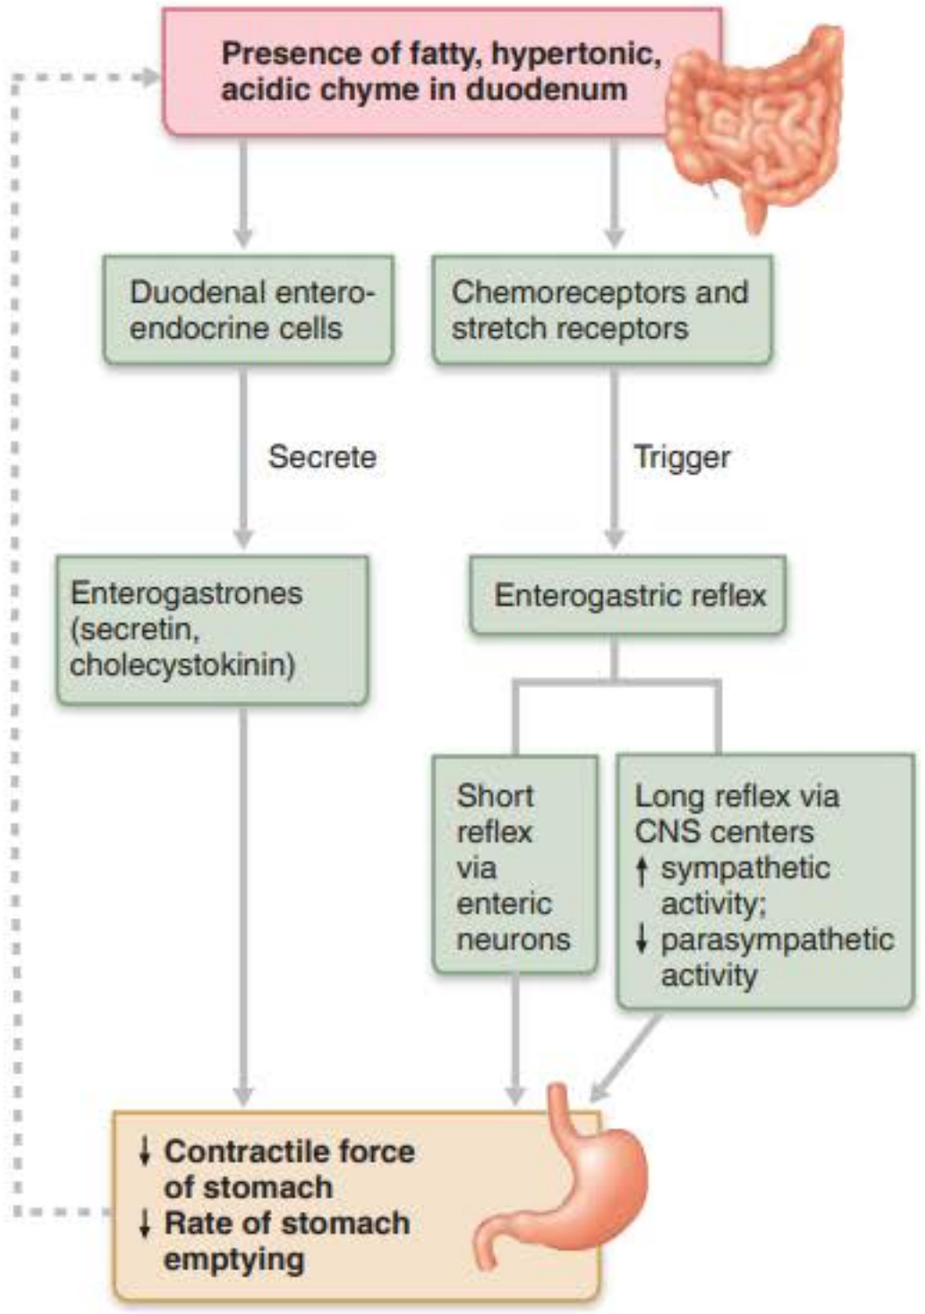

Figure 23.22 Neural and hormonal factors that inhibit gastric emptying. These controls ensure that the food is well liquefied in the stomach and prevent the small intestine from being overwhelmed.

HOMEOSTATIC IMBALANCE 23.8 CLINICAL

Vomiting, or **emesis**, is an unpleasant experience that empties the stomach by a different route. Many factors signal the stomach to "launch lunch," but the most common are extreme stretching of the stomach or intestine or irritants such as bacterial toxins, excessive alcohol, spicy foods, and certain drugs.

Bloodborne molecules and sensory impulses stream from the irritated sites to the **emetic center** (e-met′ik) of the medulla where they initiate a number of motor responses. Before vomiting, an individual typically feels nauseated, is pale, and salivates excessively. A deep inspiration directly precedes vomiting. The diaphragm and abdominal wall muscles contract, increasing intra-abdominal pressure. The gastroesophageal sphincter relaxes, and the soft palate rises to close off the nasal passages. As a result, the stomach (and perhaps duodenal) contents are forced upward through the esophagus and pharynx and out the mouth.

Excessive vomiting can cause dehydration and severely disrupt the body's electrolyte and acid-base balance. Because large amounts of HCl are lost in vomitus, the blood becomes alkaline as the stomach attempts to replace its lost acid.

Check Your Understanding

21. Describe the process by which solids are broken apart into smaller pieces in the stomach.

22. Two substances secreted by cells of the gastric glands are needed to produce the active protein-digesting enzyme pepsin. What are these substances and which cells secrete them?

23. Name the three phases of gastric secretion.

24. How does the presence of food in the small intestine inhibit gastric secretion and motility?

For answers, see Answers Appendix.

23.7 The liver secretes bile; the pancreas secretes digestive enzymes

Learning Outcomes

- **Describe the histologic anatomy of the liver and pancreas.**
- **State the roles of bile and pancreatic juice in digestion.**
- **Describe the role of the gallbladder.**
- **Describe how bile and pancreatic juice secretion into the small intestine are regulated.**

The *liver*, *gallbladder*, and *pancreas* are accessory organs associated with the small intestine. We will take a side trip to these organs before we continue our journey down the digestive tract.

The liver has many metabolic and regulatory roles. Here we focus on its *digestive* system function: producing bile for export to the duodenum (the first part of the small intestine). Bile is a fat emulsifier that breaks fats into tiny particles to make them more readily digestible. Although the liver also processes nutrient-laden venous blood delivered to it from the digestive organs, this is a metabolic rather than a digestive role (see Chapter 24). The gallbladder is chiefly a storage organ for bile. The pancreas supplies most of the enzymes that digest chyme as well as bicarbonate that neutralizes stomach acid.

The Liver

Gross Anatomy of the Liver

The ruddy, blood-rich **liver** is the largest gland in the body, weighing about 1.4 kg (3 lb) in the average adult. Shaped like a wedge, it occupies most of the right hypochondriac and epigastric regions (◀ Figure 1.13, p. 20), extending farther to the right of the body midline than to the left. Located under the diaphragm, the liver lies almost entirely within the rib cage, which provides some protection (see Figure 23.1 and **Figure 23.23**).

The liver has four primary lobes. The largest, the *right lobe*, is visible on all liver surfaces and separated from the smaller *left lobe* by a deep fissure (Figure 23.23a). The posteriormost *caudate lobe* and the *quadrate lobe*, which lies inferior to the left lobe, are visible in an inferior view of the liver (Figure 23.23b, c).

A mesentery, the **falciform ligament**, separates the right and left lobes anteriorly and suspends the liver from the diaphragm and anterior abdominal wall. Running along the inferior edge of the falciform ligament is the **round ligament**, or **ligamentum teres** (te′rēz; "round"), a fibrous remnant of the fetal umbilical vein. Except for the superiormost liver area (the *bare area*), which touches the diaphragm, the entire liver is enclosed by the visceral peritoneum.

The lesser omentum anchors the liver to the lesser curvature of the stomach (see Figure 23.34b). The **hepatic artery proper** and the **hepatic portal vein**, which enter the liver at the **porta hepatis** ("gateway to the liver"), and the common hepatic duct, which runs inferiorly from the liver, all travel through the lesser omentum to reach their destinations. The gallbladder rests in a recess on the inferior surface of the right liver lobe (Figure 23.23b, c).

The traditional scheme of defining liver lobes is based on superficial features of the liver. Hepatic surgeons use a different system that divides the liver into eight segments based on its internal anatomy relative to its vascular and biliary supply. This system delineates sections that can be removed while encountering the fewest major vascular structures and the lowest risk.

Bile leaves the liver lobes through the *right* and *left hepatic ducts*. These fuse to form the large **common hepatic duct**, which travels downward toward the duodenum. Along its course, that duct fuses with the **cystic duct** draining the gallbladder to form the **bile duct** (Figure 23.23c).

MasteringA&P® > Study Area > Lab Tools > PAL

Microscopic Anatomy of the Liver

The liver is composed of sesame seed–sized structural and functional units called **liver lobules**. Each lobule is a roughly hexagonal (six-sided) structure consisting of plates of *liver cells*, or **hepatocytes** (hep-ah′to-sīts), organized like bricks in a garden wall (**Figure 23.24**). The hepatocyte plates radiate outward from a **central vein** running in the longitudinal axis of the lobule. To make a rough model of a liver lobule, open a thick paperback book until its two covers meet: The pages represent the plates of hepatocytes, and the hollow cylinder formed by the rolled spine represents the central vein.

If you keep in mind that the liver's main function is to process the nutrient-rich blood delivered to it, its histology makes a lot of sense. At each of the six corners of a lobule is a **portal triad** (*portal tract* region), so named because it contains three basic structures (Figure 23.24c):

- A branch of the *hepatic artery* (supplying oxygen-rich arterial blood to the liver)
- A branch of the *hepatic portal vein* (carrying venous blood laden with nutrients from the digestive viscera)
- A *bile duct*

Between the hepatocyte plates are enlarged, heavily fenestrated **liver sinusoids**. Blood from both the hepatic portal vein and the hepatic artery proper percolates from the triad regions through these sinusoids and empties into the central vein. From the central veins blood eventually enters the hepatic veins, which drain the liver, and empties into the inferior vena cava. Forming part of the sinusoid walls are star-shaped **stellate macrophages**, also called **hepatic macrophages** (Figure 23.24c). They remove debris such as bacteria and worn-out blood cells from the blood as it flows past.

The versatile hepatocytes have large amounts of both rough and smooth ER, Golgi apparatus, peroxisomes, and mitochondria. Equipped in this way, the hepatocytes can:

- Secrete some 900 ml of bile daily
- Process bloodborne nutrients in various ways (e.g., they store glucose as glycogen and use amino acids to make plasma proteins)
- Store fat-soluble vitamins
- Play important roles in detoxification, such as ridding the blood of ammonia by converting it to urea (Chapter 24)

Secreted bile flows through tiny canals, called **bile canaliculi** (kan″ah-lik′u-li;), that run between adjacent hepatocytes toward the bile duct branches in the portal triads (Figure 23.24c). Although most illustrations show the canaliculi as discrete tubular structures (shown here in green), their walls are actually formed by the apical membranes of adjoining hepatocytes.

Notice that blood and bile flow in opposite directions in the liver lobule. Bile entering the bile ducts eventually leaves the liver via the common hepatic duct to travel toward the duodenum.

Bile: Composition and Enterohepatic Circulation

Bile is a yellow-green, alkaline solution containing bile salts, bile pigments, cholesterol, triglycerides, phospholipids (lecithin and others), and a variety of electrolytes. Of these, *only* bile salts and phospholipids aid the digestive process.

Bile salts, primarily salts of cholic and chenodeoxycholic acids, are cholesterol derivatives. They play a crucial role in both the digestion and absorption of fats, as we will see later.

Many substances secreted in bile leave the body in feces, but bile salts are not among them. Instead, a recycling mechanism called the *enterohepatic circulation*, shown in **Figure 23.25**, conserves bile salts. This helps minimize the amount of new bile salts that must be synthesized, which is important because they are recirculated 4 to 12 times per day.

The chief *bile pigment* is **bilirubin** (bil″ĭ-roo′bin), a yellow waste product of the heme of hemoglobin formed during the breakdown of worn-out erythrocytes (◀ p. 649). The globin and iron parts of hemoglobin are saved and recycled. Bilirubin, however, is absorbed from the blood by liver cells, excreted into bile, and metabolized in the small intestine by resident bacteria. One of its breakdown products, *stercobilin* (ster′ko-bi″lin), gives feces a brown color. In the absence of bile, feces are gray-white and have fatty streaks because essentially no fats are digested or absorbed.

Homeostatic Imbalances of the Liver

Hepatitis (hep″ah-ti′tis), or inflammation of the liver, has many causes including the toxic effects of alcohol, drugs, and wild

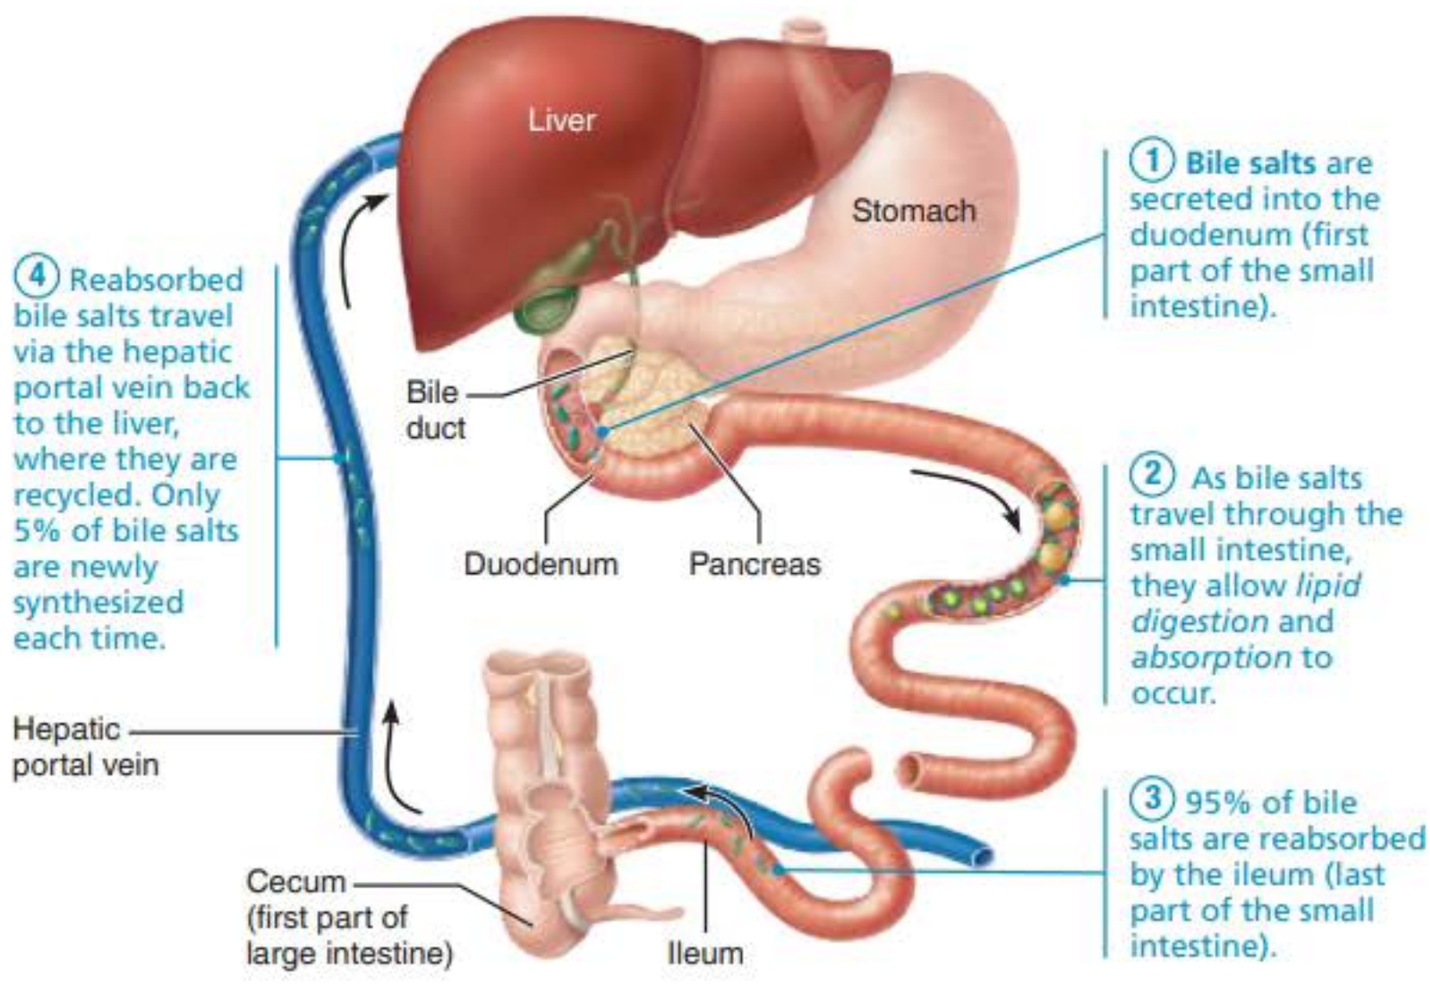

Figure 23.25 The enterohepatic circulation.

mushrooms. Six viruses that cause hepatitis have been identified and named HVA to HVF. Two of these (HVA and HVE) are transmitted enterically (acquired through eating contaminated food), and the infections they cause tend to be self-limiting. Those transmitted via blood—most importantly HVB and HVC—are linked to chronic hepatitis, liver cirrhosis, and cancer.

Hepatitis C has emerged as the most important infectious liver disease in the United States because it produces persistent or chronic liver infections. More than 4 million Americans are infected and over 10,000 die annually due to sequels of HVC infection. However, the life-threatening C form of hepatitis can now be successfully (and very expensively) treated by a 12-week combination drug therapy.

Outpacing even hepatitis C and alcohol-associated liver damage, **non-alcoholic fatty liver disease (NAFLD)** has become the most common liver disease in North America. It affects about 30% of the general population, but 70% of the obese. Obesity and increased insulin resistance are associated with abnormal lipid metabolism and liver inflammation, which cause NAFLD. There are usually no symptoms associated with NAFLD, but it predisposes the patient to develop full-blown cirrhosis or even liver cancer.

Cirrhosis (sĭr-ro′sis; "orange colored") is the last stage of progressive chronic inflammation of the liver. It typically results from severe chronic hepatitis due to chronic alcoholism, NAFLD, or viral hepatitis. While damaged hepatocytes can regenerate, the liver's connective (scar) tissue regenerates faster. Liver activity is depressed and the liver becomes fibrous with scar tissue. The scar tissue obstructs blood flow throughout the hepatic portal system, causing **portal hypertension**.

Liver transplants are the only clinically proven effective treatment for patients with end-stage liver disease. The one- and five-year survival rate of such transplants is approximately 90% and 75%, respectively. The regenerative capacity of a healthy liver is exceptional. It can regenerate to its former size in 6–12 months even after surgical removal or loss of 80% of its mass. This means that part of a living donor's liver can be removed for transplant without long-term harm to the donor.

The Gallbladder

The **gallbladder** is a thin-walled muscular sac that may appear green when filled with bile. The size of a kiwi fruit (about 10 cm or 4 inches long), it snuggles in a shallow fossa on the inferior surface of the liver from which its rounded fundus protrudes (see Figures 23.1 and 23.23).

The gallbladder stores bile that is not immediately needed for digestion and concentrates it by absorbing some of its water and ions. When empty, its mucosa is thrown into honeycomb-like folds (see Figure 23.28) that, like the rugae of the stomach, allow the organ to expand as it fills. Its muscular wall contracts to expel bile into the *cystic duct*. From there bile flows into the bile duct. The gallbladder, like most of the liver, is covered by visceral peritoneum.

HOMEOSTATIC IMBALANCE 23.9 — CLINICAL

Bile is the major vehicle for excreting cholesterol from the body, and bile salts keep the cholesterol dissolved within bile. Too much cholesterol or too few bile salts allows the cholesterol to crystallize, forming **gallstones**. Gallstones can obstruct the flow of bile from the gallbladder, a condition called *cholelithiasis* (ko-lĕ-lĭ-thi′ah-sis). When the gallbladder or its duct contracts, the sharp crystals cause agonizing pain that radiates to the right thoracic region.

Gallstones are easy to diagnose because they show up well with ultrasound imaging. Treatments for gallstones include dissolving the crystals with drugs, pulverizing them with ultrasound vibrations (lithotripsy), vaporizing them with lasers, and the classical treatment, surgically removing the gallbladder (cholecystectomy). When the gallbladder is removed, the bile duct enlarges to assume the bile-storing role.

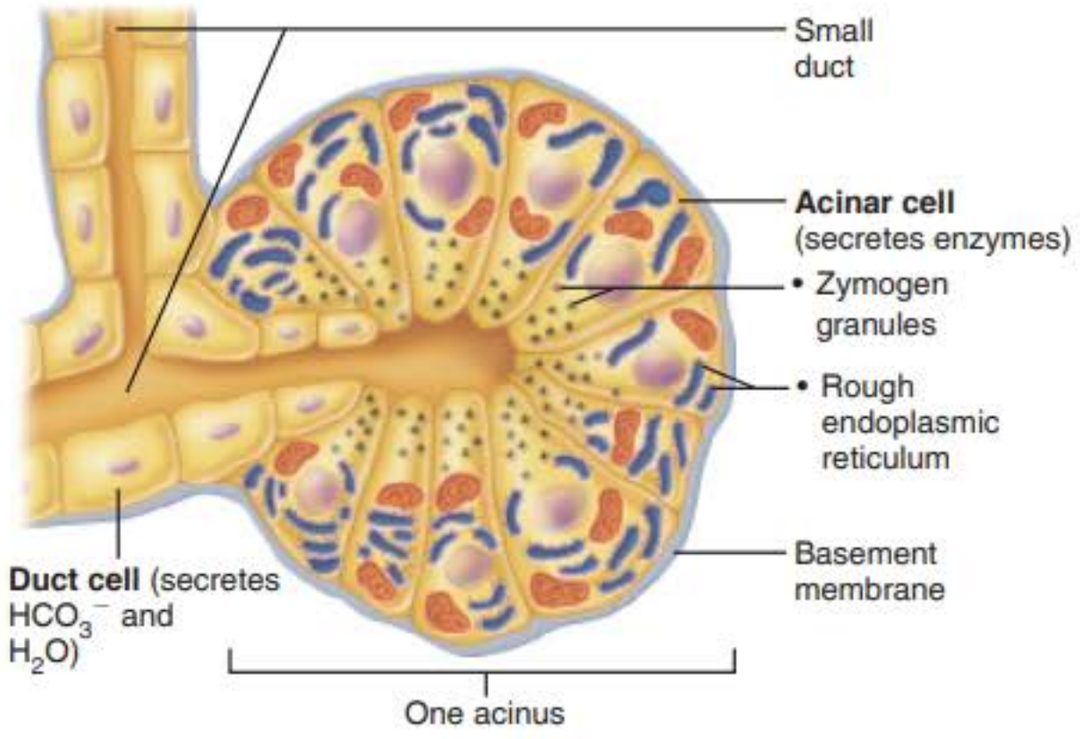
Bile duct blockage prevents both bile salts and bile pigments from entering the intestine. As a result, yellow bile pigments accumulate in blood and eventually are deposited in the skin, causing it to become yellow, or *jaundiced*. Jaundice caused by blocked ducts is called *obstructive jaundice*, but jaundice may also reflect liver disease (in which the liver is unable to carry out its normal metabolic duties).

The Pancreas

The **pancreas** (pan′kre-as; *pan* = all, *creas* = flesh, meat) is important to the digestive process because it produces enzymes that break down all categories of foodstuffs. The pancreas is a soft, tadpole-shaped gland that extends across the abdomen from its *tail* (next to the spleen) to its *head*, which is encircled by the C-shaped duodenum (see Figures 23.1 and 23.28). Most of the pancreas is retroperitoneal and lies deep to the greater curvature of the stomach.

The pancreas contains exocrine and endocrine parts. The exocrine part of the pancreas produces **pancreatic juice** and consists of the following (**Figure 23.26**):

- **Acini.** Acini (as′ĭ-ni; singular: acinus) are clusters of secretory acinar cells that produce the enzyme-rich component of pancreatic juice. Acinar cells are full of rough endoplasmic reticulum and exhibit deeply staining **zymogen granules** (zi′mo-jen; "fermenting"). These granules contain inactive digestive enzymes (proenzymes).
- **Ducts.** A system of ducts transports the secretions of the acinar cells. In addition, the epithelial cells of the smallest ducts secrete the water that makes up the bulk of the pancreatic juice and the bicarbonate that makes this secretion alkaline (about pH 8).



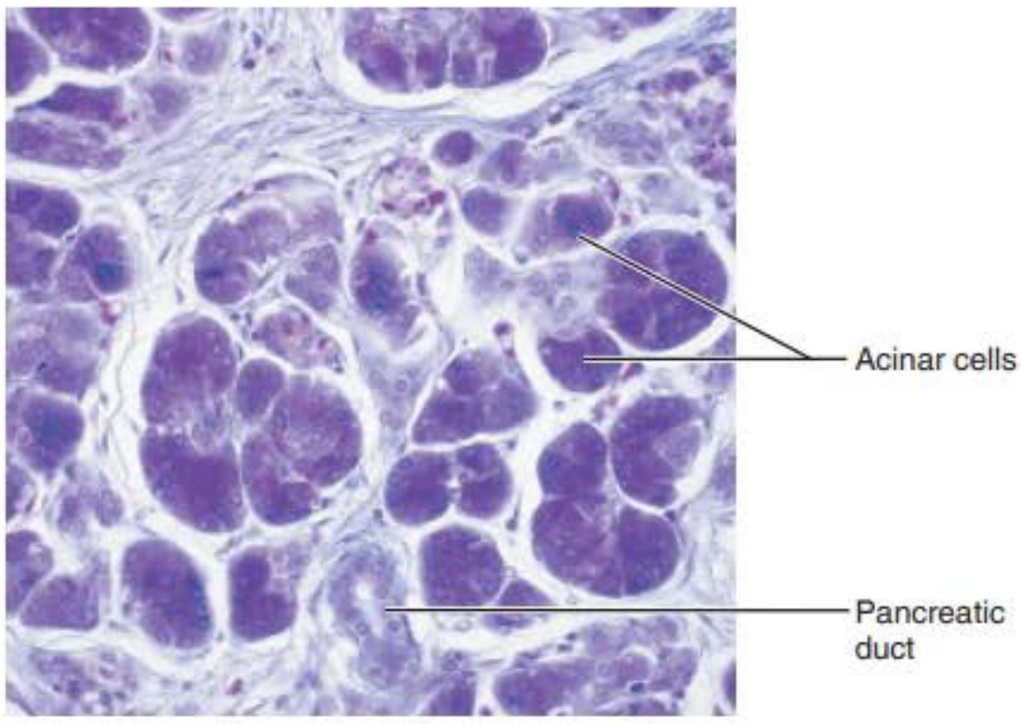


Figure 23.26 Structure of the enzyme-producing tissue of the pancreas. (a) Schematic view of one acinus (a secretory unit). The acinar cells contain abundant zymogen (enzyme-containing) granules and dark-staining rough ER (typical of gland cells producing large amounts of protein for export). **(b)** Photomicrograph of pancreatic acinar tissue (155×).

The endocrine part of the pancreas is a scattering of mini-endocrine glands called *pancreatic islets*. As we saw in Chapter 16, these islets release insulin and glucagon, hormones that play an important role in carbohydrate metabolism.

Composition of Pancreatic Juice

Approximately 1200 to 1500 ml of clear pancreatic juice is produced daily. It consists mainly of water, and contains enzymes and electrolytes (primarily bicarbonate ions). The high pH of pancreatic fluid helps neutralize acidic chyme entering the duodenum and provides the optimal environment for intestinal and pancreatic enzymes. The pancreatic enzymes include:

- **Proteases** (for proteins)
- **Amylase** (for starch)
- **Lipases** (for fats)
- **Nucleases** (for nucleic acids)

Like pepsin of the stomach, pancreatic proteases are produced and released in inactive forms that are activated in the duodenum, where they do their work. This protects the pancreas from digesting itself.

For example, within the duodenum, **enteropeptidase** (formerly called *enterokinase*), an enzyme bound to the plasma membrane of duodenal epithelial cells, activates *trypsinogen* to **trypsin**. Trypsin, in turn, activates more trypsinogen and two other pancreatic proteases (*procarboxypeptidase* and *chymotrypsinogen*) to their active forms, **carboxypeptidase** (kar-bok″se-pep′tĭ-dās) and **chymotrypsin** (ky″mo-trip′sin), respectively (**Figure 23.27**).

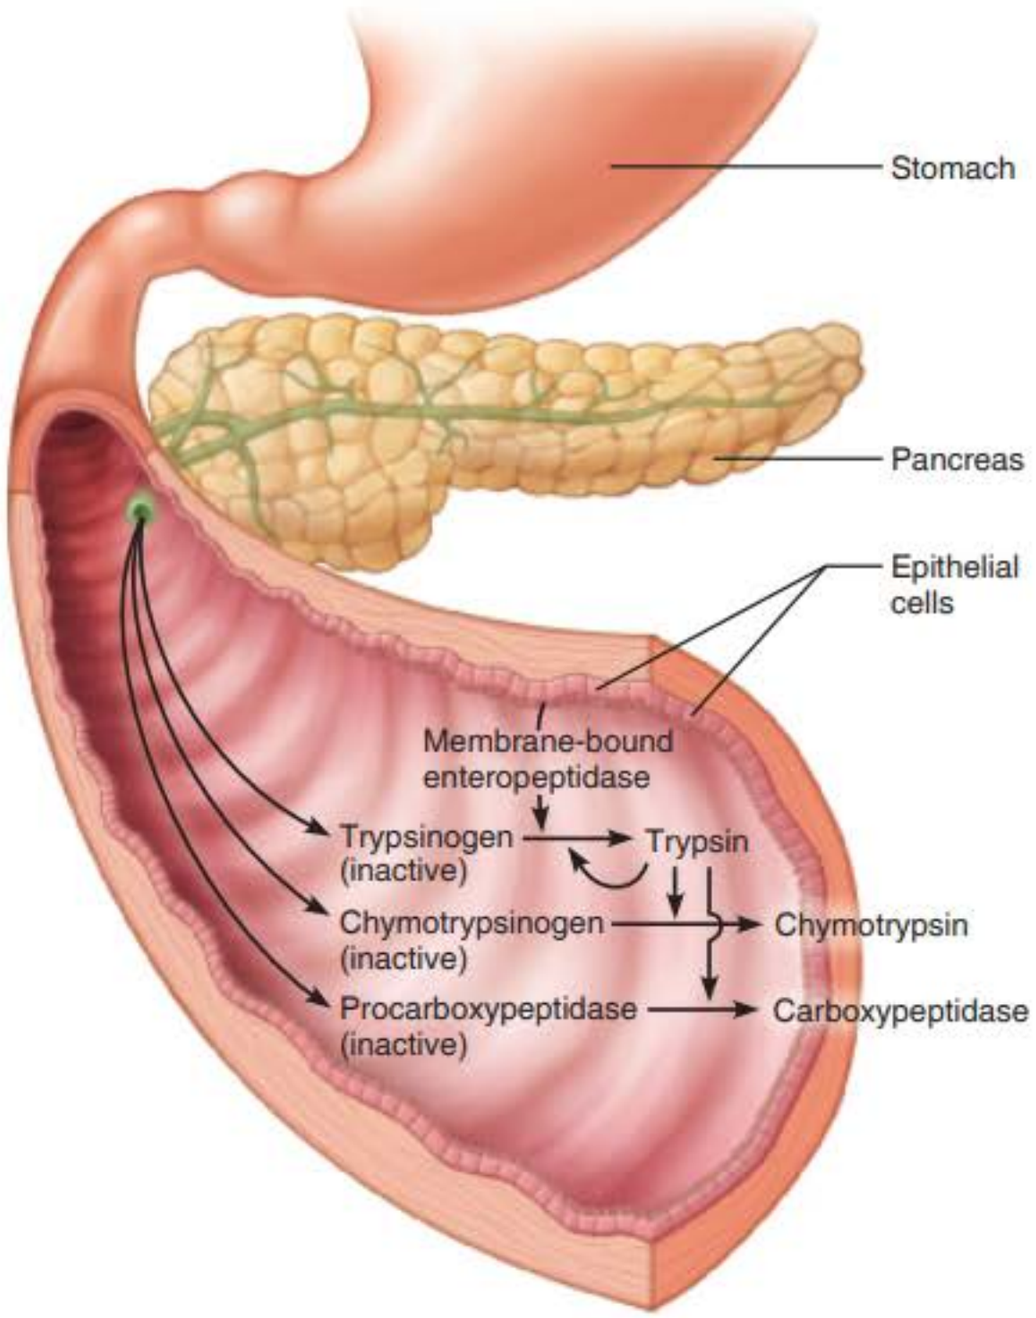

Figure 23.27 Activation of pancreatic proteases in the small intestine. Pancreatic proteases are secreted in an inactive form and are activated in the duodenum.

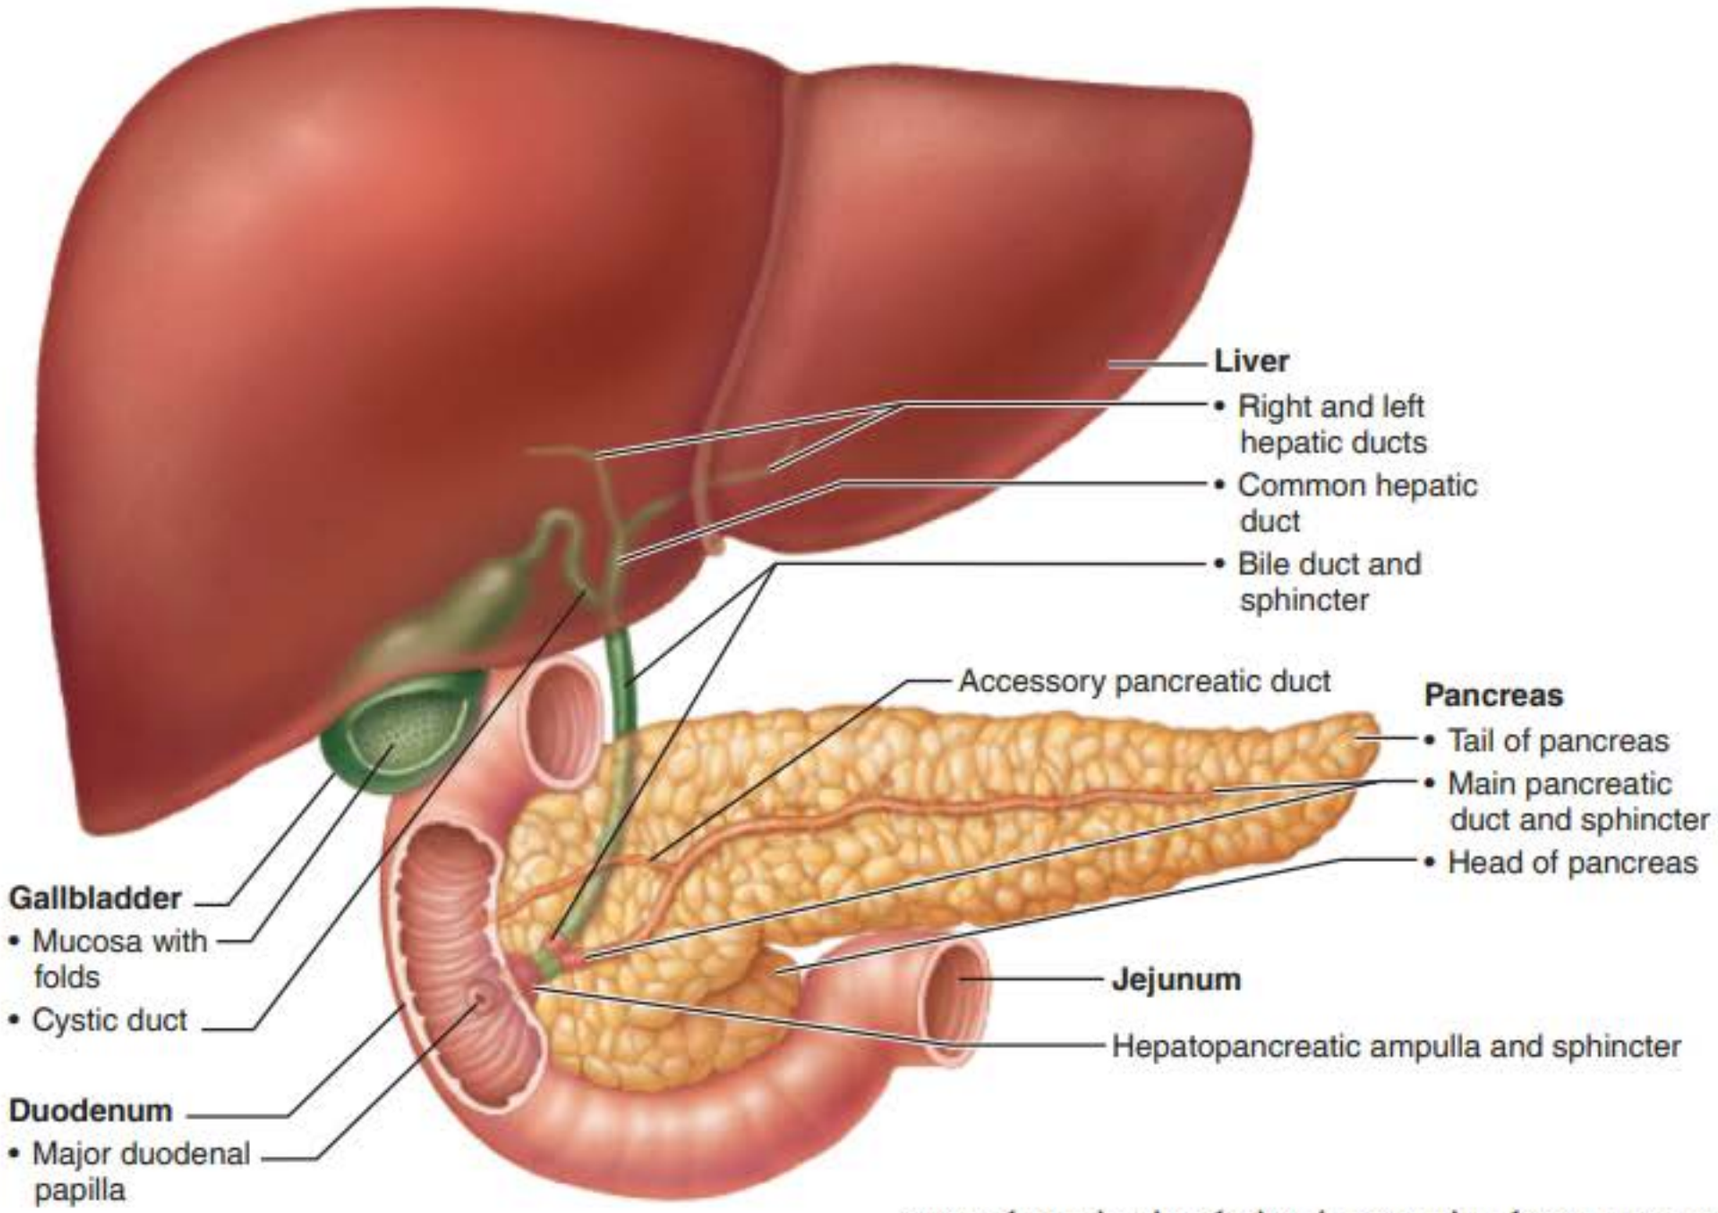

Figure 23.28 Relationship of the liver, gallbladder, and pancreas to the duodenum. Ducts from the pancreas, gallbladder, and liver empty into the duodenum.

Bile and Pancreatic Secretion into the Small Intestine

Anatomy of Duct Systems

The bile duct, delivering bile from the liver, and the **main pancreatic duct**, carrying pancreatic juice from the pancreas, unite in the wall of the duodenum, the first section of the small intestine (**Figure 23.28**). They fuse together at a bulblike structure called the **hepatopancreatic ampulla** (hep″ah-to-pan″kre-at′ik am-pul′ah; *ampulla* = flask). The ampulla opens into the duodenum via the volcano-shaped **major duodenal papilla**. A smooth muscle valve called the **hepatopancreatic sphincter** controls the entry of bile and pancreatic juice. A smaller *accessory pancreatic duct* empties directly into the duodenum just proximal to the main duct.

Regulation of Bile and Pancreatic Secretion

Hormones and neural stimuli regulate both the secretion of bile and pancreatic juice and their release into the small intestine. The hormones include two *enterogastrones* that you are already familiar with—*cholecystokinin* and *secretin* (◀ p. 891). **Figure 23.29** summarizes the hormonal and neural mechanisms that control the secretion and release of bile and pancreatic juice.

Bile salts themselves are the major stimulus for enhanced bile secretion (Figure 23.29). After a fatty meal, when the enterohepatic circulation is returning large amounts of bile salts to the liver, its output of bile rises dramatically. Secretin also stimulates liver cells to secrete bile.

When no digestion is occurring, the hepatopancreatic sphincter is closed and the released bile backs up the cystic duct into the gallbladder, where it is stored until needed. Although the liver makes bile continuously, bile does not usually enter the small intestine until the gallbladder contracts.

Check Your Understanding

25. What is the importance of the enterohepatic circulation?
26. What is the functional difference between pancreatic acini and islets?
27. What is the makeup of the fluid in the pancreatic duct? In the cystic duct? In the bile duct?
28. What stimulates CCK release and what are its effects on the digestive process?
29. DRAW Sketch a liver lobule. Add the central vein and portal triads. Label the three parts of a portal triad. Draw and label arrows to show the directions of blood and bile flow.

23.8 The small intestine is the major site for digestion and absorption

Learning Outcomes

- **Identify and describe structural modifications of the wall of the small intestine that enhance the digestive process.**
- **Differentiate between the roles of the various cell types of the intestinal mucosa.**
- **Describe the functions of intestinal hormones and paracrines.**

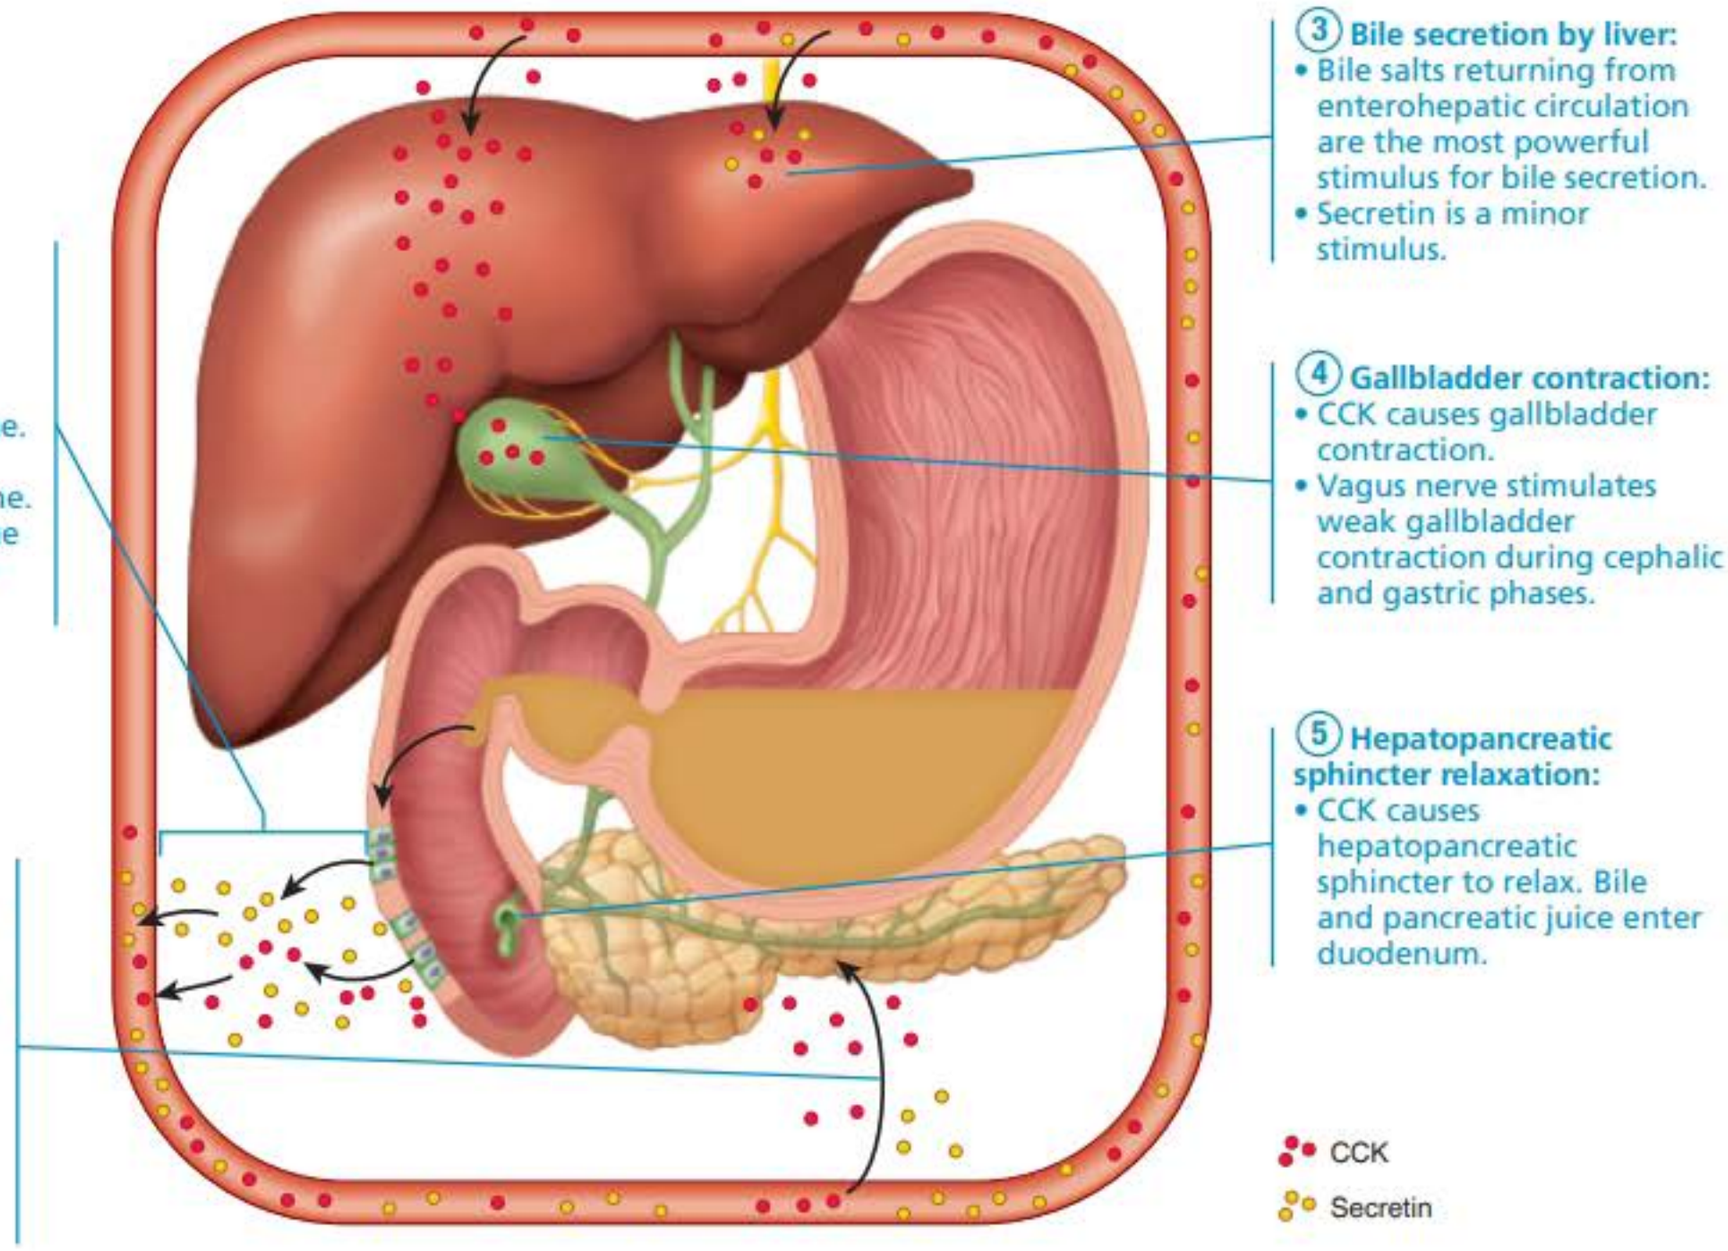

Figure 23.29 **Mechanisms promoting secretion and release of bile and pancreatic juice.**

The **small intestine** is the body's major digestive organ. Within its twisted passageway, digestion is completed (with the help of bile and pancreatic enzymes) and virtually all absorption occurs.

Gross Anatomy

The small intestine is a convoluted tube extending from the pyloric sphincter to the **ileocecal valve (sphincter)** (il″e-o-se′kal) where it joins the large intestine (**Figure 23.30**). It is the longest part of the alimentary canal, but is only about half the diameter of the large intestine, ranging from 2.5 to 4 cm (1–1.6 inches). Although 6–7 m long (approximately 20 ft) in a cadaver, the small intestine is only 2–4 m (7–13 ft) long during life because of muscle tone.

The small intestine has three subdivisions: the duodenum, which is mostly retroperitoneal, and the jejunum and ileum, both intraperitoneal organs (Figure 23.30). The relatively immovable **duodenum** (du″o-de′num; "twelve finger widths long"), which curves around the head of the pancreas, is about 25 cm (10 inches) long (Figure 23.28). Although it is the shortest intestinal subdivision, the duodenum has the most features of interest, including the *major duodenal papilla* mentioned earlier.

The **jejunum** (jĕ -joo′num; "empty"), about 2.5 m (8 ft) long, extends from the duodenum to the ileum. The **ileum** (il′e-um; "twisted"), approximately 3.6 m (12 ft) in length, joins the large intestine at the ileocecal valve. The jejunum and ileum hang in sausagelike coils in the central and lower part of the abdominal cavity, suspended from the posterior abdominal wall by a fan-shaped *mesentery* (see Figure 23.34). The large intestine encircles these more distal parts of the small intestine.

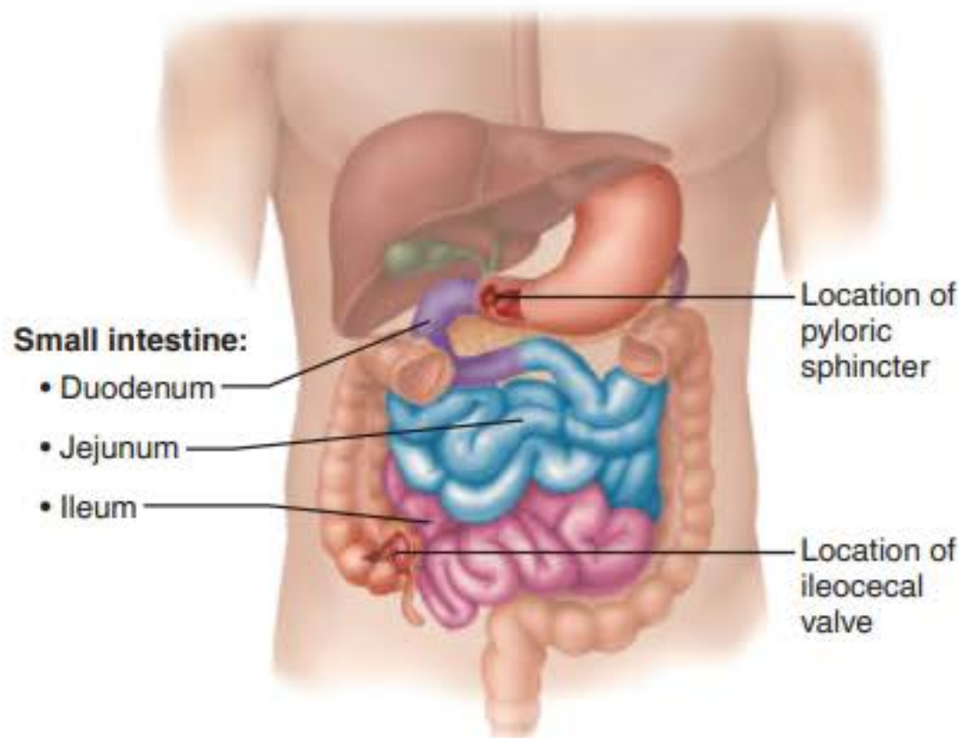

Figure 23.30 **The small intestine.**

Enlargement shows absorptive enterocytes that exhibit microvilli on their free (apical) surface. **(c)** Photomicrograph of the mucosa, showing villi (250×).

The arterial supply of the small intestine is primarily from the superior mesenteric artery (◀ pp. 746–747). The veins parallel the arteries and typically drain into the superior mesenteric vein. From there, the nutrient-rich venous blood from the small intestine drains into the hepatic portal vein, which carries it to the liver.

Nerve fibers serving the small intestine include parasympathetics from the vagus and sympathetics from the thoracic splanchnic nerves, both relayed through the superior mesenteric (and celiac) plexus.

Microscopic Anatomy

Modifications of the Small Intestine for Absorption

The small intestine is highly adapted for absorbing nutrients. Its length alone provides a huge surface area, and its wall has three structural modifications—circular folds, villi, and microvilli—that amplify its absorptive surface enormously (by a factor of more than 600 times). In fact, the intestinal surface area is about equal to 200 square meters, the size of a singles tennis court!

- The **circular folds** are deep, permanent folds of the mucosa and submucosa (**Figure 23.31a**). Nearly 1 cm tall, these folds force chyme to spiral through the lumen, slowing its movement and allowing time for full nutrient absorption.
- **Villi** (vil′i; "tufts of hair") are fingerlike projections of the mucosa, over 1 mm high, that give it a velvety texture, much

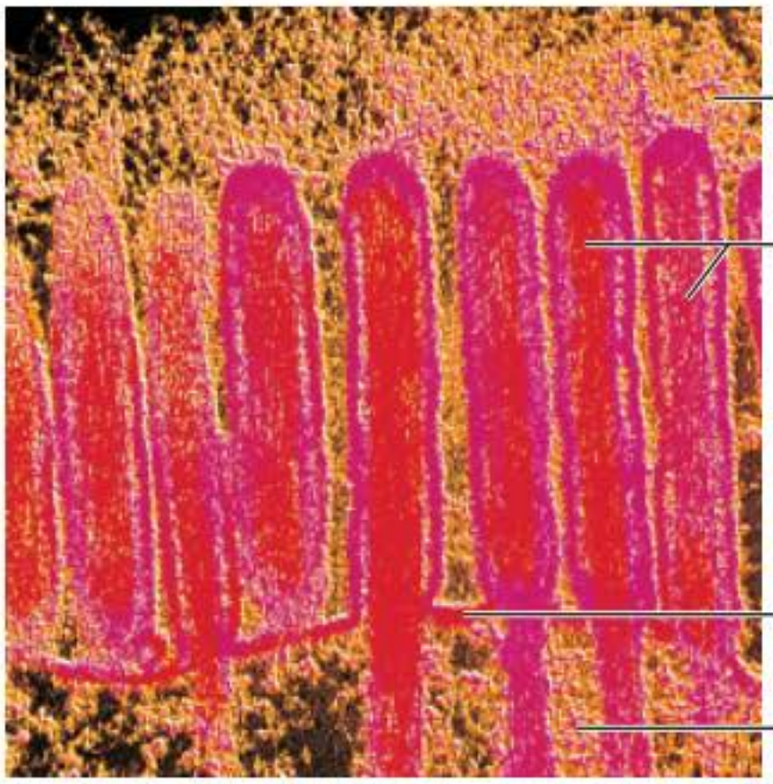

Figure 23.32 Microvilli of the small intestine. Colored electron micrograph. Microvilli (28,000×) appear as red projections from the surface of the absorptive cell.

like the soft nap of a towel (Figure 23.31). The villi are large and leaflike in the duodenum (the intestinal site of most active absorption) and gradually narrow and shorten along the length of the small intestine. In the core of each villus is a dense capillary bed and a wide lymphatic capillary called a **lacteal** (◀ p. 769). Digested foodstuffs are absorbed through the enterocytes into both the capillary blood and the lacteal.

- **Microvilli** are long, densely packed cytoplasmic extensions of the absorptive cells of the mucosa that give the mucosal surface a fuzzy appearance called the **brush border** (Figure 23.31b enlargement and **Figure 23.32**). The plasma membranes of the microvilli bear enzymes referred to as **brush border enzymes**, which complete the digestion of carbohydrates and proteins in the small intestine.

Histology of the Small Intestine Wall

The four layers typical of the GI tract are also seen in the small intestine, but the mucosa and submucosa are modified to reflect the intestine's functions in the digestive pathway.

Between the villi, which are specialized for absorption, the small intestine mucosa is studded with tubular glands called **intestinal crypts** (see Figure 23.31b, c). The crypts decrease in number along the length of the small intestine.

Five major types of cells are found in the mucosal epithelium of the villi and crypts:

- *Enterocytes* form the bulk of the epithelium. They are simple columnar absorptive cells bound by tight junctions and richly endowed with microvilli. These cells bear the primary responsibility for absorbing nutrients and electrolytes in the villi. In the crypts, enterocytes are primarily secretory cells that secrete *intestinal juice*, a watery mixture that contains mucus and serves as a carrier fluid for absorbing nutrients from chyme.
- *Goblet cells* are mucus-secreting cells found in the epithelia of the villi and crypts.
- *Enteroendocrine cells* are the source of the enterogastrones discussed earlier (p. 891)—secretin and cholecystokinin to name two. They are mostly found scattered in the crypts but some are also found in the villi.
- *Paneth cells*, found deep in the crypts, are specialized secretory cells that fortify the small intestine's defenses by releasing antimicrobial agents such as defensins and lysozyme. These secretions destroy certain bacteria and help to determine which bacteria colonize the intestinal lumen.
- *Stem cells* continuously divide in the depths of the crypts. Their daughter cells differentiate to become all of the other cell types. Most of these daughter cells (except Paneth cells) differentiate as they gradually migrate up the villi. Paneth cells, on the other hand, migrate to the very bottom of the crypts. Enterocytes at the tips of the villi undergo apoptosis and are shed, renewing the villus epithelium every three to five days.

HOMEOSTATIC IMBALANCE 23.10 CLINICAL

Treatments for cancer, such as radiation therapy and chemotherapy, preferentially target rapidly dividing cells. They kill cancer cells, but also nearly obliterate the rapidly dividing GI tract epithelium. Many patients suffer nausea, vomiting, and diarrhea after each treatment.

Mucosa-associated lymphoid tissue (MALT) includes both individual lymphoid follicles and *aggregated lymphoid nodules*, the latter called **Peyer's patches** (pi′erz; ◀ p. 775). Peyer's patches are primarily located in the lamina propria but occasionally protrude into the submucosa below. Their increasing abundance toward the distal end of the small intestine reflects the fact that this region contains huge numbers of bacteria that must be prevented from entering the bloodstream. The lamina propria of the mucosa contains large numbers of immunoglobulin A (IgA)-secreting plasma cells that help protect against intestinal pathogens (◀ p. 799).

The submucosa is typical areolar connective tissue. Elaborate mucus-secreting **duodenal glands** in the submucosa of the duodenum produce an alkaline (bicarbonate-rich) mucus that helps neutralize acidic chyme moving in from the stomach. When this protective mucus barrier is inadequate, the intestinal wall erodes and *duodenal ulcers* result.

The muscularis is typical and bilayered. Except for the bulk of the duodenum, which is retroperitoneal and has an adventitia, visceral peritoneum (serosa) covers the external intestinal surface.

Intestinal Juice

The intestinal glands normally secrete 1 to 2 L of intestinal juice daily. The major stimulus for its production comes from hypertonic or acidic chyme. Normally, intestinal juice is slightly alkaline (7.4–7.8) and isotonic with blood plasma.

Table 23.2 Overview of the Functions of the Gastrointestinal Organs

ORGAN	MAJOR FUNCTIONS*	COMMENTS/ADDITIONAL FUNCTIONS
Mouth and associated accessory organs	■ Ingestion: food is voluntarily placed into oral cavity ■ Propulsion: voluntary (buccal) phase of deglutition (swallowing) initiated by tongue; propels food into pharynx ■ Mechanical breakdown: mastication (chewing) by teeth and mixing movements by tongue ■ Digestion: salivary amylase in saliva, produced by salivary glands, begins digestion of starch	• Mouth serves as a receptacle; most functions performed by associated accessory organs. • Mucus in saliva helps dissolve food so it can be tasted and moistens food so that tongue can compact it into a bolus that can be swallowed. Saliva cleanses and lubricates oral cavity and teeth.
Pharynx and esophagus	■ Propulsion: peristaltic waves move food bolus to stomach, thus accomplishing the pharyngeal-esophageal (involuntary) phase of deglutition	• Primarily food chutes. • Mucus produced helps to lubricate food passageways.
Stomach	■ Mechanical breakdown and ■ propulsion: peristaltic waves mix food with gastric juice and propel it into the duodenum ■ Digestion: pepsin begins the digestion of proteins ■ Absorption: absorbs a few fat-soluble substances (aspirin, alcohol, some drugs)	• Also stores food until it can be moved into the duodenum. • Hydrochloric acid produced is a bacteriostatic agent and activates protein-digesting enzymes. • Mucus produced helps lubricate and protect stomach from self-digestion. • Intrinsic factor produced is required for intestinal absorption of vitamin B_{12}.
Small intestine and associated accessory organs (liver, gallbladder, pancreas)	■ Mechanical breakdown and ■ propulsion: segmentation by smooth muscle of the small intestine continually mixes contents with digestive juices and, along with short-distance peristaltic waves, moves food along tract, allowing sufficient time for digestion and absorption ■ Digestion: digestive enzymes delivered from pancreas and brush border enzymes attached to microvilli membranes complete digestion of all classes of foods ■ Absorption: breakdown products of carbohydrate, protein, fat, and nucleic acid digestion, plus vitamins, electrolytes, and water, are absorbed by active and passive mechanisms	• Small intestine is highly modified for digestion and absorption (circular folds, villi, and microvilli). • Alkaline mucus produced by intestinal glands and bicarbonate-rich juice ducted in from pancreas help neutralize acidic chyme and provide proper environment for enzymatic activity. • Bile produced by liver emulsifies fats and enhances (1) fat digestion and (2) absorption of fatty acids, monoglycerides, cholesterol, phospholipids, and fat-soluble vitamins. • Gallbladder stores and concentrates bile, releasing it to small intestine in response to hormonal signals.
Large intestine	■ Digestion: some remaining food residues are digested by gut bacteria (which also produce some vitamin K and some B vitamins) ■ Absorption: absorbs most remaining water, electrolytes (largely NaCl), and vitamins produced by bacteria ■ Propulsion: propels feces toward rectum by mass movements ■ Defecation: reflex triggered by rectal distension; eliminates feces from body	• Temporarily stores and concentrates residues until defecation can occur. • Copious mucus produced by goblet cells eases passage of feces through colon.

*The colored boxes beside the functions correspond to the color coding of digestive functions (gastrointestinal tract activities) illustrated in Figure 23.2.

Intestinal juice is largely water but also contains some mucus, which is secreted both by the duodenal glands and by goblet cells of the mucosa.

Digestive Processes in the Small Intestine

By the time food reaches the small intestine it is unrecognizable, but still far from being digested. Carbohydrates and proteins are partially degraded, but fat digestion has only begun. The process of digestion accelerates during the chyme's tortuous three- to six-hour journey through the small intestine, and it is here that most of the water and virtually all nutrients are absorbed.

Since we cover the actual chemistry of digestion and absorption in detail later, here we will examine the source of enzymes for digestion and how intestinal motility mixes and moves chyme along the length of the small intestine.

Sources of Enzymes for Digestion

Most of the substances required for digestion—bile, digestive enzymes (except for the brush border enzymes), and bicarbonate ions (to provide the proper pH for enzymatic catalysis)—are *imported* from the liver and pancreas. For this reason, anything that impairs liver or pancreatic function or delivery of their juices to the small intestine severely hinders our ability to digest food and absorb nutrients.

Brush border enzymes perform the final digestion of food into the simple components that can be absorbed by intestinal cells. Note that the brush border enzymes are *not* secreted. Instead, they remain bound to the plasma membranes of the enterocytes.

Regulating Chyme Entry

Chyme entering the duodenum is usually hypertonic. For this reason, if large amounts of chyme rushed into the small intestine, the osmotic water loss from the blood into the intestinal lumen would result in dangerously low blood volume. Additionally, the low pH of entering chyme must be adjusted upward and the chyme must be well mixed with bile and pancreatic juice for digestion to continue. These modifications take time. Feedback via the enterogastric reflex and enterogastrones to the stomach pylorus carefully controls food movement into the small intestine to prevent the duodenum from being overwhelmed (see Figure 23.22).

Notice that the feedback mechanisms regulating chyme entry (the enterogastric reflex and enterogastrones) are the same as those that decrease gastric secretion (Figure 23.19).

Motility of the Small Intestine

There are two motility patterns in the small intestine. After a meal, *segmentation* is the principal form of motility. This motor pattern ensures that chyme is thoroughly mixed with bile and pancreatic and intestinal juices. It also ensures that the absorbable products of digestion come in contact with the mucosa for absorption. Between meals, the primary motor pattern is a form of peristalsis called the *migrating motor complex*. This peristalsis is largely a housekeeping function that sweeps debris toward the large intestine.

After a Meal If we examine the small intestine with X-ray fluoroscopy after it is "loaded" with a meal, it looks like the intestinal contents are being massaged—alternately contracting and relaxing rings of smooth muscle simply move the chyme backward and forward a few centimeters at a time (see Figure 23.3b). As with stomach peristalsis, intrinsic pacemaker cells (in the myenteric plexus) initiate these segmenting movements. The intensity of segmentation is altered by long and short reflexes, which parasympathetic activity enhances and sympathetic activity decreases, and by hormones (**Table 23.3**). The more intense the contractions, the greater the mixing.

We usually think of segmentation as purely a mixing movement. How, then, does chyme move along the small intestine? First, some very weak, short-distance peristalsis does occur even in the full small intestine. Second, the pacemakers in the duodenum depolarize more frequently than those in the ileum. As a result, segmentation also moves intestinal contents slowly and steadily toward the ileocecal valve at a rate that allows ample time to complete digestion and absorption. Unlike the strength of contraction, the basic contractile rhythm of each intestinal region is not affected by reflexes or hormones.

Between Meals True peristalsis occurs only after most nutrients have been absorbed. At this point, segmenting movements

Table 23.3 Control of Small Intestinal Motility

STIMULUS	EFFECT ON SMALL INTESTINE MOTILITY	MECHANISM
↑ Gastric motility and emptying	• ↑ Motility in ileum • Relaxation of ileocecal valve	Gastroileal reflex (long neural reflex) and gastrin release (both cause same effects)
Distension of small intestine	↑ Strength of segmentation	Long and short neural reflexes
Reduced intestinal volume; fasting	Initiates migrating motor complex (peristalsis); repeats until next meal	Motilin (initiates long and short neural reflexes)

wane and the duodenal mucosa begins to release the hormone **motilin**.

As motilin blood levels rise, peristaltic waves are initiated in the proximal duodenum every 90 to 120 minutes and sweep slowly along the intestine, moving 50–70 cm (about 2 ft) before dying out. Each successive wave begins a bit more distally, a pattern of peristaltic activity called the **migrating motor complex (MMC)**. A complete "trip" from duodenum to ileum takes about two hours. The process then repeats itself, sweeping the last remnants of the meal plus bacteria, sloughed-off mucosal cells, and other debris into the large intestine.

This "housekeeping" function prevents bacteria in the large intestine from entering the small intestine. As food again enters the stomach with the next meal, segmentation replaces peristalsis.

Ileocecal Valve Control Most of the time, the ileocecal valve is closed. However, two mechanisms cause it to relax and allow food residues to enter the cecum when ileal motility increases:

- The **gastroileal reflex** (gas″tro-il′e-ul), a long neural reflex triggered by stomach activity, increases the force of segmentation in the ileum and relaxes the ileocecal valve.
- Gastrin, a hormone released by the stomach, increases the motility of the ileum and relaxes the ileocecal valve.

Once the chyme has passed through, it exerts backward pressure that closes the valve's flaps, preventing regurgitation into the ileum. This reflex sweeps the contents of the previous meal completely out of the stomach and small intestine as the next meal is eaten.

Check Your Understanding

30. What common advantage do circular folds, villi, and microvilli provide to the digestive process?
31. What are brush border enzymes?
32. Distension of the stomach and duodenal walls have different effects on stomach secretory activity. What are these effects?
33. After a meal, what is the small intestine's most common motility pattern? Why?
34. What is the MMC and why is it important?

For answers, see Answers Appendix.

23.9 The large intestine absorbs water and eliminates feces

Learning Outcomes

- **List the major functions of the large intestine.**
- **Describe the regulation of defecation.**

The **large intestine** frames the small intestine on three sides and extends from the ileocecal valve to the anus (see Figure 23.1). Its diameter, at about 7 cm, is greater than that of the small intestine, but it is much shorter (1.5 m versus 6 m). Its major digestive functions are to absorb most of the remaining water from indigestible food residues, store the residues temporarily, and then eliminate them from the body as semisolid **feces** (fe′sēz), also called *stool*. It also absorbs metabolites produced by resident bacteria as they ferment carbohydrates not absorbed in the small intestine.

Gross Anatomy

The large intestine exhibits three features not seen elsewhere—teniae coli, haustra, and epiploic appendages. Except for its terminal end, the longitudinal muscle layer of its muscularis is mostly reduced to three bands of smooth muscle called **teniae coli** (ten′ne-e ko′li; "ribbons of the colon"). Their tone puckers the wall of the large intestine into pocketlike sacs called **haustra** (haw′strah; singular: *haustrum*; "to draw up"). Another obvious feature of the large intestine is its **epiploic appendages** (ep″ĭ-plo′ik; "membrane covered"), which are small fat-filled pouches of visceral peritoneum that hang from the surface of the large intestine (**Figure 23.33a**). Their significance is not known.

Subdivisions of the Large Intestine

The large intestine has the following subdivisions: cecum, appendix, colon, rectum, and anal canal. The saclike **cecum** (se′kum; "blind pouch"), which lies below the ileocecal valve in the right iliac fossa, is the first part of the large intestine (Figure 23.33a).

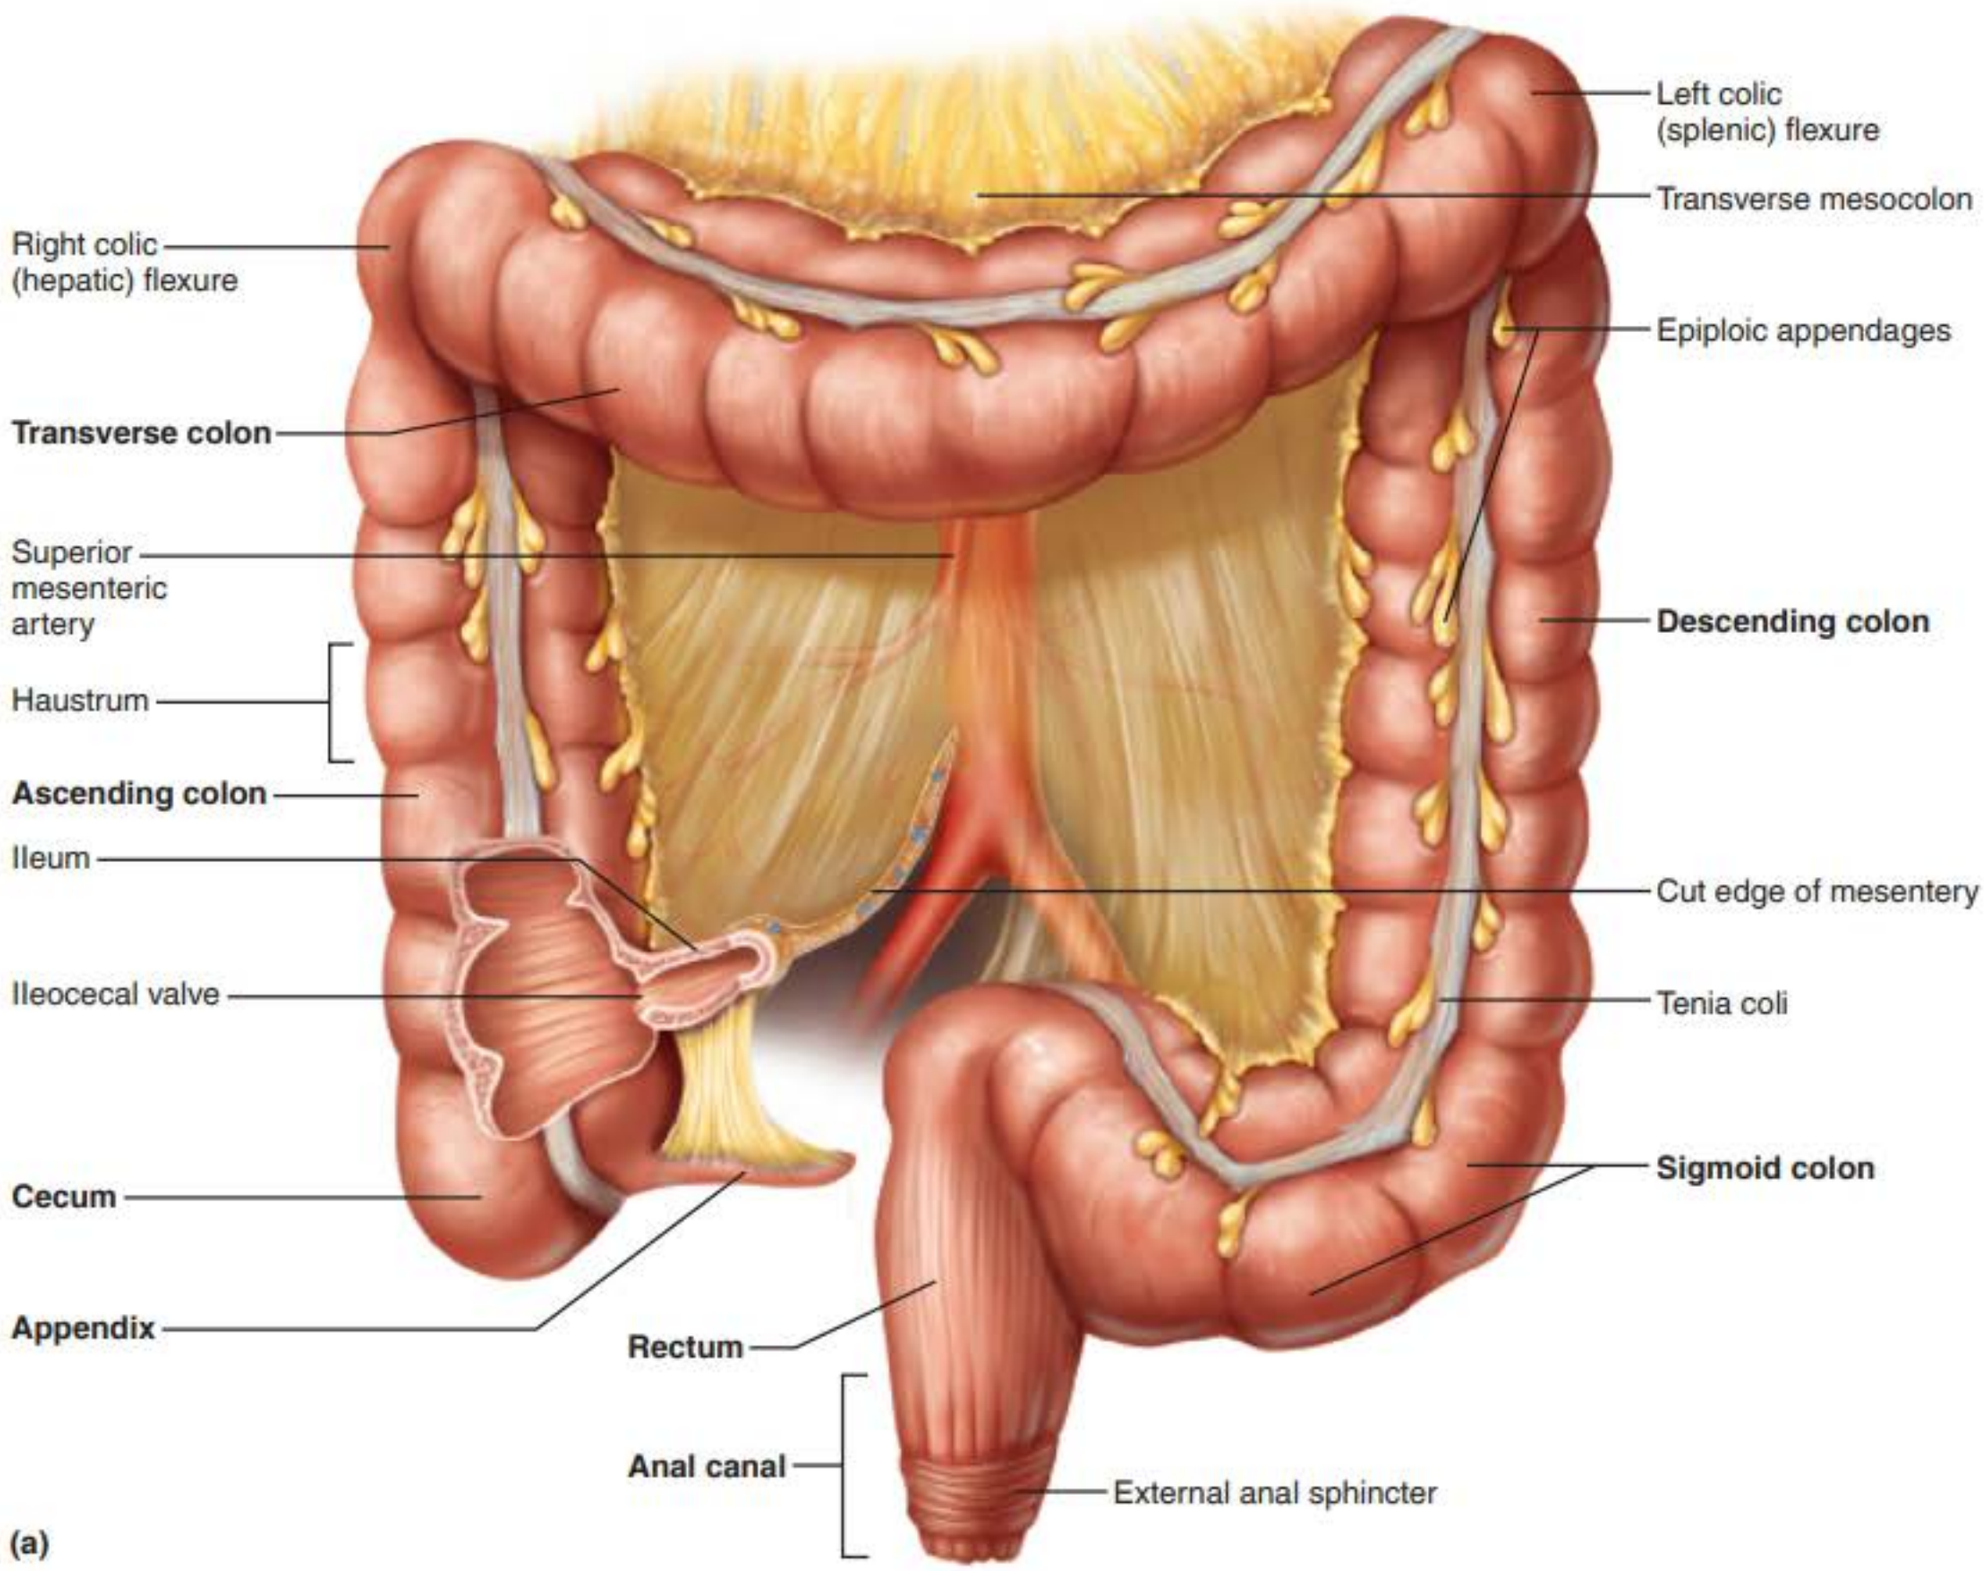
Attached to the posteromedial surface of the cecum is the blind, wormlike **appendix**. The appendix contains masses of lymphoid tissue, and as part of MALT (◀ p. 774) it plays an important role in body immunity. Additionally, it serves as a storehouse of bacteria and recolonizes the gut when needed. However, the appendix has an important structural shortcoming—its twisted structure makes it susceptible to blockage.

HOMEOSTATIC IMBALANCE 23.11 CLINICAL

Acute inflammation of the appendix, or **appendicitis**, results from a blockage (often by feces) that traps infectious bacteria in its lumen. Unable to empty its contents, the appendix swells, squeezing off venous drainage, which may lead to ischemia and necrosis (low blood flow and tissue death) of the appendix. If the appendix ruptures, feces containing bacteria spray over the abdominal contents, causing *peritonitis*.

The symptoms of appendicitis vary, but the first symptom is usually pain in the umbilical region. Loss of appetite, nausea and vomiting, and pain relocalization to the lower right abdominal quadrant follow. Appendicitis is treated with surgical removal of the appendix (appendectomy), or, in select cases, with antibiotics. Appendicitis is most common during adolescence, when the entrance to the appendix is at its widest.

The **colon** has several distinct regions. Proximally, as the **ascending colon**, it travels up the right side of the abdominal cavity to the level of the right kidney. Here it makes a right-angle turn—the **right colic (hepatic) flexure**—and travels across the abdominal cavity as the **transverse colon**. Directly anterior to the spleen, it bends acutely at the **left colic (splenic) flexure** and descends down the left side of the posterior abdominal wall as



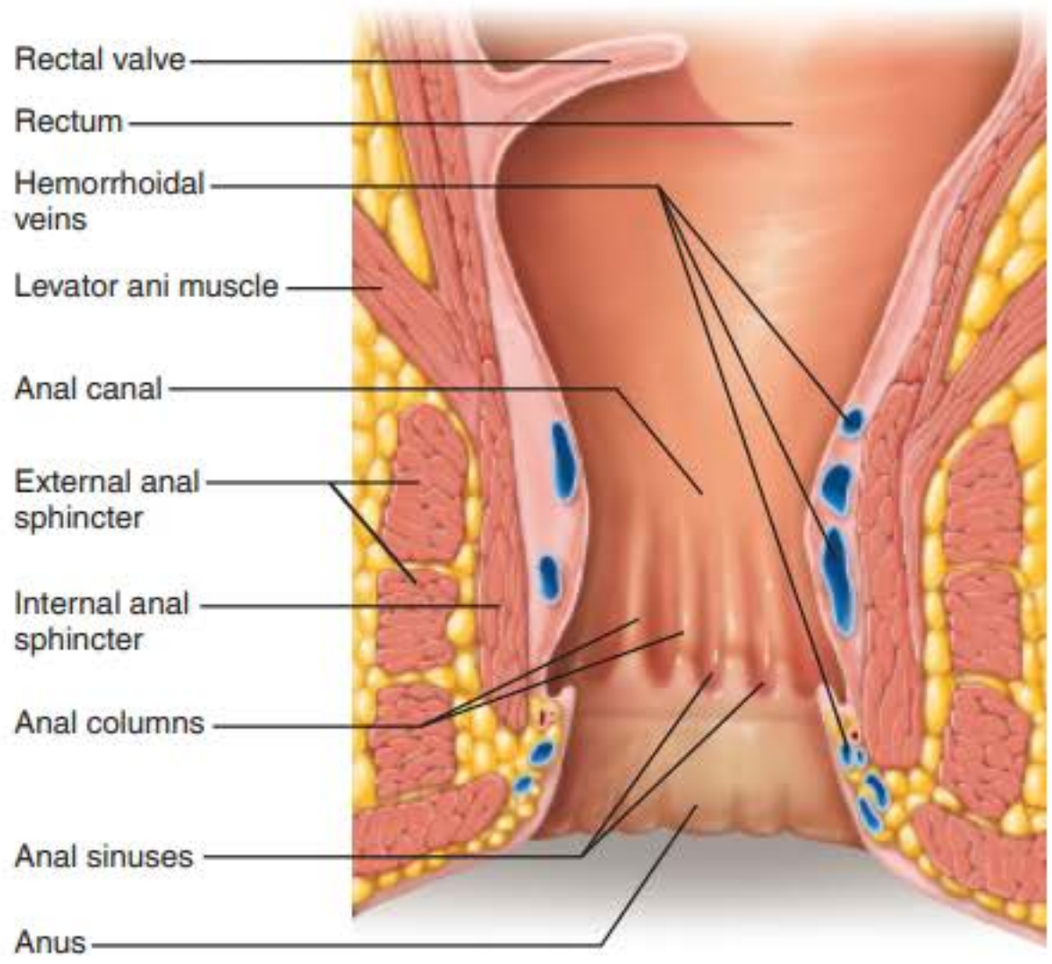


Figure 23.33 Gross anatomy of the large intestine. **(a)** Large intestine. **(b)** Structure of the anal canal.

the **descending colon**. Inferiorly, it enters the pelvis, where it becomes the S-shaped **sigmoid colon**.

In the pelvis, at the level of the third sacral vertebra, the sigmoid colon joins the **rectum**, which runs posteroinferiorly just in front of the sacrum.

Despite its name (*rectum* = straight), the rectum has three lateral curves or bends, represented internally as three transverse folds called **rectal valves** (Figure 23.33b). These valves stop feces from being passed along with gas (flatus).

The **anal canal**, the last segment of the large intestine, lies in the perineum, entirely external to the abdominopelvic cavity. About 3 cm long, it begins where the rectum penetrates the levator ani muscle of the pelvic floor and opens to the body exterior at the **anus**. The anal canal has two sphincters, an involuntary **internal anal sphincter** composed of smooth muscle (part of the muscularis), and a voluntary **external anal sphincter** composed of skeletal muscle. The sphincters, which act rather like purse strings to

Mesentery labels appear in colored boxes.

open and close the anus, are ordinarily closed except during defecation.

The rectum and anal canal lack teniae coli and haustra. However, the rectum's muscularis muscle layers are complete and well developed, consistent with its role in generating strong contractions to expel feces.

Relationship of the Large Intestine to the Peritoneum

The colon is retroperitoneal, except for its transverse and sigmoid parts. These parts are intraperitoneal and anchored to the posterior abdominal wall by mesentery sheets called **mesocolons** (**Figure 23.34c, d**). The rectum (and sometimes the cecum) is also retroperitoneal.

Microscopic Anatomy

The wall of the large intestine differs in several ways from that of the small intestine:

- There are no circular folds, villi, or brush border because most food is absorbed before reaching the large intestine.
- Its mucosa is thicker, its abundant crypts are deeper, and the crypts contain tremendous numbers of goblet cells. Mucus produced by goblet cells eases the passage of feces and protects the intestinal wall from irritation by acids and gases released by resident bacteria.

Like the small intestine, the large intestine *mucosa* is simple columnar epithelium except in the anal canal.

The mucosa of the anal canal, a stratified squamous epithelium, merges with the true skin surrounding the anus and is quite different from the mucosa in the rest of the colon, reflecting the greater abrasion that this region receives. Superiorly, it hangs in long ridges or folds called **anal columns**. **Anal sinuses**, recesses between the anal columns, exude mucus when compressed by feces, which aids in emptying the anal canal (Figure 23.33b).

Together, the inferior margins of the anal sinuses form a wavy line. Superior to this line, visceral sensory fibers innervate the mucosa, and so it is relatively insensitive to pain. The area inferior to the line, however, is very sensitive to pain because it is innervated by somatic sensory fibers.

Two superficial venous plexuses are associated with the anal canal, one with the anal columns and the other with the anus itself. If these (hemorrhoidal) veins become dilated and inflamed, itchy varicosities called *hemorrhoids* result.

Bacterial Microbiota

The **bacterial microbiota** (also called the **bacterial flora**) of the large intestine consists of over a thousand different types of bacteria and accounts for a couple of pounds of our body weight. Some of these bacteria colonize the colon via the anus, but others enter from the small intestine still "alive and kicking" after running the gauntlet of antimicrobial defenses (lysozyme, defensins, HCl, and protein-digesting enzymes). We provide a home for these bacteria, but what's in it for us? We are just beginning to understand that we depend upon these bacteria just as much as they depend upon us.

Metabolic Functions

Our gut bacteria help us by recovering energy from otherwise indigestible foods and synthesizing some vitamins.

- **Fermentation.** Gut bacteria ferment some indigestible carbohydrates and the mucin in gut mucus. The resulting short-chain fatty acids can be absorbed and used for fuel by the body's cells. Unfortunately, fermentation also produces a mixture of gases (including dimethyl sulfide, H_2, N_2, CH_4, and CO_2). Some of these gases, such as dimethyl sulfide, are quite odorous (smelly). About 500 ml of gas (flatus) is produced each day, much more when we eat foods (such as beans) rich in indigestible carbohydrates.
- **Vitamin synthesis.** B complex vitamins and some of the vitamin K the liver needs in order to produce several clotting proteins are synthesized by gut bacteria.

Keeping Pathogenic Bacteria in Check

The immune system and the gut bacteria live in a dynamic equilibrium. The immune system destroys any bacteria that threaten to breach the mucosal barrier. The gut bacteria, on the other hand, instruct the immune system not to overreact to their presence in the lumen.

Potentially harmful bacteria in our large intestine are kept in check in two ways. First, beneficial bacteria outcompete and actively suppress harmful bacteria, and as a result normally vastly outnumber them. Second, our immune system prevents bacteria from entering the body through the gut epithelium. An elegant system keeps the bacteria from breaching the mucosal barrier. Dendritic cells sample the microbial antigens in the lumen. They then migrate to the nearby lymphoid follicles within the gut mucosa (MALT) and trigger an IgA antibody–mediated response restricted to the gut lumen. This prevents the bacteria from straying into tissues deep to the mucosa where they might elicit a much more widespread systemic response.

HOMEOSTATIC IMBALANCE 23.12 **CLINICAL**

Clostridium difficile, an anaerobic bacterium, is the most common cause of *antibiotic-associated diarrhea*, accounting for 14,000 deaths per year in the U.S. Where does it come from? For some people, *C. difficile* is a normal, but small, fraction of the gut's bacteria. Other people acquire *C. difficile* through the fecal-oral route (poor hand washing), particularly in hospital or long-term care settings. In either case, when other bacteria are wiped out by antibiotics, *C. difficile* flourishes in the gut and may cause pseudomembranous colitis (inflammation of the colon) that leads to bowel perforation and sepsis.

Because *C. difficile* infections are resistant to many antibiotics, they are notoriously difficult to treat and often recur. Instead of using ever more powerful antibiotics, a new treatment strategy seeks to restore competitive bacteria to the gut's ecosystem by perfoming a *fecal transplant*. Transferring fecal bacteria from an uninfected donor to the patient (e.g., by enema or during colonoscopy) cures *C. difficile* infections 90–100% of the time. In spite of the considerable "yuck factor," this treatment

is becoming more and more mainstream. It is likely that optimized mixtures of cultured bacteria will become available for transplantation to treat *C. difficile* in the future.

While the immune system keeps the gut bacteria in check, the gut bacteria also profoundly shape our immune system responses. For example, the type of bacteria present influences the balance between subtypes of T cells, which in turn affects the balance between pro- and anti-inflammatory responses.

The coexistence of the bacterial microbiota with our immune system does sometimes fail. When that happens, the painful and debilitating condition known as inflammatory bowel disease (see Related Clinical Terms, p. 921) may result.

Gut Bacteria in Health and Disease

We are only just beginning to learn how gut bacteria affect the body. There is mounting evidence that the kinds and proportions of the bacteria in our gut can influence our body weight, our susceptibility to various diseases (including diabetes, atherosclerosis, fatty liver disease), and even our mood. Manipulating our various gut bacteria may become a routine health-care strategy in the near future.

Digestive Processes in the Large Intestine

What is finally delivered to the large intestine contains few nutrients, but it still has 12 to 24 hours more to spend there. Except for a small amount of digestion of that residue by the gut bacteria, no further food breakdown occurs in the large intestine.

The large intestine harvests vitamins made by the gut bacteria and reclaims most of the remaining water and some of the electrolytes (particularly sodium and chloride). However, nutrient absorption is not its *major* function. As mentioned, the primary concerns of the large intestine are propulsive activities that force fecal material toward the anus and eliminate it from the body (defecation).

HOMEOSTATIC IMBALANCE 23.13 CLINICAL

The large intestine is important for our comfort, but it is not essential for life. If the colon is removed, the terminal ileum can be brought out to the abdominal wall in a procedure called an *ileostomy* (il″e-os′to-me). From there food residues are eliminated into a sac attached to the abdominal wall.

Motility of the Large Intestine

When food residue enters the colon through the ileocecal valve, the colon becomes motile, but its contractions are sluggish or short-lived compared to those of the small intestine. The movements most seen in the colon are **haustral contractions**, slow segmenting movements that last about one minute and occur every 30 minutes or so.

These contractions, which occur mainly in the ascending and transverse colon, reflect local controls of smooth muscle within the walls of the individual haustra. As a haustrum fills with food residue, the distension stimulates its muscle to contract. These movements mix the residue, which aids in water absorption.

Mass movements (mass peristalsis) are long, slow-moving, but powerful contractile waves that move over large areas of the colon three or four times daily and force the contents toward the rectum. Typically, they occur during or just after eating. The presence of food in the stomach activates the gastroileal reflex in the small intestine and the propulsive **gastrocolic reflex** in the colon.

Haustral contractions in the descending and sigmoid colon promote the final drying out of the feces. This part of the colon also stores feces until mass movements propel the feces into the rectum. Fiber in the diet strengthens colon contractions and softens the feces, allowing the colon to act like a well-oiled machine.

HOMEOSTATIC IMBALANCE 23.14 CLINICAL

When the diet lacks fiber and the volume of residues in the colon is small, the colon narrows and its contractions become more powerful, increasing the pressure on its walls. This promotes formation of **diverticula** (di″ver-tik′u-lah), small herniations of the mucosa through the colon walls.

This condition, called **diverticulosis**, most commonly occurs in the sigmoid colon, and affects over half of people over age 70. In 4–10% of cases, diverticulosis progresses to **diverticulitis**, in which the diverticula become inflamed and may rupture, leaking into the peritoneal cavity, which can be life threatening.

Irritable bowel syndrome (*IBS*) is a functional GI disorder not explained by anatomical or biochemical abnormalities. Affected individuals have recurring (or persistent) abdominal pain that is relieved by defecation. Additionally, they may have changes in the consistency and frequency of their stools, and varying complaints of bloating, flatulence, nausea, and depression. Stress is a common precipitating factor, and stress management is an important aspect of treatment.

The semisolid feces delivered to the rectum contain undigested food residues, mucus, sloughed-off epithelial cells, millions of bacteria, and just enough water to allow their smooth passage. Of the 500 ml or so of food residue entering the cecum daily, approximately 150 ml becomes feces.

Defecation

The rectum is usually empty, but when mass movements force feces into it, stretching of the rectal wall initiates the **defecation reflex**. This parasympathetic spinal reflex causes the sigmoid colon and the rectum to contract, and the internal anal sphincter to relax (**Figure 23.35** ① and ②). As feces are forced into the anal canal, messages reach the brain allowing us to decide whether the external (voluntary) anal sphincter should open or remain constricted to stop passage of feces temporarily (Figure 23.35 ③).

If defecation is delayed, the reflex contractions end within a few seconds and the rectal walls relax. The next mass movement

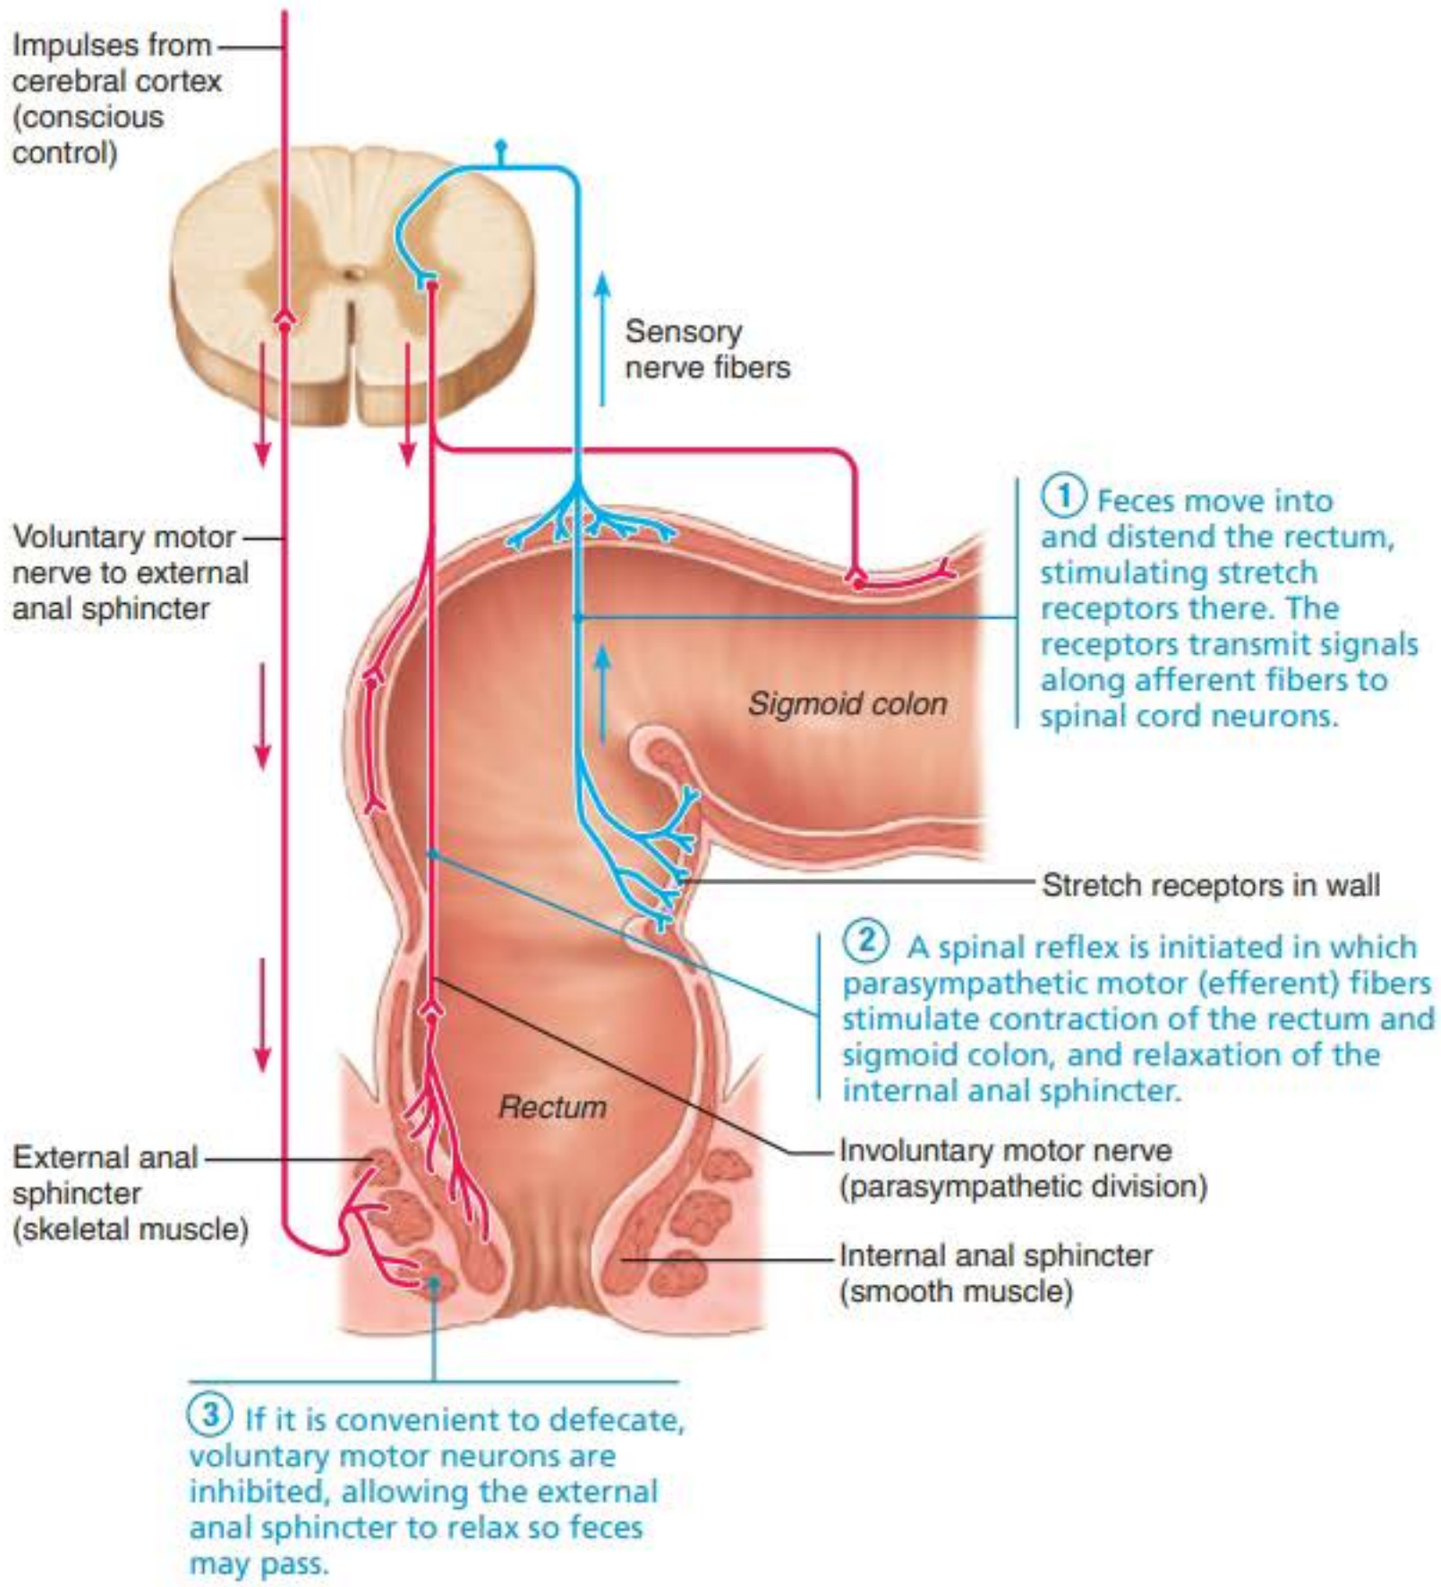

Figure 23.35 Defecation reflex.

initiates the defecation reflex again—and so on, until the person chooses to defecate or the urge becomes irresistible.

During defecation, the muscles of the rectum contract to expel the feces. We aid this process voluntarily by closing the glottis and contracting our diaphragm and abdominal wall muscles to increase the intra-abdominal pressure (a procedure called the *Valsalva maneuver*). We also contract the levator ani muscle (◀ pp. 348–349), which lifts the anal canal superiorly. This lifting action leaves the feces below the anus—and outside the body. Involuntary or automatic defecation (fecal incontinence) occurs in infants because they have not yet gained control of their external anal sphincter. It also occurs in those with spinal cord transections.

HOMEOSTATIC IMBALANCE 23.15 — CLINICAL

Watery stools, or **diarrhea**, result from any condition that rushes food residue through the large intestine before that organ has had sufficient time to absorb the remaining water. Causes include irritation of the colon by bacteria or, less commonly, prolonged physical jostling of the digestive viscera (occurs in marathon runners). Prolonged diarrhea may result in dehydration and electrolyte imbalance (acidosis and loss of potassium).

Conversely, when food remains in the colon for extended periods, too much water is absorbed and the stool becomes hard and difficult to pass. This condition, called **constipation**, may result from insufficient fiber or fluid in the diet, improper bowel habits (failing to heed the "call"), lack of exercise, or laxative abuse.

Check Your Understanding

35. Name and briefly describe the types of motility that occur in the large intestine.

36. What is the result of stimulation of stretch receptors in the rectal walls?

37. In what ways are gut bacteria important to our nutrition?

For answers, see Answers Appendix.

PART 3

PHYSIOLOGY OF DIGESTION AND ABSORPTION

So far in this chapter, we have examined the structure and function of the organs that make up the digestive system. Now let's investigate the chemical processing (enzymatic breakdown) and absorption of each class of foodstuffs as it moves through the GI tract. As you read along, you may find it helpful to refer to the summary in **Figure 23.36**.

23.10 Digestion hydrolyzes food into nutrients that are absorbed across the gut epithelium

Learning Outcome

- **Describe the general processes of digestion and absorption.**

After foodstuffs have spent even a short time in the stomach, they are unrecognizable, but mechanical breakdown has only changed their appearance. In contrast, digestion breaks down ingested foods into their chemical building blocks, which are very different molecules chemically. Only these molecules are small enough to be absorbed across the wall of the small intestine.

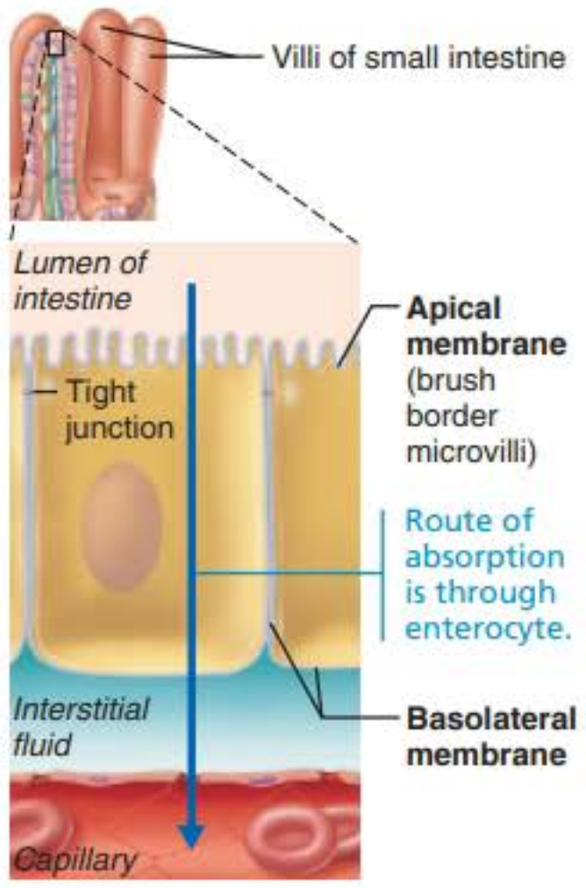
Mechanism of Digestion: Enzymatic Hydrolysis

Digestion is a catabolic process that breaks down large food molecules to *monomers* (chemical building blocks). Digestion is accomplished by enzymes secreted into the lumen of the alimentary canal by intrinsic and accessory glands. Recall from Chapter 2 that enzymatic breakdown of any food molecule is **hydrolysis** (hi-drol′ĭ-sis) because it involves adding a water molecule to each molecular bond to be broken (lysed).

Most digestion is done in the small intestine. Pancreatic enzymes break large chemicals (usually polymers) into smaller pieces that are, in turn, broken down into individual components by the intestinal (brush border) enzymes. Alkaline pancreatic juice neutralizes the acidic chyme that enters the small intestine from the stomach. This provides the proper environment for operation of the enzymes. Both pancreatic juice (the main source of lipases) and bile are necessary for fat breakdown.

Mechanisms of Absorption

Absorption is the process of moving substances from the lumen of the gut into the body. Recall from Chapter 4 (◀ p. 117) that epithelia are polarized and have an apical and basal side. Because tight junctions join the epithelial cells (enterocytes) of the intestinal mucosa at their apical surfaces, substances usually cannot move *between* cells. Instead, materials must pass *through* the enterocytes. Materials enter an enterocyte through its *apical membrane* from the lumen of the gut, and exit through the *basolateral membrane* into the interstitial fluid on the other side of the cell (as shown at right). Once in the interstitial fluid, substances diffuse into the blood capillaries. From the capillary blood in the villus they are transported in the hepatic portal vein to the liver. The exception is some lipid digestion products, which enter the lacteal in the villus to be carried via lymphatic fluid to the blood.



Remember that the structure of the plasma membrane means that nonpolar substances, which can dissolve in the lipid core of the membrane, can be absorbed passively. All other substances need a carrier mechanism (◀ p. 70). Most nutrients are absorbed by *active transport* processes driven directly or indirectly (secondarily) by metabolic energy (ATP; ◀ p. 75).

There is much more flowing through the alimentary tube than food monomers. Indeed, up to 10 L of food, drink, and GI secretions enter the alimentary canal daily, but only 1 L or less reaches the large intestine. Virtually all of the foodstuffs, 80% of the electrolytes, and most of the water (remember water follows salt) are absorbed in the small intestine. Although absorption occurs all along the length of the small intestine, most of it is completed by the time chyme reaches the ileum. The major absorptive role of the ileum is to reclaim bile salts to be recycled back to the liver for resecretion. The absorptive capacity of the small intestine is truly remarkable and it is virtually impossible to exceed.

Check Your Understanding

38. In order to be absorbed, nutrients must pass through two plasma membranes. Name these membranes.

39. MAKE CONNECTIONS Name the layer and sublayer of the alimentary canal wall that houses the capillaries into which nutrients are absorbed.

For answers, see Answers Appendix.

23.11 How is each type of nutrient processed?

Learning Outcomes

- **List the enzymes involved in digestion; name the foodstuffs on which they act.**
- **List the end products of protein, fat, carbohydrate, and nucleic acid digestion.**
- **Describe the processes by which breakdown products of foodstuffs are absorbed in the small intestine.**

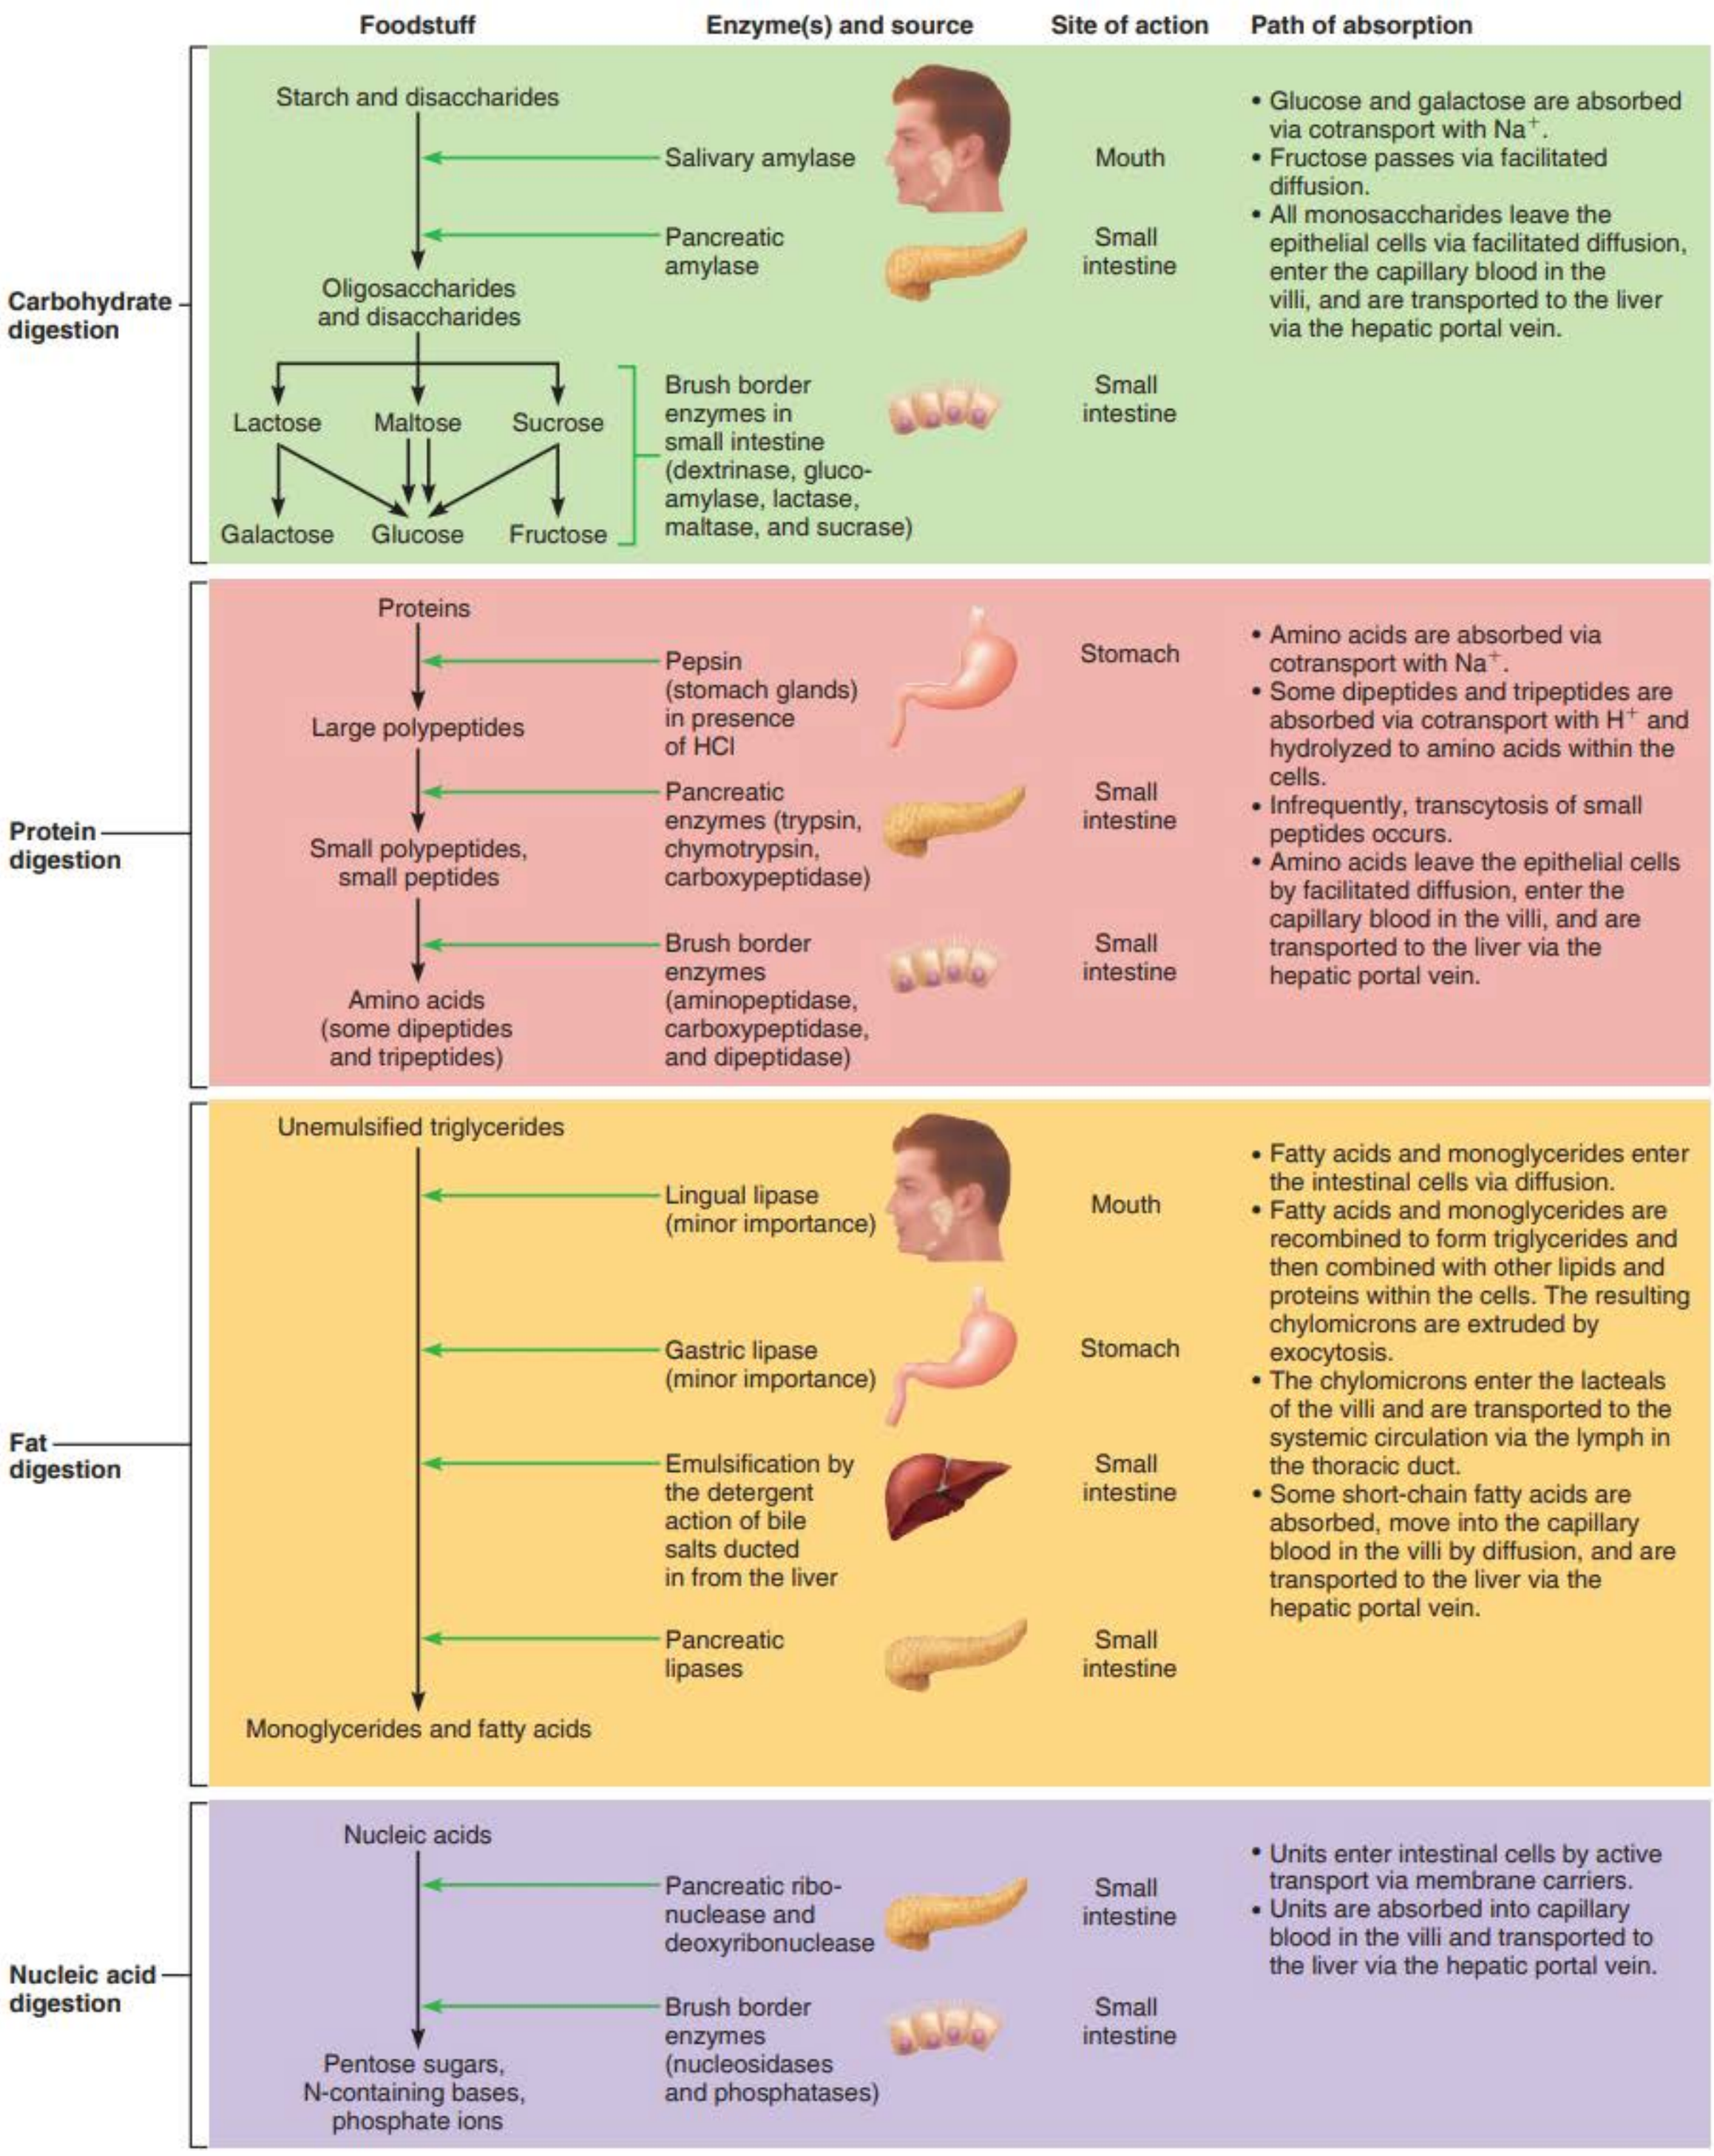


Figure 23.36 Flowchart of digestion and absorption of foodstuffs.

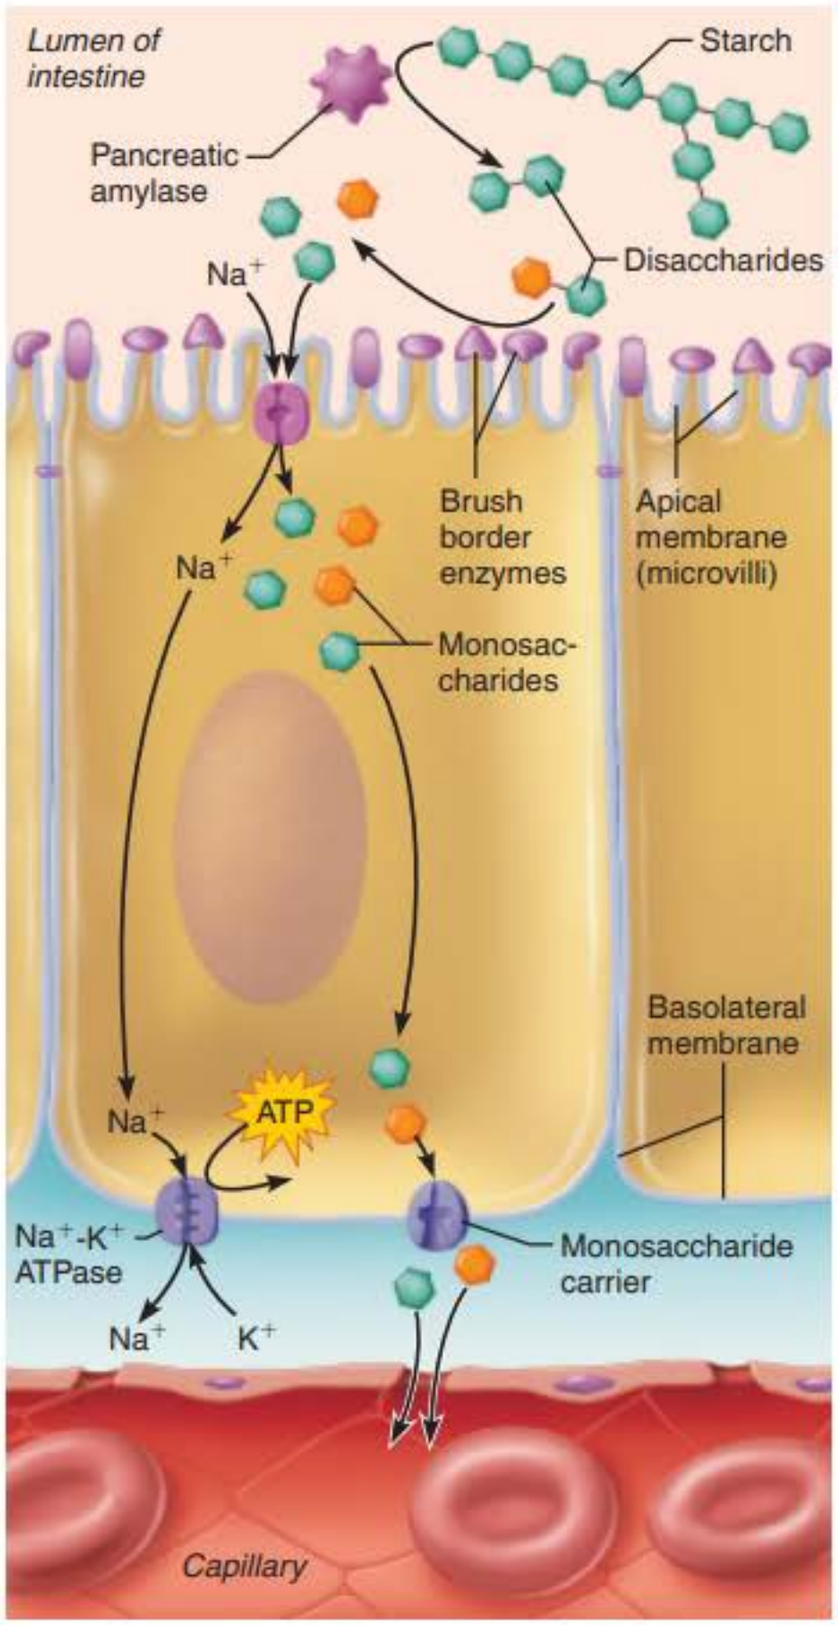

Figure 23.37 Carbohydrate digestion and absorption in the small intestine. Note that fructose enters enterocytes via facilitated diffusion (not shown).

23

Carbohydrates

In the average diet, most (up to 60%) digestible carbohydrates are in the form of starch, with smaller amounts of disaccharides and monosaccharides. Only three monosaccharides are common in our diet: *glucose*, *fructose*, and *galactose*. The more complex carbohydrates that our digestive system is able to break down to monosaccharides are the disaccharides *sucrose* (table sugar), *lactose* (milk sugar), and *maltose* (grain sugar), and the polysaccharides *glycogen* and *starch*. (See ◀ pp. 43–44 to review carbohydrate structures.)

Digestion of starch (and perhaps glycogen) begins in the mouth (Figure 23.36). **Salivary amylase**, present in saliva, splits starch into *oligosaccharides*, smaller fragments of two to eight linked glucose molecules. Starch digestion continues until salivary amylase is inactivated by stomach acid and broken apart by the stomach's protein-digesting enzymes. Generally speaking, the larger the meal, the longer salivary amylase continues to work in the stomach because foodstuffs in its relatively immobile fundus are poorly mixed with gastric juices.

The process of digesting and absorbing carbohydrates in the small intestine is summarized in **Figure 23.37**.

1. **Pancreatic amylase breaks down starch and glycogen into oligosaccharides and disaccharides.** Starchy foods and other digestible carbohydrates that escape being broken down by salivary amylase are acted on by **pancreatic amylase** in the small intestine. About 10 minutes after entering the small intestine, starch is entirely converted to various oligosaccharides, mostly maltose.
2. **Brush border enzymes break oligo- and disaccharides into monosaccharides.** Intestinal brush border enzymes further digest these products to monosaccharides. The most important brush border enzymes are **dextrinase** and **glucoamylase**, which act on oligosaccharides composed of more than three simple sugars, and **maltase**, **sucrase**, and **lactase**, which hydrolyze maltose, sucrose, and lactose respectively into their constituent monosaccharides. Because the intestine can absorb only monosaccharides, all dietary carbohydrates must be digested to monosaccharides to be absorbed.
3. **Monosaccharides are cotransported across the apical membrane of the enterocyte.** Glucose and galactose, liberated by the breakdown of starch and disaccharides, are shuttled by secondary active transport with Na^+ into the enterocytes. Fructose, on the other hand, enters the cells by facilitated diffusion (not shown). The proteins that transport monosaccharides into the cells are located very close to the disaccharidase enzymes on the brush border. They combine with the monosaccharides as soon as the disaccharides are broken down.
4. **Monosaccharides exit across the basolateral membrane by facilitated diffusion.** All types of monosaccharides move out of the enterocytes by facilitated diffusion and pass into the capillaries via intercellular clefts.

Humans lack enzymes capable of breaking down most other polysaccharides, such as cellulose. As a result, indigestible polysaccharides do not nourish us, but they do help move food along the GI tract by providing fiber.

HOMEOSTATIC IMBALANCE 23.16 CLINICAL

In some people, intestinal lactase is present at birth but then becomes deficient due to genetic factors. When people with *lactose*

intolerance consume lactose, the undigested disaccharides create osmotic gradients that prevent water from being absorbed in the intestines and also pull water from the interstitial space into the intestines. The result is diarrhea. Bacterial metabolism of the undigested solutes produces large amounts of gas that result in bloating, flatulence, and cramping pain. For the most part, the solution to this problem is simple—add lactase enzyme "drops" to your milk or take a lactase tablet before consuming milk products.

Proteins

Proteins digested in the GI tract include:

- Dietary proteins (typically about 125 g per day)
- Enzyme proteins secreted into the GI tract by its various glands (15–25 g)
- Protein derived from sloughed and disintegrating mucosal cells

Healthy individuals digest much of this protein all the way to its **amino acid** monomers.

Protein digestion begins in the stomach when pepsinogen secreted by the chief cells is activated to **pepsin** (Figure 23.36). Pepsin functions optimally in the acidic pH range found in the stomach: 1.5–2.5. It preferentially cleaves bonds involving the amino acids tyrosine and phenylalanine, breaking the proteins down into polypeptides and free amino acids. Pepsin, which hydrolyzes 10–15% of ingested protein, is inactivated by the high pH in the duodenum, so its proteolytic activity is restricted to the stomach.

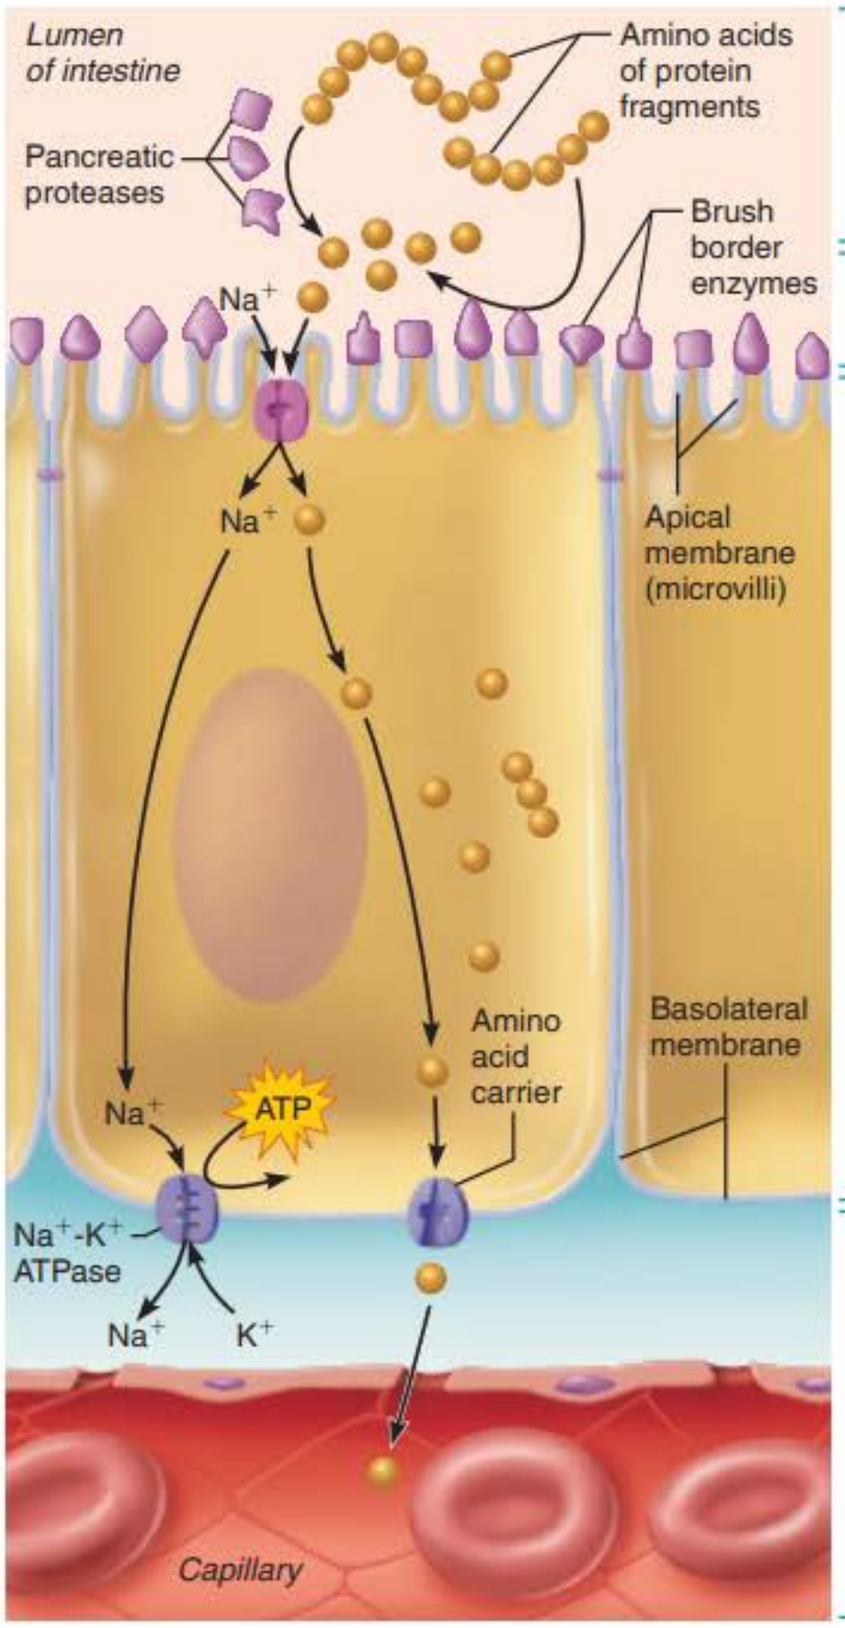

Figure 23.38 Protein digestion and absorption in the small intestine.

The process of digesting and absorbing proteins in the small intestine is summarized in **Figure 23.38**.

1. **Pancreatic proteases break down proteins and protein fragments into smaller pieces and some individual amino acids.** Protein fragments entering the small intestine are greeted by a host of proteolytic enzymes. **Trypsin** and **chymotrypsin** cleave the proteins into smaller peptides. **Carboxypeptidases** split off one amino acid at a time from the end of the polypeptide chain that bears the carboxyl group.
2. **Brush border enzymes break oligo- and dipeptides into amino acids.** A variety of brush border peptidases liberate individual amino acids from either end of a peptide chain (*carboxypeptidases* and *aminopeptidases*), while *dipeptidases* break pairs of amino acids apart. Carboxypeptidases and aminopeptidases can independently dismantle a protein, but the teamwork between these enzymes and between trypsin and chymotrypsin, which attack the more internal parts of the protein, speeds up the process tremendously.
3. **Amino acids are cotransported across the apical membrane of the enterocyte.** Several types of carriers transport the different amino acids resulting from protein digestion. Most of these carriers, like those for glucose and galactose, are coupled to the active transport of sodium. Short chains of two or three amino acids (dipeptides and tripeptides, respectively) are also actively absorbed using H^+-dependent cotransport. They are digested to their amino acids within the enterocytes.
4. **Amino acids exit across the basolateral membrane via facilitated diffusion.** They then enter capillaries via intercellular clefts.

Lipids

Triglycerides are the most abundant fats in the diet (◀ p. 45). The small intestine is the primary site of lipid digestion because the pancreas is the major source of fat-digesting enzymes, or **lipases** (see Figure 23.36).

The steps of lipid digestion and absorption in the small intestine are shown in **Figure 23.39**.

① **Emulsification.** Because triglycerides and their breakdown products are insoluble in water, fats need special "pretreatment" with bile salts to be digested in the watery environment of the small intestine. In aqueous solutions, triglycerides aggregate to form large fat globules, and only the triglyceride molecules at the surfaces of such fatty masses are accessible to the water-soluble lipase enzymes. However, bile salts vastly increase the surface area exposed to pancreatic lipases by breaking large fat globules into many smaller droplets. Without bile, lipids could not be completely digested during the time food spends in the small intestine.

Bile salts have both nonpolar and polar regions. Their nonpolar (hydrophobic) parts cling to the fat molecules, and their polar (ionized hydrophilic) parts allow them to repel each other and interact with water. As a result, fatty droplets are pulled off the large fat globules, forming a stable *emulsion*—an aqueous suspension of fatty droplets, each about 1 μm in diameter. Emulsification does *not* break chemical bonds. It just reduces the attraction between fat molecules so they can be more widely dispersed, just as dish detergent breaks up a pool of fat drippings.

② **Digestion.** Pancreatic lipases catalyze the breakdown of triglycerides by splitting off two of the fatty acid chains, yielding free **fatty acids** and **monoglycerides** (glycerol with one fatty acid chain attached).

③ **Micelle formation.** Just as bile salts accelerate lipid digestion, they are also essential for the *absorption* of its end products. As the water-insoluble products of fat digestion—the monoglycerides and free fatty acids—are liberated by lipase activity, they quickly become associated with bile salts and *lecithin* (a phospholipid found in bile) to form micelles. **Micelles** (mi-selz′) are collections of fatty elements clustered together with bile salts in such a way that the polar (hydrophilic) ends of the molecules face the water and the nonpolar portions form the core. Also nestled in the hydrophobic core are cholesterol molecules and fat-soluble vitamins. Although micelles are similar to emulsion droplets, they are about 500 times smaller and easily diffuse between microvilli to come into close contact with the apical cell surface. Without micelles, the lipids would simply float on the surface of the chyme (like oil on water), inaccessible to the absorptive surfaces of the enterocytes.

④ **Diffusion.** Upon reaching the enterocytes, the various lipid substances leave the micelles and move through the apical plasma membrane by simple diffusion.

⑤ **Chylomicron formation.** Once the free fatty acids and monoglycerides enter the enterocytes, the smooth ER converts them back into triglycerides. The triglycerides are then combined with lecithin and other phospholipids and cholesterol, and coated with a "skin" of proteins to form water-soluble lipoprotein droplets called **chylomicrons** (ki″-lo-mi′kronz). This series of events is quite different from the absorption of amino acids and simple sugars, which pass through the enterocytes unchanged.

⑥ **Chylomicron transport.** The milky-white chylomicrons are too large to pass through either the plasma membrane of the enterocyte or the basement membrane of a blood capillary. Instead, the chylomicron-containing vesicles migrate to the basolateral membrane and are extruded by exocytosis. They then enter the more permeable lacteals (◀ p. 769).

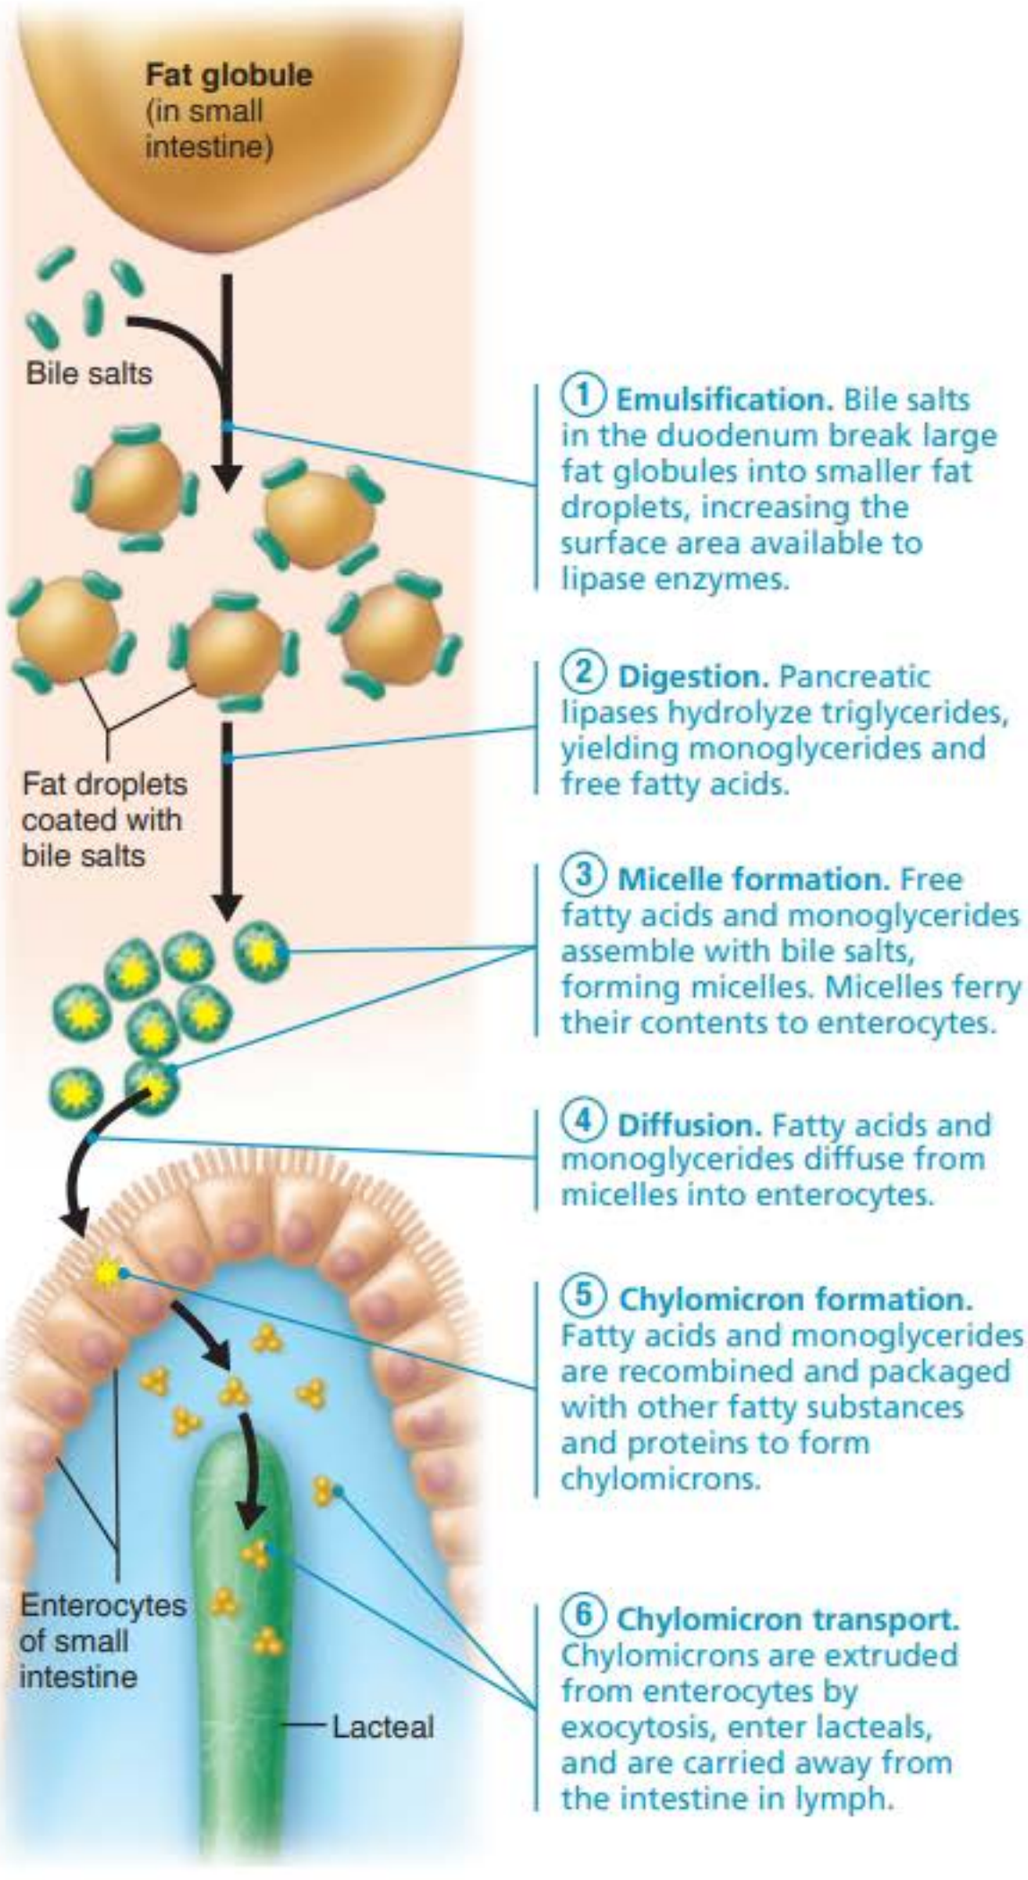

Figure 23.39 Emulsification, digestion, and absorption of fats.

Thus, most fat enters the lymphatic stream for distribution in the lymph. Eventually the chylomicrons are emptied into the venous blood via the thoracic duct, which drains the lymphatics of the digestive viscera.

While in the bloodstream, the triglycerides of the chylomicrons are hydrolyzed to free fatty acids and glycerol by **lipoprotein lipase**, an enzyme associated with capillary endothelium. The fatty acids and glycerol can then pass through the capillary walls to be used by tissue cells for energy or stored as fats in adipose tissue. Liver cells then endocytose and process the residual chylomicron material.

Passage of short-chain fatty acids is quite different from what we have just described. These fat breakdown products do not depend on the presence of bile salts or micelles and are not recombined to form triglycerides within the intestinal cells. They simply diffuse into the portal blood for distribution.

Generally, fat absorption is completed in the ileum, but in the absence of bile (as might occur when a gallstone blocks the cystic duct), it happens so slowly that most of the fat passes into the large intestine and is lost in feces.

Nucleic Acids

The nuclei of the cells of ingested foods contain DNA and RNA. **Pancreatic nucleases** in pancreatic juice hydrolyze the nucleic acids to their **nucleotide** monomers. Intestinal brush border enzymes (**nucleosidases** and **phosphatases**) then break the nucleotides apart to release their nitrogenous bases, pentose sugars, and phosphate ions (see Figure 23.36).

Special carriers in the epithelium of the villi actively transport the breakdown products of nucleic acid digestion across the epithelium. These then enter the blood.

Absorption of Vitamins, Electrolytes, and Water

Vitamin Absorption

The small intestine absorbs dietary vitamins, and the large intestine absorbs some of the K and B vitamins made by its gut bacterial "guests." As we already noted, fat-soluble vitamins (A, D, E, and K) dissolve in dietary fats, become incorporated into the micelles, and move across the villus epithelium passively (by diffusion). It follows that gulping pills containing fat-soluble vitamins without simultaneously eating some fat-containing food results in little or no absorption of these vitamins.

Most water-soluble vitamins (B vitamins and vitamin C) are absorbed via specific active or passive transporters. The exception is vitamin B_{12}, which is a very large, charged molecule. *Intrinsic factor*, produced by the stomach (◀ p. 889), binds to vitamin B_{12}. The vitamin B_{12}–intrinsic factor complex then binds to specific mucosal receptor sites in the terminal ileum, which trigger its active uptake by endocytosis.

Electrolyte Absorption

Absorbed electrolytes come from both ingested foods and gastrointestinal secretions. Most ions are actively absorbed along the entire length of the small intestine. But absorption of iron and calcium is largely limited to the duodenum.

For most nutrients, the amount *reaching* the intestine is the amount absorbed, regardless of the nutritional state of the body. In contrast, absorption of iron and calcium is intimately related to the body's need for them at the time.

Sodium, Chloride, and Bicarbonate As we mentioned earlier, absorption of sodium ions in the small intestine is coupled to active absorption of glucose and amino acids. For the most part, anions passively follow the electrical potential established by sodium transport. In other words, Na^+ is actively pumped out of the enterocytes by a Na^+-K^+ pump after entering those cells. Usually, chloride ions passively follow Na^+. In the terminus of the small intestine, HCO_3^- is actively secreted into the lumen in exchange for Cl^-.

Potassium Potassium ions move across the intestinal mucosa passively by facilitated diffusion (or leaky tight junctions). As water is absorbed from the lumen, rising potassium levels in chyme create a concentration gradient for its absorption. Anything that interferes with water absorption (resulting in diarrhea) not only reduces potassium absorption but also "pulls" K^+ from the interstitial space into the intestinal lumen.

Iron Ionic iron, essential for hemoglobin production, is actively transported into the mucosal cells, where it binds to the protein **ferritin** (fer′ĭ-tin). The intracellular iron-ferritin complexes then serve as local storehouses for iron. When body reserves of iron are adequate, only 10–20% is allowed to pass into the portal blood, and most of the stored iron is lost as the enterocytes later slough off. However, when iron reserves are depleted (as during acute or chronic hemorrhage), iron uptake from the intestine and its release to the blood accelerate. In the blood, iron binds to **transferrin**, a plasma protein that transports it in the circulation.

Menstrual bleeding is a major route of iron loss in females, and premenopausal women require about 50% more iron in their diets. The intestinal enterocytes of women have about four times as many iron transport proteins as do those of men, and little iron is lost from the body other than that lost in menses.

Calcium Calcium absorption is closely related to blood levels of ionic calcium. The active form of **vitamin D** promotes active calcium absorption. Decreased blood levels of ionic calcium prompt *parathyroid hormone* (*PTH*) release from the parathyroid glands (◀ p. 622). Besides facilitating the release of calcium ions from bone matrix and enhancing the reabsorption of calcium by the kidneys, PTH stimulates activation of vitamin D to calcitriol by the kidneys, which in turn accelerates calcium ion absorption in the small intestine.

Water Absorption

Approximately 9 L of water, mostly derived from GI tract secretions, enter the small intestine daily. Water is the most abundant substance in chyme, and 95% of it is absorbed in the small intestine by osmosis. Most of the rest is absorbed in the large intestine, leaving only about 0.1 L to soften the feces.

The normal rate of water absorption is 300 to 400 ml per hour. Water moves freely in both directions across the intestinal

mucosa, but *net osmosis* occurs whenever a concentration gradient is established by the active transport of solutes (particularly Na^+) into the mucosal cells. In this way, water uptake is effectively coupled to solute uptake and, in turn, affects the absorption of substances that normally pass by diffusion. As water moves into mucosal cells, these substances follow along their concentration gradients.

HOMEOSTATIC IMBALANCE 23.17 CLINICAL

Malabsorption, or impaired nutrient absorption, has many and varied causes. It can result from anything that interferes with the delivery of bile or pancreatic juice to the small intestine. Factors that damage the intestinal mucosa (severe bacterial infections and some antibiotics) or reduce its absorptive surface area are also common causes.

A common malabsorption syndrome is *gluten-sensitive enteropathy* or *celiac disease*, which affects one in 100 people. This chronic genetic condition is caused by an immune reaction to gluten, a protein plentiful in all grains but corn and rice. Breakdown products of gluten interact with molecules of the immune system in the GI tract, forming complexes. These complexes activate T cells, which then attack the intestinal lining, damaging intestinal villi and reducing the surface area of the brush border. Bloating, diarrhea, pain, and malnutrition result.

The usual treatment is to eliminate gluten-containing grains from the diet. In recent years, many gluten-free products have become available.

Check Your Understanding

40. Fill in the blank: Amylase is to starch as ___ is to fats.

41. WHAT IF? Suppose you had a patient that was unable to make bile salts. What digestive processes would be affected and what might be some of the consequences?

For answers, see Answers Appendix.

Developmental Aspects of the Digestive System

As previously described, the very young embryo is flat and consists of three germ layers. From top to bottom, they are ectoderm, mesoderm, and endoderm. This flattened cell mass soon folds to form a cylindrical body, and its internal cavity becomes the cavity of the alimentary canal, which is initially closed at both ends.

The epithelial lining of the developing alimentary canal, or **primitive gut**, forms from endoderm (**Figure 23.40a**). The rest of the wall arises from mesoderm. The anteriormost endoderm (that of the foregut) touches a depressed area of the surface ectoderm called the **stomodeum** (sto″mo-de′um). The two membranes fuse, forming the **oral membrane**, which soon breaks through to form the opening of the mouth. Similarly, the end of the hindgut fuses with an ectodermal depression, the **proctodeum** (*procto* = anus), to form the **cloacal membrane** (*cloaca* = sewer), which then breaks through to form the anus.

By week 5, the alimentary canal is a continuous "tube" extending from mouth to anus and opens to the external environment at each end. Shortly after, the glandular organs (salivary glands,

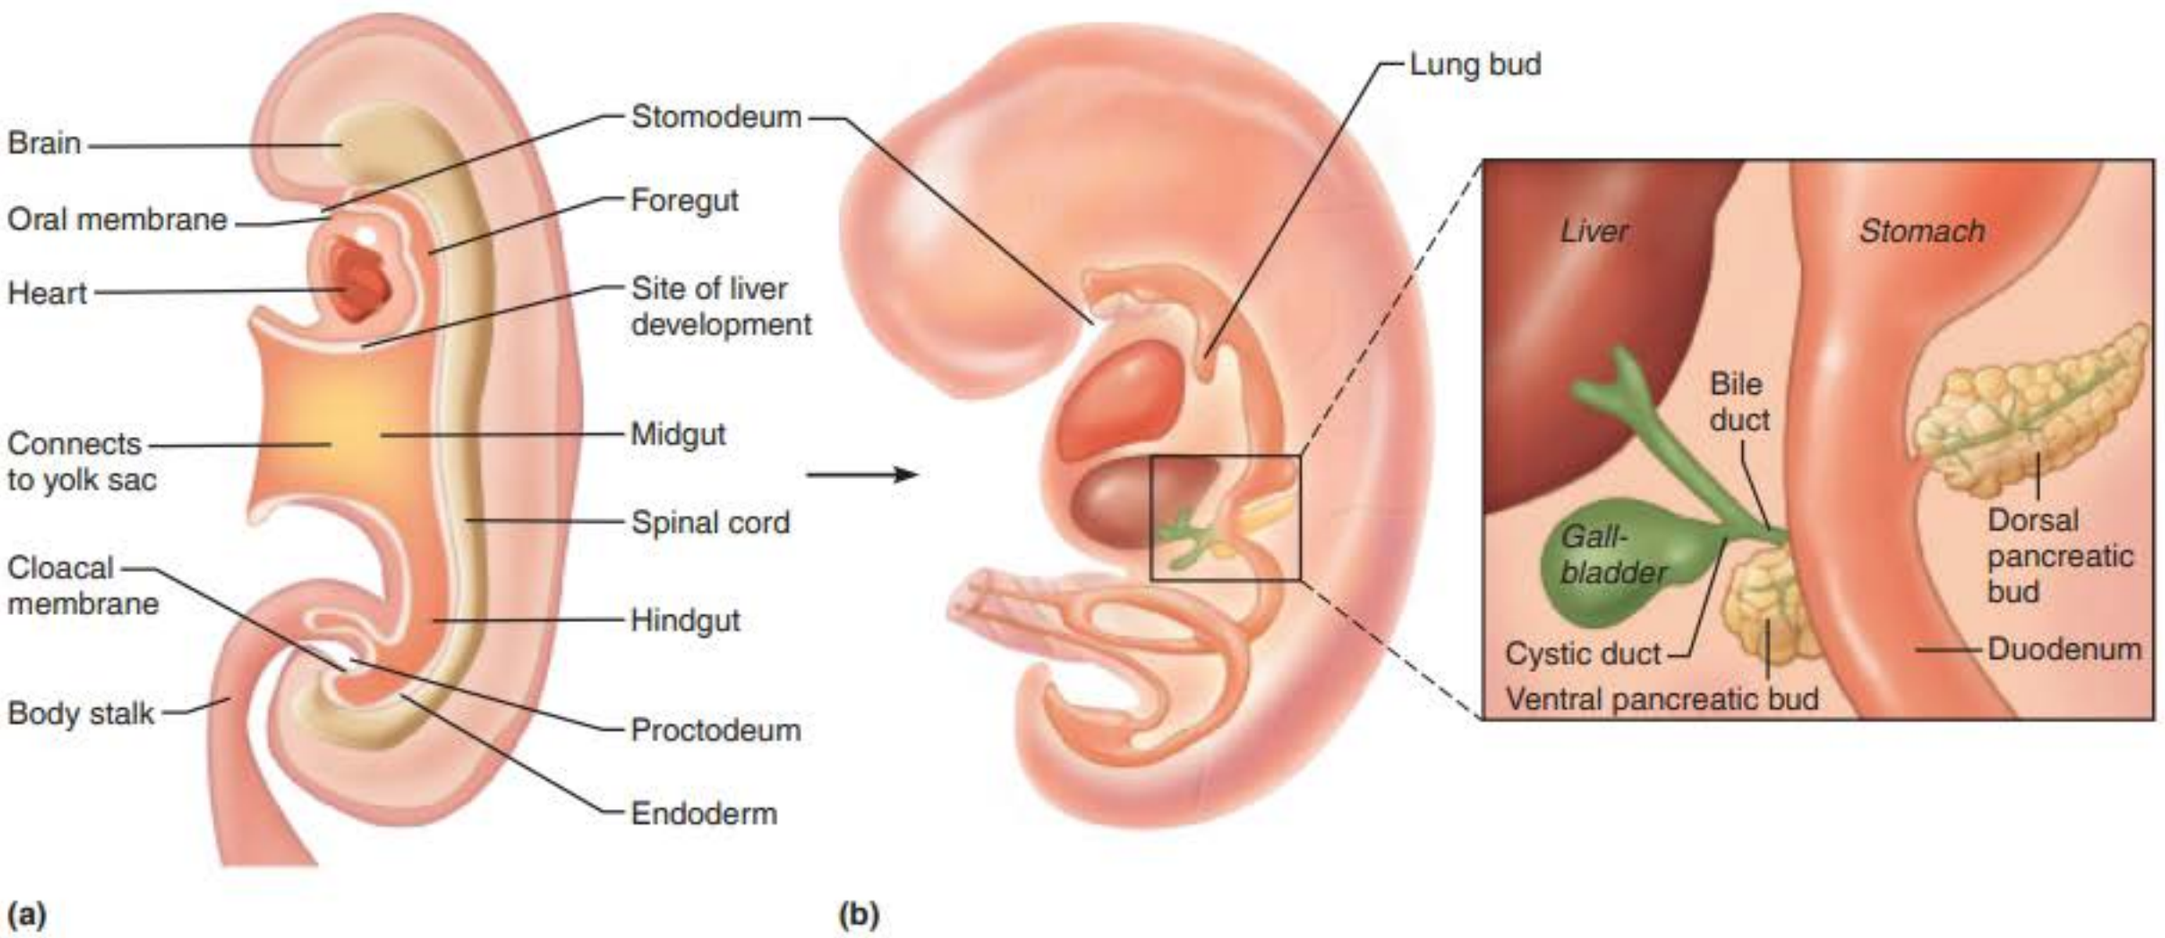

Figure 23.40 Embryonic development of the digestive system. (a) Three-week-old embryo. The endoderm has folded, and the foregut and hindgut have formed. (The midgut is still open and continuous with the yolk sac.) **(b)** By five weeks of development, the accessory organs are budding out from the endodermal layer, as shown in the enlargement.

liver with gallbladder, and pancreas) bud out from the mucosa at various points (Figure 23.40b). These glands retain their connections, which become ducts leading into the digestive tract.

HOMEOSTATIC IMBALANCE 23.18 — CLINICAL

The digestive system is susceptible to many congenital defects that interfere with feeding. The most common are **cleft palate**, in which the palatine bones or palatine processes of the maxillae (or both) fail to fuse, and **cleft lip**, which often occur together (◀ Figure 7.39, p. 246). Of the two, cleft palate is far more serious because the child is unable to suck properly.

Another common defect is *tracheoesophageal fistula*, in which there is an opening between the esophagus and the trachea, and the esophagus often lacks a connection to the stomach. The baby chokes and becomes cyanotic during feedings because food enters the respiratory passageways. Surgery can usually correct these defects.

Cystic fibrosis (described in more detail in Chapter 22, ◀ p. 861) primarily affects the lungs, but it also impairs the activity of the pancreas. In this genetic disease, the mucous glands produce abnormally thick mucus, which blocks ducts and passageways of organs. Blockage of the pancreatic duct prevents pancreatic juice from reaching the small intestine. This impairs digestion, and most fats and fat-soluble vitamins are not digested or absorbed. Consequently the stools are bulky and fat laden. The pancreatic problems can be handled by administering pancreatic enzymes with meals.

During fetal life, the developing infant receives all of its nutrients through the placenta. Nonetheless, the fetal GI tract is "trained" in utero for future food digestion as the fetus naturally swallows some of the surrounding amniotic fluid. This fluid contains several chemicals that stimulate GI maturation, including gastrin and epidermal growth factor.

Digestive System after Birth

Feeding is a newborn baby's most important activity, and several reflexes enhance the infant's ability to obtain food: The *rooting reflex* helps the infant find the nipple, and the *sucking reflex* helps the baby hold onto the nipple and swallow.

Newborn babies tend to double their birth weight within six months, and their caloric intake and food processing ability are extraordinary. For example, a 6-week-old infant weighing about 4 kg (less than 9 lb) drinks about 600 ml of milk daily. A 65-kg adult (143 lb) would have to drink 10 L of milk to ingest a corresponding volume of fluid! However, the stomach of a newborn infant is very small, so feeding must be frequent (every 3–4 hours). Peristalsis is inefficient, and vomiting is not unusual. As the teeth break through the gums, the infant progresses to solid foods and is usually eating an adult diet by the age of 2 years.

As a rule, the digestive system operates throughout childhood and adulthood with relatively few problems. However, contaminated food or extremely spicy or irritating foods sometimes cause **gastroenteritis** (gas″tro-en″tĕ-ri′tis), inflammation of the GI tract. Ulcers and gallbladder problems—inflammation or **cholecystitis** (ko″le-sis-ti′tis), and gallstones—are problems of middle age.

Aging and the Digestive System

During old age, GI tract activity declines. Fewer digestive juices are produced, absorption is less efficient, and peristalsis slows. The result is less frequent bowel movements and, often, constipation. Taste and smell are less acute, and periodontal disease often develops. Many elderly people live alone or on a reduced income. These factors, along with increasing physical disability, tend to make eating less appealing, and many of our elderly citizens are poorly nourished.

Diverticulosis, fecal incontinence, and cancer of the GI tract are fairly common problems of the aged. Stomach and colon cancers rarely have early signs, and often metastasize before a person seeks medical attention. (*A Closer Look*, ◀ p. 144, describes the development of colorectal cancer.) Should metastasisoccur, secondary cancer of the liver is almost guaranteed because of the "detour" the splanchnic venous blood takes through the liver via the hepatic portal circulation.

However, when detected early, most GI tract cancers are treatable. The best advice is to have regular dental and medical checkups. Most oral cancers are detected during routine dental examinations, 50% of all rectal cancers can be felt digitally, and nearly 80% of colon cancers can be seen and removed during a colonoscopy. Screening for colon cancer is recommended after age 50.

RELATED CLINICAL TERMS

Achalasia (a-kah-la′ze-ah) A disorder in which swallowing is hindered or prevented. Botox injections can relax the esophageal sphincter.

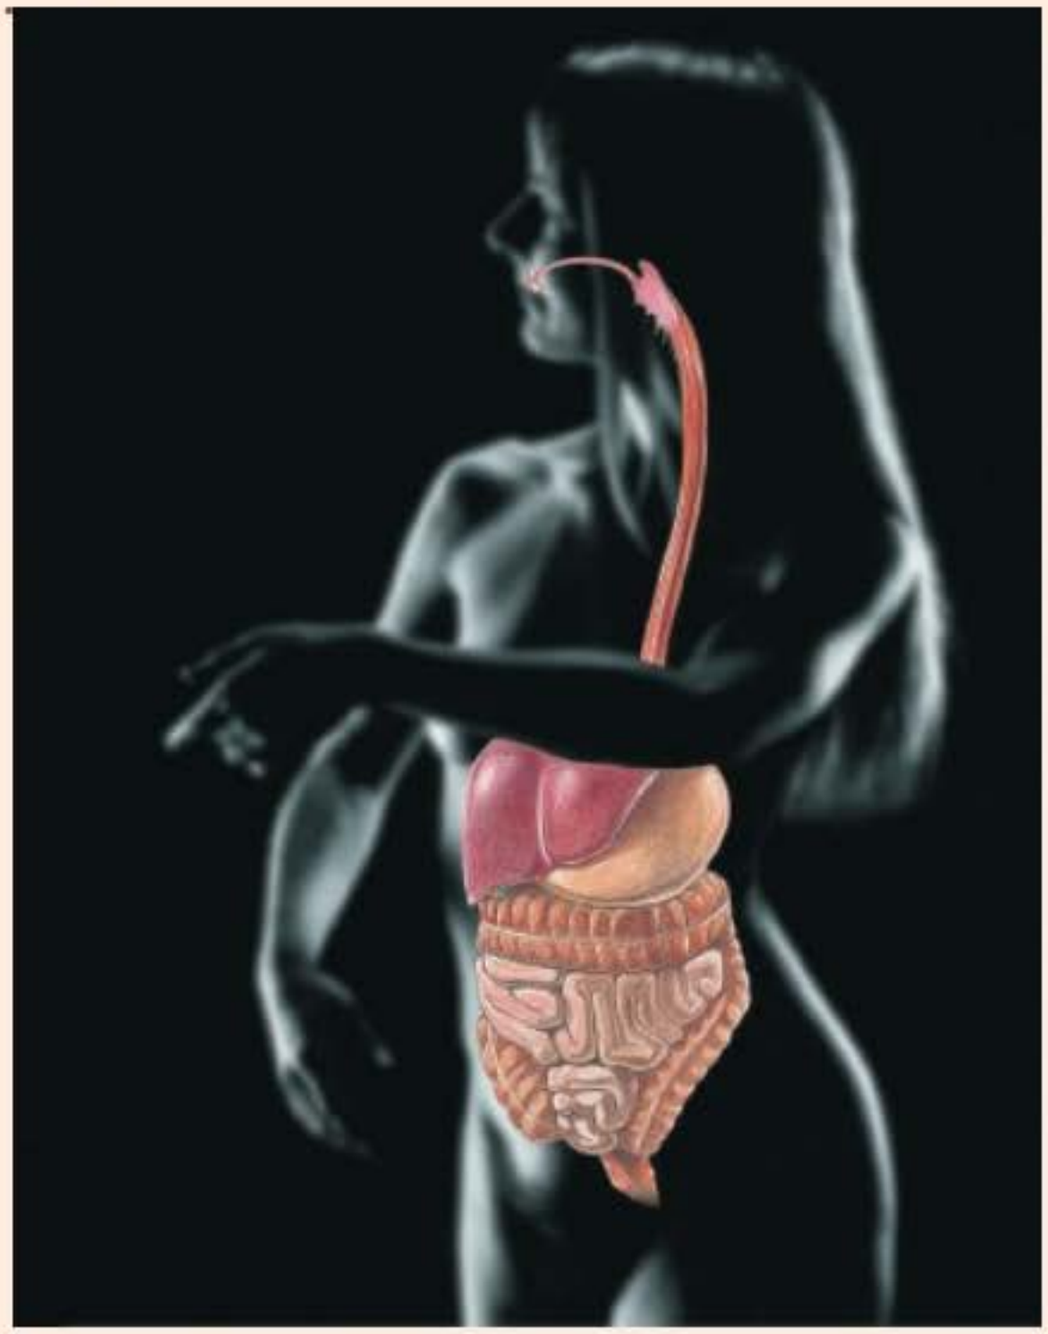
Ascites (ah-si′tēz; *asci* = bag, bladder) Abnormal accumulation of fluid within the peritoneal cavity; if excessive, causes visible bloating of the abdomen. May result from portal hypertension caused by liver cirrhosis or by heart or kidney disease.

Barrett's esophagus A pathological change in the epithelium of the lower esophagus from stratified squamous to a columnar epithelium. A possible sequel to untreated chronic gastroesophageal reflux due to hiatal hernia, it predisposes the individual to aggressive esophageal cancer (adenocarcinoma).

Bruxism (bruck′sizm) Grinding or clenching of teeth, usually at night during sleep in response to stress. Can wear down and crack the teeth.

Bulimia (bu-lim′e-ah; *bous* = ox; *limos* = hunger) Binge-purge behavior—episodes of overeating followed by purging (self-induced vomiting, taking laxatives or diuretics, or excessive exercise). Most common in women of high school or college age. Often associated with stress and depression. Consequences include eroded tooth enamel, stomach trauma or rupture (from vomiting), and severe electrolyte disturbances, which impair heart activity. Therapy includes hospitalization to control behavior, and nutritional counseling.

Homeostatic Interrelationships between the Digestive System and Other Body Systems



Integumentary System Chapter 5

- Digestive system provides nutrients needed for energy, growth, and repair; supplies fats that provide insulation in the dermis and subcutaneous tissue
- The skin synthesizes vitamin D needed for calcium absorption from the intestine; protects by enclosure

Skeletal System Chapters 6–8

- Digestive system provides nutrients needed for energy, growth, and repair; absorbs calcium needed for bone salts
- Skeletal system protects some digestive organs by bone; bones and bone cavities store some nutrients (e.g., calcium, fats)

Muscular System Chapters 9–10

- Digestive system provides nutrients needed for energy, growth, and repair; liver removes lactic acid, resulting from muscle activity, from the blood
- Skeletal muscle activity increases motility of GI tract

Nervous System Chapters 11–15

- Digestive system provides nutrients needed for normal neural functioning; nutrient signals influence neural regulation of satiety
- Nervous system controls digestive function; in general, parasympathetic fibers accelerate and sympathetic fibers inhibit digestive activity; reflex and voluntary controls of defecation

Endocrine System Chapter 16

- Liver removes hormones from blood, ending their activity; digestive system provides nutrients needed for energy, growth, and repair; pancreas, stomach, and small intestine have hormone-producing cells
- Hormones and paracrines help regulate digestive function

Cardiovascular System Chapters 17–19

- Digestive system provides nutrients to heart and blood vessels; absorbs iron needed for hemoglobin synthesis; absorbs water necessary for normal plasma volume; liver secretes bilirubin resulting from hemoglobin breakdown in bile and stores iron for reuse
- Cardiovascular system transports nutrients absorbed by alimentary canal to all tissues of body; distributes hormones of the digestive tract

Lymphatic System/Immunity Chapters 20–21

- Digestive system provides nutrients for normal functioning; lysozyme of saliva and HCl of stomach provide nonspecific protection against bacteria
- Lacteals drain fatty lymph from digestive tract organs and convey it to blood; Peyer's patches and lymphoid tissue in mesentery house macrophages and immune cells that protect digestive tract organs against infection; plasma cells provide IgA in digestive tract secretions

Respiratory System Chapter 22

- Digestive system provides nutrients needed for energy, growth, and repair
- Respiratory system provides oxygen to and disposes of carbon dioxide produced by digestive system organs

Urinary System Chapters 25–26

- Digestive system provides nutrients for energy, growth, and repair
- Kidneys transform vitamin D to its active form, which is needed for calcium absorption

Reproductive System Chapter 27

- Digestive system provides nutrients for energy, growth, and repair and extra nutrition needed to support fetal growth

Dysphagia (dis-fa′je-ah; *dys* = difficult, abnormal; *phag* = eat) Difficulty swallowing; usually due to obstruction or physical trauma to the esophagus.

Endoscopy (en-dos′ko-pe; *endo* = within, inside; *scopy* = viewing) Visual examination of a ventral body cavity or the interior of a visceral organ with a flexible tubelike device called an endoscope, which contains a light source and a lens. A general term for a colonoscopy (viewing the colon), sigmoidoscopy (viewing the sigmoid colon), etc.

Enteritis (*enteron* = intestine) Inflammation of the intestine, especially the small intestine.

Hemochromatosis (he″mo-kro″mah-to′sis; *hemo* = blood; *chroma* = color; *osis* = condition of) A disorder in iron metabolism due to excessive/prolonged iron intake or a breakdown of the mucosal iron barrier; excess iron is deposited in the tissues, increasing skin pigmentation and the risk of hepatic cancer and liver cirrhosis. Also called bronze diabetes and iron storage disease.

Ileus (il′e-us) A condition in which all GI tract movement stops and the gut appears to be paralyzed. Can result from electrolyte imbalances and blockade of parasympathetic impulses by drugs (such as those commonly used during abdominal surgery); usually reversed when these interferences end. The reappearance of intestinal sounds (gurgling, etc.) indicates restoration of motility.

Inflammatory bowel disease (IBD) A noncontagious, periodic inflammation of the intestinal wall now understood to be an abnormal immune and inflammatory response to bacterial antigens that normally occur in the intestine. Linked to T_H17 cells, certain cytokines, and the loss of a normal epithelial barrier. Afflicts up to two of every 1000 people. Symptoms include cramping, diarrhea, weight loss, and intestinal bleeding. Two subtypes occur: (1) Crohn's disease is a syndrome characterized by relapsing and remitting periods. Deep ulcers and fissures can develop anywhere along the GI tract, but mostly occur in the terminal ileum. (2) Ulcerative colitis is characterized by inflammation of the large-intestinal mucosa, mainly in the rectum. Both types are treated with anti-inflammatory and immunosuppressant drugs and sometimes probiotic agents and antibiotics. Extremely severe cases of ulcerative colitis are treated by colectomy (removal of a portion of the colon).

Laparoscopy (lap″ah-ros′ko-pe; *lapar* = the flank; *scopy* = observation) Examination of the peritoneal cavity and its organs with an endoscope inserted through the anterior abdominal wall. Often used to assess the condition of the digestive organs and the pelvic reproductive organs of females.

Mumps An inflammation of the parotid glands caused by the mumps virus (myxovirus). A once-common childhood illness now prevented by vaccination with the MMR (measles, mumps, rubella) vaccine. In 25% of mumps cases in adult males, the testes are also infected, which can lead to sterility.

Orthodontics (or″tho-don′tiks; *ortho* = straight) Branch of dentistry that prevents and corrects misaligned teeth.

Pancreatitis (pan″kre-ah-ti′tis) A rare but extremely serious inflammation of the pancreas. May result from excessively high levels of fat in the blood or excessive alcohol ingestion, but most acute cases arise from gallstones that block the bile duct. Pancreatic enzymes are activated in the pancreatic duct, causing the pancreatic tissue and duct to be digested (literally, eaten from within). This painful condition can lead to nutritional deficiencies because pancreatic enzymes are essential to food digestion in the small intestine.

Peptic ulcers Term referring to gastric and duodenal ulcers.

Proctology (prok-tol′o-je; *procto* = rectum, anus; *logy* = study of) Branch of medicine dealing with treatment of diseases of the colon, rectum, and anus.

Pyloric stenosis (pi-lor′ik stĕ-no′sis; *stenosis* = narrowing, constriction) Congenital abnormality in which the pyloric sphincter is abnormally constricted. There is usually no problem until the baby begins to take solid food, and then projectile vomiting begins. Corrected surgically.

Vagotomy (va-got′o-me) Cutting or severing of the vagus nerve to decrease secretion of gastric juice in those with peptic ulcers that do not respond to medication.

CHAPTER SUMMARY

PART 1

OVERVIEW OF THE DIGESTIVE SYSTEM

1. The digestive system includes organs of the alimentary canal (mouth, pharynx, esophagus, stomach, small and large intestines) and accessory digestive organs (teeth, tongue, salivary glands, liver, gallbladder, and pancreas).

23.1 What major processes occur during digestive system activity? (pp. 870–871)

1. Digestive system activities include six processes: ingestion (food intake); propulsion (movement of food through the tract); mechanical breakdown (processes that physically mix or break foods down into smaller fragments); digestion (food breakdown by enzymatic action); absorption (transport of products of digestion through the intestinal mucosa into the blood); and defecation (elimination of the undigested residues [feces] from the body).

23.2 The GI tract has four layers and is usually surrounded by peritoneum (pp. 871–874)

1. The parietal and visceral layers of the peritoneum are continuous with one another via several extensions (mesenteries, falciform ligament, lesser and greater omenta), and are separated by a potential space containing serous fluid, which decreases friction during organ activity.
2. All organs of the GI tract have the same basic pattern of tissue layers in their walls; all have a mucosa, submucosa, muscularis externa, and serosa (or adventitia). Intrinsic nerve plexuses (enteric nervous system) are found within the wall.
3. The digestive viscera are served by the splanchnic circulation, consisting of arterial branches of the celiac trunk and aorta and the hepatic portal circulation.

23.3 The GI tract has its own nervous system called the enteric nervous system (pp. 874–875)

1. The digestive system controls the environment within its lumen to ensure optimal conditions for digestion and absorption of foodstuffs.
2. Receptors and hormone-secreting cells in the alimentary canal wall respond to stretch and chemical signals that result in stimulation or inhibition of GI secretory activity or motility. The alimentary canal has an intrinsic nerve supply.

PART 2
FUNCTIONAL ANATOMY OF THE DIGESTIVE SYSTEM

23.4 Ingestion occurs only at the mouth (pp. 876–881)

1. Food enters the GI tract via the mouth, which is continuous with the oropharynx posteriorly. The boundaries of the mouth are the lips and cheeks, palate, and tongue.
2. The oral mucosa is stratified squamous epithelium, an adaptation seen where abrasion occurs.
3. The tongue is mucosa-covered skeletal muscle. Its intrinsic muscles allow it to change shape; its extrinsic muscles allow it to change position.
4. Saliva is produced by many minor salivary glands and three pairs of major salivary glands—parotid, submandibular, and sublingual—that secrete their product into the mouth via ducts. Largely water, saliva also contains ions, proteins, metabolic wastes, lysozyme, defensins, IgA, salivary amylase, and mucin.
5. Saliva moistens and cleanses the mouth; moistens foods, aiding their compaction; dissolves food chemicals to allow for taste; and begins digestion of starch (salivary amylase). Saliva output is increased by parasympathetic reflexes initiated by activation of chemical and pressure receptors in the mouth and by the sight or smell of food. The sympathetic nervous system depresses salivation.
6. The 20 deciduous teeth begin to be shed at the age of 6 and are gradually replaced during childhood and adolescence by the 32 permanent teeth.
7. Teeth are classed as incisors, canines, premolars, and molars. Each tooth has an enamel-covered crown and a cement-covered root. The bulk of the tooth is dentin, which surrounds the central pulp cavity. A periodontal ligament secures the tooth to the bony alveolus.
8. The mouth and associated accessory organs accomplish food ingestion and mechanical breakdown (chewing and mixing), initiate the digestion of starch (salivary amylase), and propel food into the pharynx (buccal phase of swallowing).
9. Teeth masticate food. Chewing is initiated voluntarily and then controlled reflexively.

23.5 The pharynx and esophagus move food from the mouth to the stomach (pp. 881–884)

1. Food propelled from the mouth passes through the oropharynx and laryngopharynx. The mucosa of the pharynx is stratified squamous epithelium; skeletal muscles in its wall (constrictor muscles) move food toward the esophagus.
2. The esophagus extends from the laryngopharynx and joins the stomach at the cardial orifice, which is surrounded by the gastroesophageal sphincter.
3. The esophageal mucosa is stratified squamous epithelium. Its muscularis is skeletal muscle superiorly and changes to smooth muscle inferiorly. It has an adventitia rather than a serosa.
4. The pharynx and esophagus are primarily food conduits that conduct food to the stomach by peristalsis.
5. Swallowing is initiated by the mouth (the buccal phase) after the tongue has compacted food and saliva into a bolus. The pharyngeal-esophageal phase is controlled reflexively by the swallowing center in the medulla and pons. When the peristaltic wave approaches the gastroesophageal sphincter, the sphincter relaxes to allow food to enter the stomach.

23.6 The stomach temporarily stores food and begins protein digestion (pp. 884–893)

1. The J-shaped stomach lies in the upper left quadrant of the abdomen. Its major regions are the cardia, fundus, body, and pyloric part. When empty, its internal surface exhibits rugae.
2. The stomach muscularis contains a third (oblique) layer of smooth muscle.
3. The stomach mucosa is simple columnar epithelium dotted with gastric pits that lead into gastric glands. Secretory cells in the gastric glands include pepsinogen-producing chief cells; parietal cells, which secrete hydrochloric acid and intrinsic factor; mucous neck cells, which produce mucus; and enteroendocrine cells, which secrete hormones and paracrines.
4. The mucosal barrier, which protects the stomach from self-digestion and HCl, reflects the fact that the mucosal cells are connected by tight junctions, secrete a thick mucus, and are quickly replaced when damaged.
5. Protein digestion is initiated in the stomach by activated pepsin and requires acidic conditions (provided by HCl). Few substances are absorbed in the stomach.
6. Both nervous and hormonal factors control gastric secretory activity. The three phases of gastric secretion are cephalic, gastric, and intestinal. Most food-related stimuli acting on the head and stomach (cephalic and gastric, respectively) stimulate gastric secretion. Most stimuli acting on the small intestine trigger the enterogastric reflex and release of secretin and CCK, both of which inhibit gastric secretory activity. Sympathetic activity also inhibits gastric secretion.
7. Mechanical breakdown in the stomach is triggered by stomach distension and coupled to food propulsion and stomach emptying. Food movement into the duodenum is controlled by the pylorus and feedback signals from the small intestine. Pacemaker cells in the smooth muscle sheet set the rate of peristalsis.

23.7 The liver secretes bile; the pancreas secretes digestive enzymes (pp. 893–900)

1. The liver is a lobed organ overlying the stomach. Its digestive role is to produce bile, which it secretes into the common hepatic duct.
2. The structural and functional units of the liver are the liver lobules. Blood flowing to the liver via the hepatic artery proper and hepatic portal vein flows into its sinusoids, from which stellate macrophages remove debris and hepatocytes remove nutrients. Hepatocytes store glucose as glycogen, use amino acids to make plasma proteins, and detoxify metabolic wastes and drugs.
3. Bile is made continuously by the hepatocytes. Bile salts and secretin stimulate bile production.
4. The gallbladder, a muscular sac that lies beneath the right liver lobe, stores and concentrates bile.
5. Bile contains electrolytes, a variety of fatty substances, bile salts, and bile pigments in an aqueous medium. Bile salts are emulsifying agents; they disperse fats and form water-soluble micelles, which solubilize the products of fat digestion.
6. The pancreas is retroperitoneal between the spleen and small intestine. Its exocrine product, pancreatic juice, is carried to the duodenum via the pancreatic duct.

7. The bile duct and pancreatic duct join to form the hepatopancreatic ampulla and empty their secretions into the duodenum through the hepatopancreatic sphincter.
8. Pancreatic juice is a HCO_3^--rich fluid containing enzymes that digest all categories of foods. Intestinal hormones and the vagus nerves control secretion of pancreatic juice.
9. Cholecystokinin released by the small intestine stimulates the gallbladder to contract and the hepatopancreatic sphincter to relax, allowing bile (and pancreatic juice) to enter the duodenum.

23.8 The small intestine is the major site for digestion and absorption (pp. 900–906)

1. The small intestine extends from the pyloric sphincter to the ileocecal valve. Its three subdivisions are the duodenum, jejunum, and ileum.
2. Circular folds, villi, and microvilli increase the intestinal surface area for digestion and absorption.
3. The duodenal submucosa contains elaborate mucus-secreting duodenal glands. The mucosa of the ileum contains Peyer's patches (aggregated lymphoid nodules). The duodenum is covered not with a serosa but with an adventitia.
4. Intestinal juice is largely water with mucus. The major stimuli for its release are hypertonic and acidic chyme.
5. Segmentation is the principal motility pattern of the small intestine after a meal. It promotes mechanical breakdown and mixing of chyme with digestive juices and bile. Together with short-distance peristalsis, it also causes slow propulsion. Pacemaker cells set the rate of segmentation. Ileocecal valve opening is controlled by the gastroileal reflex and gastrin.
6. Between meals, the basic motor pattern is the migrating motor complex (a type of peristalsis) that sweeps any remaining contents of the small intestine toward the large intestine.

23.9 The large intestine absorbs water and eliminates feces (pp. 906–911)

1. The subdivisions of the large intestine are the cecum (and appendix), colon (ascending, transverse, descending, and sigmoid portions), rectum, and anal canal. It opens to the body exterior at the anus.
2. The longitudinal muscle in the muscularis is reduced to three bands (teniae coli), which pucker its wall, producing haustra. The mucosa of most of the large intestine is simple columnar epithelium containing abundant goblet cells.
3. The major functions of the large intestine are absorption of water, some electrolytes, and vitamins made by gut bacteria, and defecation (evacuation of food residues from the body).
4. The defecation reflex is triggered when feces enter the rectum. It involves parasympathetic reflexes leading to contraction of the rectal walls and is aided by the Valsalva maneuver.

PART 3
PHYSIOLOGY OF DIGESTION AND ABSORPTION

23.10 Digestion hydrolyzes food into nutrients that are absorbed across the gut epithelium (p. 912)

1. Digestion is accomplished by hydrolysis catalyzed by enzymes.
2. Virtually all of the foodstuffs and most of the water and electrolytes are absorbed in the small intestine. Most nutrients are absorbed by active transport processes.

23.11 How is each type of nutrient processed? (pp. 912–918)

1. Carbohydrates and proteins are digested to monomers, taken up into enterocytes of the small intestine by cotransport with Na^+, and passively transported across the basolateral membane into the capillaries.
2. Fat breakdown products are emulsified for digestion. The products of digestion are solubilized by bile salts (in micelles), resynthesized to triglycerides in the intestinal mucosal cells, and combined with other lipids and protein as chylomicrons that enter the lacteals.
3. Nucleic acids are digested into their components and actively transported into enterocytes.
4. Fat-soluble vitamins are absorbed by diffusion. Water-soluble vitamins are absorbed by active or passive transport.
5. Absorbed substances other than fat enter the villus blood capillaries and are transported to the liver via the hepatic portal vein.

Developmental Aspects of the Digestive System (pp. 918–919)

1. The mucosa of the alimentary canal develops from the endoderm, which folds to form a tube. The remaining three layers of the alimentary canal wall are formed by mesoderm. The glandular accessory organs (salivary glands, liver, pancreas, and gallbladder) form from outpocketings of the mucosa.
2. Important congenital abnormalities of the digestive tract include cleft palate/lip, tracheoesophageal fistula, and cystic fibrosis. All interfere with normal nutrition.
3. Various inflammations plague the digestive system throughout life. Appendicitis is common in adolescents, gastroenteritis and food poisoning can occur at any time (given the proper irritating factors), and ulcers and gallbladder problems increase in middle age.
4. The efficiency of all digestive system processes declines in the elderly, and periodontal disease is common. Diverticulosis, fecal incontinence, and GI tract cancers such as stomach and colon cancer appear with increasing frequency in an aging population.

REVIEW QUESTIONS

To access additional practice questions using your smartphone, tablet, or computer: MasteringA&P® > Study Area > Practice Tests & Quizzes

Level 1 Remember/Understand

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. The peritoneal cavity **(a)** is the same thing as the abdominopelvic cavity, **(b)** is filled with air, **(c)** like the pleural and pericardial cavities is a potential space containing serous fluid, **(d)** contains the pancreas and all of the duodenum.
2. Obstruction of the hepatopancreatic sphincter impairs digestion by reducing the availability of **(a)** bile and HCl, **(b)** HCl and intestinal juice, **(c)** pancreatic juice and intestinal juice, **(d)** pancreatic juice and bile.
3. The lamina propria forms part of the **(a)** muscularis externa, **(b)** submucosa, **(c)** serosa, **(d)** mucosa.
4. Carbohydrates are acted on by **(a)** peptidases, trypsin, and chymotrypsin, **(b)** amylase, maltase, and sucrase, **(c)** lipases, **(d)** peptidases, lipases, and galactase.

5. The parasympathetic nervous system influences digestion by **(a)** relaxing smooth muscle, **(b)** stimulating peristalsis and secretory activity, **(c)** constricting sphincters, **(d)** none of these.
6. The digestive juice product containing enzymes capable of digesting all four major foodstuff categories is **(a)** pancreatic, **(b)** gastric, **(c)** salivary, **(d)** biliary.
7. The site of production of cholecystokinin is **(a)** the stomach, **(b)** the small intestine, **(c)** the pancreas, **(d)** the large intestine.
8. Which of the following is not characteristic of the colon? **(a)** It is divided into ascending, transverse, and descending portions; **(b)** it contains abundant bacteria, some of which synthesize certain vitamins; **(c)** it is the main absorptive site; **(d)** it absorbs much of the water and salts remaining in the wastes.
9. The gallbladder **(a)** produces bile, **(b)** is attached to the pancreas, **(c)** stores and concentrates bile, **(d)** produces secretin.
10. The sphincter between the stomach and duodenum is **(a)** the pyloric sphincter, **(b)** the gastroesophageal sphincter, **(c)** the hepatopancreatic sphincter, **(d)** the ileocecal valve.
11. Name the six functional activities of the digestive system.
12. **(a)** What is the normal number of permanent teeth? Of deciduous teeth? **(b)** What substance covers the tooth crown? Its root? **(c)** What substance makes up the bulk of a tooth? **(d)** What and where is pulp?

Level 2 Apply/Analyze

13. Someone has eaten a meal of buttered toast, cream, and eggs. Which of the following would you expect to happen? **(a)** Compared to the period shortly after the meal, gastric motility and secretion of HCl decrease when the food reaches the duodenum; **(b)** gastric motility increases even as the person is chewing the food (before swallowing); **(c)** fat will be emulsified in the duodenum by the action of bile; **(d)** all of these.

In items 14–17, trace the path of a single protein molecule that has been ingested.

14. The protein molecule will be digested by enzymes made by **(a)** the mouth, stomach, and colon, **(b)** the stomach, liver, and small intestine, **(c)** the small intestine, mouth, and liver, **(d)** the pancreas, stomach, and small intestine.
15. The protein molecule must be digested before it can be transported to and utilized by the cells because **(a)** protein is only useful directly, **(b)** protein has a low pH, **(c)** proteins in the circulating blood produce an adverse osmotic pressure, **(d)** the protein is too large to be readily absorbed.
16. The products of protein digestion enter the bloodstream largely through cells lining **(a)** the stomach, **(b)** the small intestine, **(c)** the large intestine, **(d)** the bile duct.
17. Before the blood carrying the products of protein digestion reaches the heart, it first passes through capillary networks in **(a)** the spleen, **(b)** the lungs, **(c)** the liver, **(d)** the brain.
18. Make a simple line drawing of the organs of the alimentary canal and label each organ. Then add three labels to your drawing—salivary glands, liver, and pancreas—and use arrows to show where each of these organs empties its secretions into the alimentary canal.
19. Lara was on a diet but she could not eat less and kept claiming her stomach had a mind of its own. She was joking, but indeed, there is a "gut brain" called the enteric nervous system. Is it part of the parasympathetic and sympathetic nervous system? Explain.
20. **(a)** Describe the boundaries of the oral cavity. **(b)** Why do you suppose its mucosa is stratified squamous epithelium rather than the more typical simple columnar epithelium?
21. Describe the two phases of swallowing, noting the organs involved and the activities that occur.
22. Describe the role of these cells found in gastric glands: parietal, chief, mucous neck, and enteroendocrine.
23. Describe the regulation of the cephalic, gastric, and intestinal phases of gastric secretion.
24. **(a)** What is the relationship between the cystic, common hepatic, bile, and pancreatic ducts? **(b)** What is the point of fusion of the bile and pancreatic ducts called?
25. Explain why fatty stools result from the absence of bile or pancreatic juice.
26. Indicate the function of the stellate macrophages and the hepatocytes of the liver.
27. Explain why activation of pancreatic enzymes is delayed until they reach the small intestine.

Level 3 Evaluate/Synthesize

28. After a heavy meal rich with fried foods, Debby Collins, an overweight 45-year-old woman, was rushed to the emergency room with severe spasmodic pains in her epigastric region that radiated to the right side of her rib cage. She indicated that the attack came on suddenly, and her abdomen was found to be tender to the touch and somewhat rigid. What do you think is this patient's problem and why is her pain discontinuous (colicky)? What are the treatment options and what might happen if the problem is not resolved?
29. A baby is admitted to the hospital with a history of diarrhea and watery feces occurring over the last three days. The baby has sunken fontanelles, indicating extreme dehydration. Tests indicate that the baby has a bacterium-induced colitis, and antibiotics are prescribed. Because of the baby's loss of intestinal juices, do you think that his blood pH would indicate acidosis or alkalosis? Explain your reasoning.
30. Troy Francis, a middle-aged salesman, complains of a burning pain in the "pit of his stomach," usually beginning about two hours after eating and abating after drinking a glass of milk. When asked to indicate the site, he points to his epigastric region. The GI tract is examined by X-ray fluoroscopy. A gastric ulcer is visualized, and drug therapy using a proton pump inhibitor and antibiotics is recommended. **(a)** Why is this treatment suggested? **(b)** What are the possible consequences of nontreatment?
31. Dr. Dolan used an endoscope to view Mr. Habib's colon. He noted the presence of several polyps and removed them during the same procedure. What is an endoscope? Why did Dr. Dolan opt to remove the polyps immediately? (Hint: See *A Closer Look* on pp. 144–145.)
32. Mr. Holden has had severe diarrhea all day and is severely weakened. Explain why his nurse is concerned about his present condition.

CLINICAL CASE STUDY

48-Year-Old Female with Gallstones

Ms. Burton, 48, presents at the clinic complaining of abdominal pain. She is a middle-aged woman, overweight, pale and sweating, with jaundice (yellowish skin and sclerae). Her heart rate is 102 beats/min and BP is 145/98 mm Hg. She describes the pain as "severe" and "steady" over the past night, accompanied by nausea and vomiting. She sits leaning forward and indicates that the pain is in the epigastric region radiating up to the tip of the right shoulder.

Ms. Burton's medical history shows that she has had several episodes of biliary colic (pain caused by gallstones going through the bile duct). She says her current pain is "sort of like that, but it's lasted longer." She says her last meal was a seven-cheese pizza the previous night, and that the pain began 3–4 hours after eating. She denies drinking or smoking.

1. Do any of Ms. Burton's signs and symptoms suggest that her current problem is related to the biliary system? Why or why not?
2. Why would pain related to gallstones begin after a high-fat meal?
3. When Ms. Burton previously had gallstones, they passed through her biliary ducts into her duodenum and the pain resolved. What structures (in order) did the stones pass through?
4. + NCLEX-STYLE If Ms. Burton's current problem is related to obstruction of the biliary ducts, which other signs or symptoms would you expect her to develop?
   - **a.** Blood in her stool
   - **b.** Dizziness and decreased consciousness
   - **c.** Fatty and gray stools
   - **d.** Low RBC count

Ms. Burton's doctor orders a complete blood count, tests for liver and pancreatic enzymes in her blood, and bedside ultrasonography. The ultrasonography reveals dilation of her bile and pancreatic ducts and a gallstone lodged in the hepatopancreatic ampulla. Blood tests come back positive for pancreatic amylase and pancreatic lipase.

5. + NCLEX-STYLE Which of the following correctly interprets these results?
   - **a.** The location of the gallstone is good news because it shows that the stone has almost passed into the duodenum.
   - **b.** The location of the gallstone is a problem because it blocks bile from entering the duodenum and forces bile up into the pancreas.
   - **c.** The presence of pancreatic enzymes in the blood is good news because it indicates that the pancreas is still functioning.
   - **d.** The dilation of the ducts is good news because that will make it easier for gallstones to pass.

Ms. Burton was diagnosed with acute pancreatitis secondary to a gallstone and taken to surgery where the gallstone and her gallbladder were removed. After surgery, her abdominal pain resolved and her blood values returned to normal.

24 Nutrition, Metabolism, and Energy Balance

In this chapter, you will learn that

Nutrients are metabolized (used for building blocks or energy), and energy intake and output of the body are regulated

by investigating

- **Part 1 Nutrients** (by asking)
  - 24.1 What are carbohydrates, lipids, and proteins used for?
  - 24.2 What are vitamins and minerals used for?
- **Part 2 Metabolism** (by asking)
  - 24.3 What is metabolism? (looking closer at)
    - 24.4 Carbohydrate metabolism
    - 24.5 Lipid metabolism
    - 24.6 Protein metabolism
    - 24.7 Metabolic states of the body
    - 24.8 The metabolic role of the liver
- **Part 3 Energy Balance** (by asking)
  - 24.9 How is food intake regulated?
  - 24.10 What factors affect metabolic rate?
  - 24.11 How is body temperature regulated?

and finally, exploring

Developmental Aspects of Nutrition and Metabolism

Are you a food lover? We are too. In fact, most people fall into one of two groups—those who live to eat and those who eat to live. The saying "you are what you eat" is true in that part of the food we eat is converted to our living flesh. In other words, our bodies use some nutrients to build cell structures, replace worn-out parts, and synthesize functional molecules. However, most nutrients we ingest are used as metabolic fuel. That is, they are oxidized and transformed to **ATP**, the chemical energy form used by cells (◀ pp. 55–56).

In Chapter 23, we talked about how foods are digested and absorbed, but what happens to these foods once they enter the blood? We will answer this question as we examine both the nature of nutrients and their metabolic roles.

PART 1

NUTRIENTS

Learning Outcomes

- **Define nutrient, essential nutrient, and calorie.**
- **List the five major nutrient categories. Note important sources and main cellular uses.**

A **nutrient** is a substance in food the body uses to promote normal growth, maintenance, and repair. The nutrients needed for health divide into five categories. Three of these—carbohydrates, lipids, and proteins—are **macronutrients** that make up most of what we eat. The fourth and fifth categories, vitamins and minerals, though equally crucial for health, are **micronutrients** required in only minute amounts.

Water accounts for about 60% by volume of the food we eat. We described its importance in the body in Chapter 2, so here we consider only the five nutrient categories listed above.

About 40 molecules, called **essential nutrients**, cannot be made fast enough to meet the body's needs, so our diet must provide them. As long as we ingest all the essential nutrients, the body can synthesize the hundreds of additional molecules required for life and good health. The ability of cells, especially liver cells, to convert one type of molecule to another is truly remarkable. These interconversions allow the body to use a wide range of foods and to adjust to varying food intakes. While "essential" is a standard way to describe the chemicals that must be obtained from outside sources, both essential and nonessential nutrients are equally vital for normal functioning.

Most foods offer a combination of nutrients. A balanced diet of foods from each of the different food groups normally guarantees adequate amounts of all the needed nutrients and adequate energy.

The energy value of foods is measured in **kilocalories (kcal)**. One kilocalorie is the amount of heat energy needed to raise the temperature of 1 kilogram of water 1°C (1.8°F). This unit is the "calorie" (C) that dieters count so conscientiously. Not all foods have the same amount of energy. Carbohydrates and proteins each have 4 kcal per gram, but lipids have almost 9 kcal per gram.

Various organizations release dietary recommendations. Most of these emphasize eating more vegetables, whole grains, and fruits.

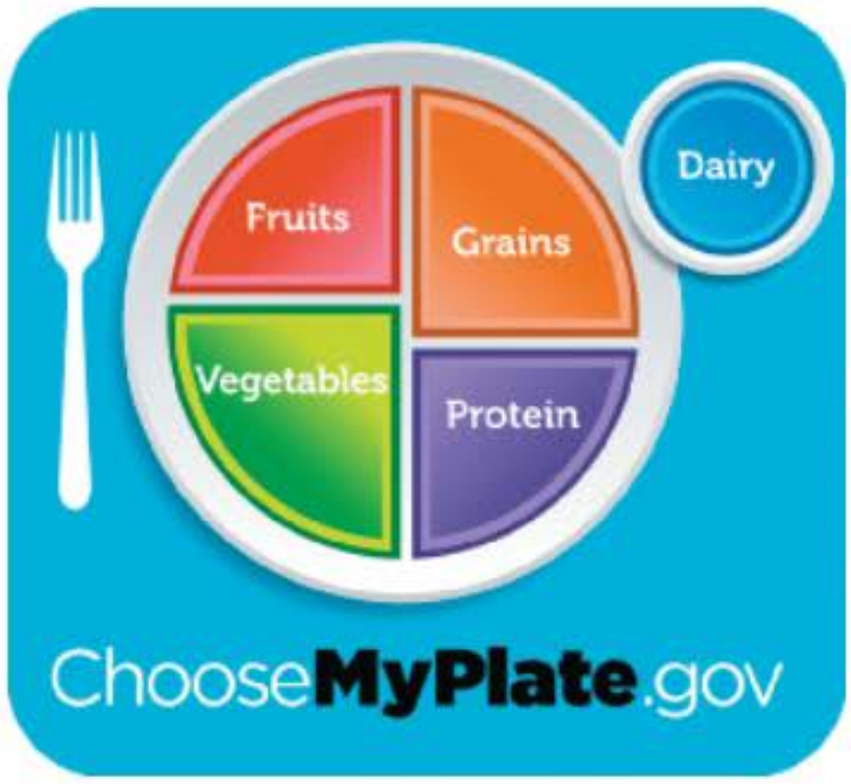

Figure 24.1 USDA's MyPlate food guide.

For example, the U.S. Department of Agriculture (USDA) guidelines are represented as portions of a dinner plate (**Figure 24.1**). This image suggests how consumers might plan their meals relative to amounts and variety of foods from each food group. The MyPlate website provides details on healthy choices in each food group as well as personalized information according to age, sex, and activity level (www.choosemyplate.gov).

Nutrition advice is constantly in flux and often mired in the self-interest of food companies. Nonetheless, basic dietary principles have not changed in years and are not in dispute: Eat only what you need; eat plenty of fruits, vegetables, and whole grains; avoid junk food.

24.1 Carbohydrates, lipids, and proteins supply energy and are used as building blocks

Learning Outcomes

- **Distinguish between simple and complex carbohydrate sources.**
- **Distinguish between saturated, unsaturated, and trans fatty acid sources.**
- **Distinguish between nutritionally complete and incomplete proteins.**
- **Define nitrogen balance and indicate possible causes of positive and negative nitrogen balance.**
- **Indicate the major uses of carbohydrates, lipids, and proteins in the body.**

Carbohydrates

Dietary Sources

Except for milk sugar (lactose) and negligible amounts of glycogen in meats, all the carbohydrates we ingest are derived from plants. Sugars (monosaccharides and disaccharides;

◀ pp. 43–44) come from fruits, sugar cane, sugar beets, honey, and milk. The polysaccharide starch is found in grains and vegetables.

Two varieties of polysaccharides provide fiber (◀ p. 44). Cellulose, plentiful in most vegetables, is not digested by humans but provides roughage, or *insoluble fiber*, which increases the bulk of the stool and facilitates defecation. *Soluble fiber*, such as pectin found in apples and citrus fruits, reduces blood cholesterol levels.

Uses in the Body

The monosaccharide **glucose** is *the* carbohydrate molecule ultimately used as fuel by body cells to produce ATP. Carbohydrate digestion also yields fructose and galactose, but the liver converts these monosaccharides to glucose before they enter the general circulation.

Many body cells also use fats as energy sources, but neurons and red blood cells rely almost entirely on glucose for their energy needs. Because even a temporary shortage of blood glucose can severely depress brain function and lead to neuron death, the body carefully monitors and regulates blood glucose levels. Any glucose in excess of what is needed for ATP synthesis is converted to glycogen or fat and stored for later use.

There are few other uses for carbohydrates. Small amounts of pentose sugars are used to synthesize nucleic acids, and short chains of sugars are attached to externally facing plasma membrane proteins and lipids to form the glycocalyx (◀ pp. 66–67).

Dietary Requirements

The low-carbohydrate diet of the Inuit (Eskimos) and the high-carbohydrate diet of peoples in the Far East indicate that humans can be healthy even with wide variations in carbohydrate intake. The recommended intake to maintain health is 45–65% of total calorie intake, with the emphasis on *complex* carbohydrates (whole grains and vegetables) rather than simple carbohydrates (monosaccharides and disaccharides).

American adults typically consume about 46% of dietary food energy in the form of carbohydrates. Because starchy foods (rice, pasta, breads) cost less than meat and other high-protein foods, carbohydrates often make up a greater percentage of the diet in low-income groups. Highly processed carbohydrate foods such as candy and soft drinks only provide concentrated energy sources—so-called empty calories. Eating refined, sugary foods instead of more complex carbohydrates may cause nutritional deficiencies as well as obesity. **Table 24.1** (p. 930) lists other possible consequences of excessive intake of carbohydrates.

Lipids

Dietary Sources

The most abundant dietary lipids are triglycerides (◀ p. 45). We eat saturated fats (◀ p. 46) in animal products such as meat and dairy foods, in a few tropical plant products such as coconut, and in hydrogenated oils (trans fats) such as margarine and solid shortenings used in baking. Unsaturated fats (◀ p. 46) are present in seeds, nuts, olive oil, and most vegetable oils.

Major sources of cholesterol (◀ p. 48) are egg yolk, meats and organ meats, shellfish, and milk products. However, the liver produces about 85% of blood cholesterol regardless of dietary intake.

The liver is also adept at converting one fatty acid to another, but there are two *essential fatty acids* that it cannot synthesize:

- *Linoleic acid* (lin″o-le′ik), an omega-6 fatty acid that is a component of *lecithin* (les′ĭ-thin)
- *Linolenic acid*, an omega-3 fatty acid

Fortunately, most vegetable oils contain both linoleic and linolenic acids.

Uses in the Body

Fats make foods tender, flaky, or creamy, and make us feel full and satisfied. Fats in the body are necessary for several reasons:

- Fatty deposits in adipose tissue provide (1) a protective cushion around body organs, (2) an insulating layer beneath the skin, and (3) an easy-to-store concentrated source of energy.
- Phospholipids (◀ p. 47) are an integral component of myelin sheaths and cellular membranes.
- Cholesterol is a stabilizing component of plasma membranes and is the precursor from which bile salts, steroid hormones, and other important molecules are formed. Unlike triglycerides, cholesterol is not used for energy.
- *Prostaglandins* (pros″tah-glan′dinz; ◀ p. 48), regulatory molecules formed from linoleic acid via arachidonic acid (ah″rah-kĭ-don′ik), play a role in smooth muscle contraction, control of blood pressure, and inflammation.
- Triglycerides are the major energy fuel of skeletal muscle and hepatocytes.
- Fats help the body absorb fat-soluble vitamins.

Dietary Requirements

Fats represent over 40% of the calories in the typical American diet. Once viewed as detrimental, fat intake in the diet is being reconsidered. Most current guidelines suggest:

- Fats should represent 20–35% of total caloric intake.
- Saturated fats should be limited to 10% or less of total caloric intake.

Because the body can synthesize as much cholesterol as it needs, cholesterol is not required in the diet. Many guidelines still recommend keeping cholesterol intake as low as possible. This is particularly important for individuals who already have high total blood cholesterol levels, which have been associated with cardiovascular disease. Table 24.1 summarizes sources of the various lipid classes and consequences of deficiency or excessive intake.

Proteins

Dietary Sources

Proteins in eggs, milk, fish, and most meats are **complete proteins** that meet all the body's amino acid (◀ p. 48) requirements

for tissue maintenance and growth (Table 24.1). Legumes (beans and peas), nuts, and cereals are protein-rich, but their proteins are nutritionally incomplete because they are low in one or more of the essential amino acids. The exception to this generalization is soybeans, which provide plant-derived complete proteins. Animal products contain the highest-quality proteins, in other words, those with the greatest amount and best ratios of *essential amino acids* (**Figure 24.2**).

Strict vegetarians must carefully plan their diets to obtain all the essential amino acids and prevent protein malnutrition. When ingested together, cereal grains and legumes provide all the essential amino acids (Figure 24.2b). Some combination of these foods is found in the diets of all cultures (for instance, the rice and beans seen on nearly every plate in a Mexican restaurant). For nonvegetarians, grains and legumes are useful as partial substitutes for more expensive animal proteins.

Uses in the Body

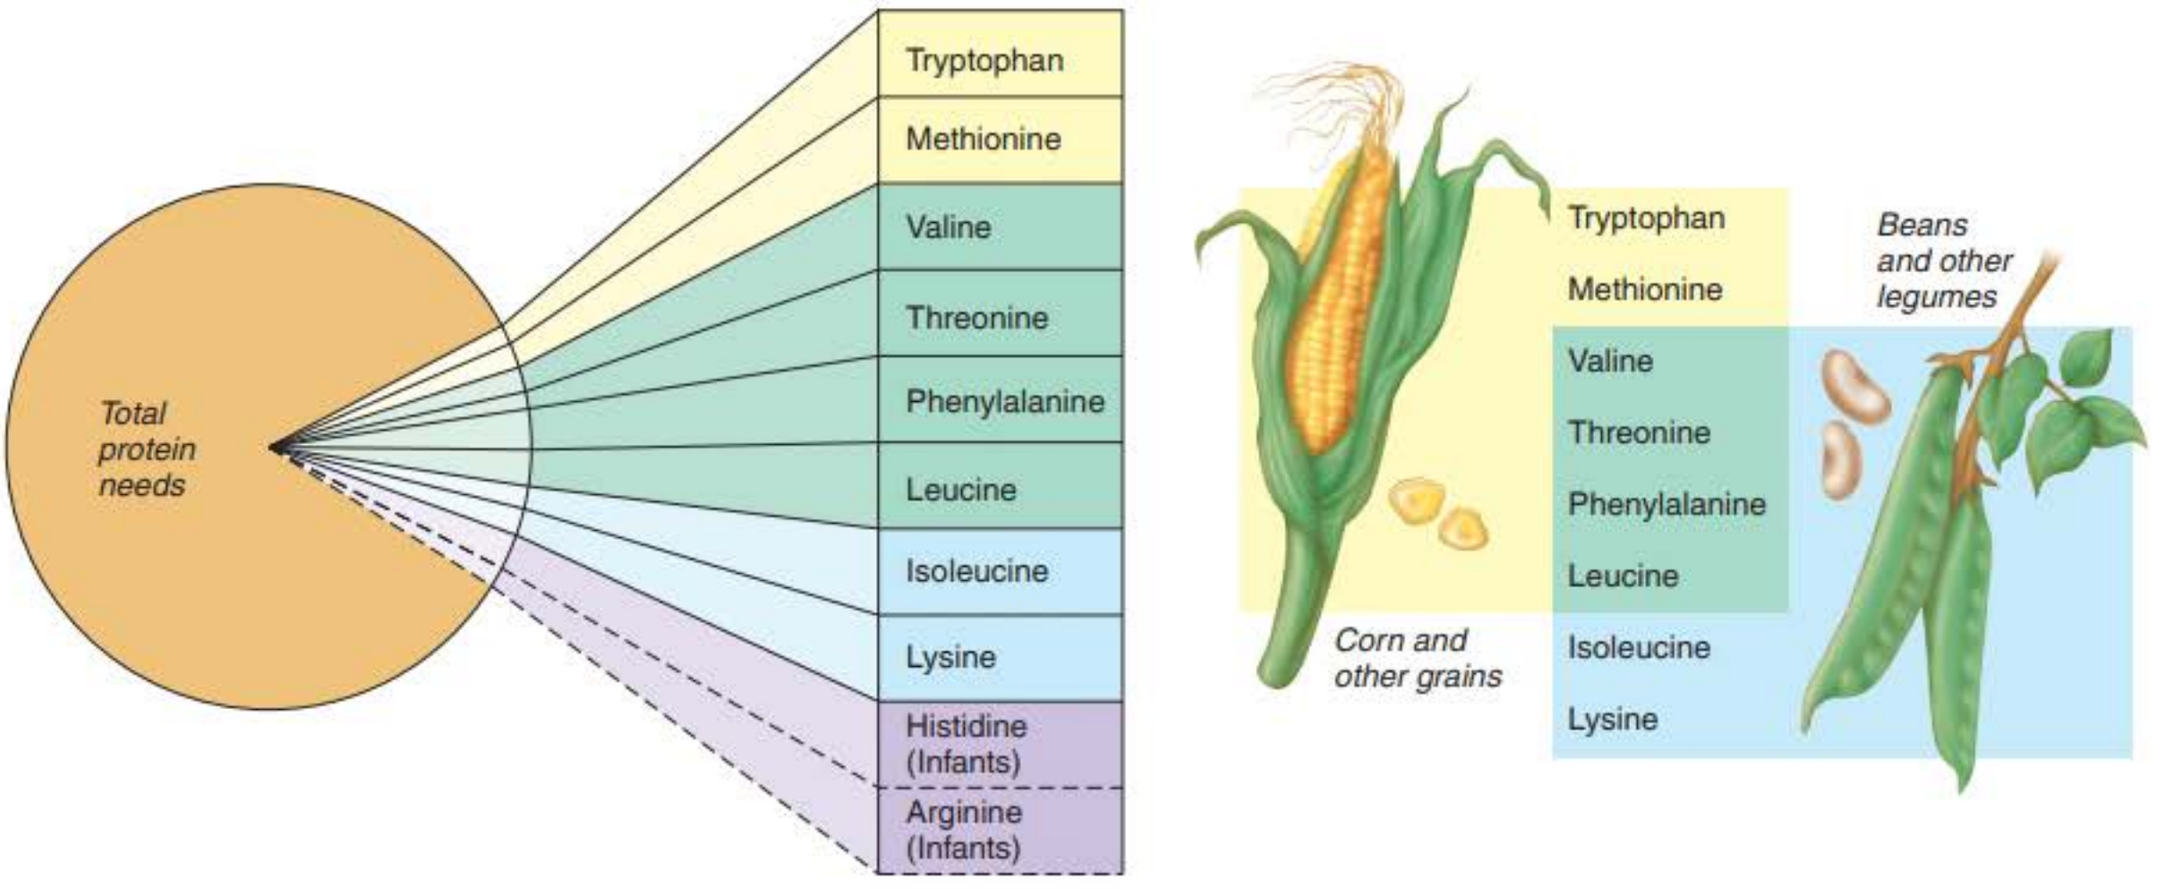
Proteins are important structural materials of the body, including, for example, keratin in skin, collagen and elastin in connective tissues, and muscle proteins. In addition, functional proteins such as enzymes and some hormones regulate an incredible variety of body functions. Whether amino acids are used to synthesize new proteins or burned for energy depends on a number of factors:

- **The all-or-none rule.** All amino acids needed to make a particular protein must be present in a cell at the same time and in sufficient amounts. If one is missing, the protein cannot be made. Because essential amino acids cannot be stored, those not used immediately to build proteins are oxidized for energy or converted to carbohydrates or fats.
- **Adequacy of caloric intake.** For optimal protein synthesis, the diet must supply sufficient carbohydrate or fat calories for ATP production. When it doesn't, dietary and tissue proteins are used for energy.
- **Hormonal controls.** Certain hormones, called *anabolic hormones*, accelerate protein synthesis and growth. The effects of these hormones vary continually throughout life. For example, pituitary growth hormone stimulates tissue growth during childhood and conserves protein in adults, and estrogens trigger the growth spurt of adolescence (◀ p. 188). Other hormones, such as the adrenal glucocorticoids released during stress, enhance protein breakdown and conversion of amino acids to glucose.

In healthy adults the rate of protein synthesis equals the rate of protein breakdown and loss, a homeostatic state called **nitrogen balance**. The body is in nitrogen balance when the amount of nitrogen ingested in proteins equals the amount excreted in urine and feces.

The body is in *positive nitrogen balance* when the amount of protein incorporated into tissue is greater than the amount being broken down and used for energy—the normal situation in growing children and pregnant women. A positive balance also occurs when tissues are being repaired following illness or injury.

In *negative nitrogen balance*, protein breakdown for energy exceeds the amount of protein being incorporated into tissues.



(a) Essential amino acids

(b) Corn and beans together can provide all eight essential amino acids

Figure 24.2 Essential amino acids. (a) The essential amino acids represent only a small percentage of the total recommended protein intake. Histidine and arginine are essential in infants but not in adults. **(b)** Incomplete proteins from different sources can be combined in one meal to provide all essential amino acids.

Table 24.1 Summary of Carbohydrate, Lipid, and Protein Nutrients

FOOD SOURCES	RECOMMENDED DAILY ALLOWANCE (RDA) FOR ADULTS	*PROBLEMS*	
		EXCESSES	DEFICITS
Carbohydrates			
Total Digestible	130 g	Obesity; diabetes mellitus; nutritional deficits; dental caries; gastrointestinal irritation; elevated triglycerides in plasma	Tissue wasting (in extreme deprivation); metabolic acidosis resulting from accelerated fat use for energy
• **Complex carbohydrates** (starches): bread, cereal, crackers, flour, pasta, rice, potatoes	45–65% of total caloric intake		
• **Simple carbohydrates (sugars):** carbonated drinks, candy, fruit, ice cream, pudding, young (immature) vegetables			
Total Fiber (indigestible)	25–30 g		
Lipids			
Total: Animal sources (such as meat and dairy products) and plant sources (such as oils from nuts and seeds)	65 g 20–35% of total caloric intake	Obesity; may increase risk of cardiovascular disease (particularly with trans fat)	Weight loss; fat stores and tissue proteins catabolized to provide metabolic energy; problems controlling heat loss (due to depletion of subcutaneous fat)
• **Linoleic acid (an omega-6 fatty acid):** nuts, seeds, and vegetable oils (e.g., corn, soy, safflower)	11–17 g		
• **Linolenic acid (an omega-3 fatty acid):** fish oil, vegetable oils (e.g., canola, soy, flax), walnuts	1.1–1.6 g	Excess dietary intake of omega-3 fatty acid may increase risk of atherosclerosis	Poor growth; skin lesions (eczema-like); depression
• **Cholesterol:** organ meats (liver, kidneys, brains), egg yolks, fish roe; smaller concentrations in milk products and meat	As low as possible	Levels of blood cholesterol and low-density lipoproteins may increase; correlated with increased risk of cardiovascular disease	Possible increased risk of stroke (CVA) in susceptible individuals
Proteins			
• **Complete proteins:** eggs, milk, milk products, meat (fish, poultry, pork, beef, lamb), soybeans	0.8 g/kg body weight 12–20% of total caloric intake	Obesity; enhanced calcium excretion and bone loss; high cholesterol levels in blood; kidney stones	Profound weight loss and tissue wasting; retarded growth in children; anemia; edema (due to deficits of plasma proteins)
• **Incomplete proteins:** legumes (lima beans, kidney beans, lentils); nuts and seeds; grains and cereals; vegetables			During pregnancy: miscarriage or premature birth

This occurs during physical and emotional stress (for example, infection, injury, or burns), when the quality or quantity of dietary protein is poor, or during starvation.

Dietary Requirements

Besides supplying essential amino acids, dietary proteins furnish the raw materials for making nonessential amino acids and various nonprotein nitrogen-containing substances. The amount of protein a person needs to ingest reflects his or her age, size, metabolic rate, and the need to build new proteins (whether the body is in positive nitrogen balance). As a rule of thumb, nutritionists recommend a daily intake of 0.8 g per kilogram of body weight.

Check Your Understanding

24.2 Most vitamins act as coenzymes; minerals have many roles in the body

Learning Outcomes

- **Distinguish between fat- and water-soluble vitamins, and list the vitamins in each group.**
- **For each vitamin, list important sources, body functions, and important consequences of its deficit or excess.**
- **List minerals essential for health.**
- **Indicate important dietary sources of minerals and describe how each is used.**

Vitamins

Vitamins (*vita* = life) are organic compounds needed in minute amounts for growth and good health. Unlike other organic nutrients, vitamins do not serve as an energy source nor as building blocks, but they are crucial in helping the body use those nutrients that do. Without vitamins, all the carbohydrates, proteins, and fats we eat would be useless.

Most vitamins function as **coenzymes** (or parts of coenzymes), which act with an enzyme to accomplish a particular chemical task. For example, the B vitamins act as coenzymes when glucose is oxidized for energy.

Most vitamins are not made in the body, so we must ingest them in foods or vitamin supplements. The exceptions are vitamin D made in the skin, and small amounts of B vitamins and vitamin K synthesized by intestinal bacteria. In addition, the body can convert *beta-carotene* (kar′o-tēn), the orange pigment in carrots and other foods, to vitamin A. (For this reason, beta-carotene and substances like it are called *provitamins*.)

Vitamins are found in all major food groups, but no one food contains all the required vitamins. A balanced diet is the best way to ensure a full vitamin complement.

Initially vitamins were given letter designations that indicated the order of their discovery. Although more chemically descriptive names have been assigned to them, this earlier terminology is still commonly used.

Vitamins are either water soluble or fat soluble. **Water-soluble** vitamins—the B-complex vitamins and vitamin C—are absorbed along with water from the gastrointestinal tract. (The exception is vitamin B_{12}: To be absorbed, it must bind to *intrinsic factor*, a stomach secretion; ◀ p. 917.) The body's lean tissue stores insignificant amounts of water-soluble vitamins, and any ingested amounts not taken up by cells within an hour or so are excreted in urine. Consequently, health problems resulting from excessive levels of these vitamins are rare.

Fat-soluble vitamins (A, D, E, and K) are absorbed together with other lipids in the gut. Anything that interferes with lipid absorption also interferes with the uptake of fat-soluble vitamins. Except for vitamin K, fat-soluble vitamins are stored in the body, and pathologies due to fat-soluble vitamin toxicity, particularly excess vitamin A, are well documented.

Metabolism uses oxygen, and sometimes these reactions generate potentially tissue-damaging free radicals (molecules with an unpaired electron; ◀ p. 86). Vitamins A, C, E, and the mineral selenium participate in *antioxidant reactions* that neutralize free radicals. The whole story of how antioxidants interact in the body is still murky. Chemists propose that antioxidants pass the dangerous free electron from one molecule to the next. Eventually, a chemical such as glutathione absorbs and neutralizes the unpaired electron. Broccoli, cabbage, cauliflower, and brussels sprouts are all good sources of vitamins A and C.

The notion that megadoses of vitamin supplements are the road to eternal youth and glowing health is useless at best—and at worst, may cause serious health problems, particularly in the case of fat-soluble vitamins. **Table 24.2** (p. 932) contains an overview of the roles of vitamins in the body.

Minerals

The body requires moderate amounts of seven **minerals** (calcium, phosphorus, potassium, sulfur, sodium, chlorine, magnesium) and trace amounts of about a dozen others (**Table 24.3** on p. 933). Minerals make up about 4% of the body by weight, with calcium and phosphorus (as bone salts) accounting for about three-quarters of this amount.

Minerals, like vitamins, are not used for fuel but work with other nutrients to ensure a smoothly functioning body. Incorporating minerals into structures makes them stronger. For example, calcium, phosphorus, and magnesium salts harden the teeth and strengthen the skeleton.

Most minerals are ionized in body fluids or bound to organic compounds to form phospholipids, hormones, and various proteins. For example, iron is essential to the oxygen-binding heme of hemoglobin, and sodium and chloride ions are the major electrolytes in blood. The amount of a particular mineral in the body gives very few clues to its importance in body function.

Table 24.2 Vitamins

VITAMIN	MAJOR DIETARY SOURCES	MAJOR FUNCTIONS IN THE BODY	SYMPTOMS OF DEFICIENCY OR EXTREME EXCESS
Water-Soluble Vitamins			
Vitamin B_1 (thiamine)	Pork, legumes, peanuts, whole grains	Coenzyme used in removing CO_2 from organic compounds	Beriberi (nerve disorder—tingling, poor coordination, reduced heart function)
Vitamin B_2 (riboflavin)	Dairy products, meats, enriched grains, vegetables	Component of coenzymes FAD and FMN	Skin lesions such as cracks at corners of mouth
Vitamin B_3 (niacin)	Nuts, meats, grains	Component of coenzymes NAD^+ and $NADP^+$	Skin and gastrointestinal lesions, nervous disorders Liver damage
Vitamin B_5 (pantothenic acid)	Most foods: meats, dairy products, whole grains, etc.	Component of coenzyme A	Fatigue, numbness, tingling of hands and feet
Vitamin B_6 (pyridoxine)	Meats, vegetables, whole grains	Coenzyme used in amino acid metabolism	Irritability, convulsions, muscular twitching, anemia Unstable gait, numb feet, poor coordination
Vitamin B_7 (biotin)	Legumes, other vegetables, meats	Coenzyme in synthesis of fat, glycogen, and amino acids	Scaly skin inflammation, neuromuscular disorders
Vitamin B_9 (folic acid)	Green vegetables, oranges, nuts, legumes, whole grains	Coenzyme in nucleic acid and amino acid metabolism	Anemia, birth defects May mask deficiency of vitamin B_{12}
Vitamin B_{12}	Meats, eggs, dairy products	Coenzyme in nucleic acid metabolism; maturation of red blood cells	Anemia, nervous system disorders (numbness, loss of balance)
Vitamin C (ascorbic acid)	Fruits and vegetables, especially citrus fruits, broccoli, tomatoes	Used in collagen synthesis (such as for bone, cartilage, gums); antioxidant	Scurvy (degeneration of skin, teeth, blood vessels), weakness, delayed wound healing Gastrointestinal upset
Fat-Soluble Vitamins			
Vitamin A (retinol)	Provitamin A (beta-carotene) in deep green and orange vegetables and fruits; retinol in dairy products	Component of visual pigments; maintenance of epithelial tissues; antioxidant	Blindness, skin disorders, impaired immunity Headache, irritability, vomiting, hair loss, blurred vision, liver and bone damage
Vitamin D	Dairy products, egg yolk; also made in human skin in presence of sunlight	Aids in absorption and use of calcium and phosphorus	Rickets (bone deformities) in children, bone softening in adults Brain, cardiovascular, and kidney damage
Vitamin E (tocopherol)	Vegetable oils, nuts, seeds	Antioxidant; helps prevent damage to cell membranes	Degeneration of the nervous system
Vitamin K (phylloquinone)	Green vegetables, tea; also made by colon bacteria	Important in blood clotting	Defective blood clotting Liver damage and anemia

For example, just a few milligrams of iodine (required for thyroid hormone synthesis) can make a critical difference to health.

A fine balance between uptake and excretion is crucial for retaining needed amounts of minerals while preventing toxic overload. Sodium present in virtually all natural and minimally processed foods poses little or no health risk. However, the large amounts added to processed foods and sprinkled on food prior to eating may contribute to fluid retention and high blood pressure.

Fats and sugars are practically devoid of minerals, and highly refined cereals and grains are poor sources. The most mineral-rich foods are legumes and other vegetables, milk, and some meats.

Check Your Understanding

5. Vitamins are not used for energy fuels. What are they used for?
6. Which mineral is essential for thyroxine synthesis? For making bones hard? For hemoglobin synthesis?
7. MAKE CONNECTIONS Which B vitamin requires the help of a product made in the stomach to be absorbed? What is that gastric product and which cells in the gastric mucosa secrete it? What part of the small intestine ultimately absorbs this B vitamin? (Hint: See Chapter 23.) Lack of this B vitamin causes what kind of anemia? (Hint: See Chapter 17.)

For answers, seeAnswers Appendix.

Table 24.3 Minerals in the Body

MINERAL	MAJOR DIETARY SOURCES	MAJOR FUNCTIONS IN THE BODY	SYMPTOMS OF DEFICIENCY*
Greater than 200 mg per Day Required			
Calcium (Ca)	Dairy products, dark green vegetables, legumes	Bone and tooth formation, blood clotting, nerve and muscle function	Impaired growth, possibly loss of bone mass
Phosphorus (P)	Dairy products, meats, grains	Bone and tooth formation, acid-base balance, nucleotide synthesis	Weakness, loss of minerals from bone, calcium loss
Sulfur (S)	Proteins from many sources	Component of certain amino acids	Symptoms of protein deficiency
Potassium (K)	Meats, dairy products, many fruits and vegetables, grains	Nerve function, acid-base balance	Muscular weakness, paralysis, nausea, heart failure
Chlorine (Cl)	Table salt	Acid-base balance, formation of gastric juice, nerve function, osmotic balance	Muscle cramps, reduced appetite
Sodium (Na)	Table salt	Water balance, blood pressure, nerve function	Muscle cramps, reduced appetite
Magnesium (Mg)	Whole grains, green leafy vegetables	Cofactor; ATP bioenergetics	Nervous system disturbances
Trace Amounts Required			
Iron (Fe)	Meats, eggs, legumes, whole grains, green leafy vegetables	Component of hemoglobin and of electron carriers in energy metabolism; enzyme cofactor	Iron-deficiency anemia, weakness, impaired immunity
Fluorine (F)	Drinking water, tea, seafood	Maintenance of tooth (and probably bone) structure	Higher frequency of tooth decay
Zinc (Zn)	Meats, seafood, grains	Component of certain digestive enzymes and other proteins	Growth failure, skin abnormalities, reproductive failure, impaired immunity
Copper (Cu)	Seafood, nuts, legumes, organ meats	Enzyme cofactor in iron metabolism, melanin synthesis, electron transport	Anemia, cardiovascular abnormalities
Manganese (Mn)	Nuts, grains, vegetables, fruits, tea	Enzyme cofactor	Abnormal bone and cartilage
Iodine (I)	Seafood, iodized salt	Component of thyroid hormones	Goiter (enlarged thyroid)
Cobalt (Co)	Meats and dairy products	Component of vitamin B_{12}	None, except as B_{12} deficiency
Selenium (Se)	Seafood, meats, whole grains	Enzyme cofactor for antioxidant enzymes	Muscle pain, possibly heart muscle deterioration
Chromium (Cr)	Brewer's yeast, liver, seafood, meats, some vegetables	Involved in glucose and energy metabolism	Impaired glucose metabolism
Molybdenum (Mo)	Legumes, grains, some vegetables	Enzyme cofactor	Disorder in excretion of nitrogen-containing compounds

*All of these minerals are also harmful when consumed in excess.

PART 2

METABOLISM

Once inside body cells, nutrients become involved in an incredible variety of biochemical reactions known collectively as **metabolism** (*metabol* = change). During metabolism, substances are constantly built up and torn down. Cells use energy to extract more energy from foods, and then use some of this extracted energy to drive their activities. Even at rest, the body uses energy on a grand scale.

24.3 Metabolism is the sum of all biochemical reactions in the body

Learning Outcomes

- **Define metabolism. Explain how catabolism and anabolism differ.**
- **Define oxidation and reduction and indicate the importance of these reactions in metabolism.**
- **Indicate the role of coenzymes used in cellular oxidation reactions.**
- **Explain the difference between substrate-level phosphorylation and oxidative phosphorylation.**

Anabolism and Catabolism

Metabolic processes are either *anabolic* (synthetic, building up) or *catabolic* (degradative, tearing down). **Anabolism** (ah-nab′o-lizm) is the general term for all reactions that build larger molecules or structures from smaller ones, such as the bonding together of amino acids to build proteins. **Catabolism** (kah-tab′o-lizm) refers to all processes that break down complex structures to simpler ones—for example, the hydrolysis of foods in the digestive tract.

Three major stages are involved in processing energy-containing nutrients in the body (**Figure 24.3**).

- *Stage 1* is digestion and absorption in the gastrointestinal tract (◀ p. 912). The absorbed nutrients are then transported in blood to the tissue cells.
- *Stage 2* occurs in the cytoplasm of tissue cells. Newly delivered nutrients are either built into lipids, proteins, and glycogen by anabolic pathways or broken down by catabolic pathways to smaller fragments. Many molecules end up as *pyruvic acid* (pi-roo′vik), an important metabolic intermediate.
- *Stage 3*, which occurs in the mitochondria, is almost entirely catabolic. It requires oxygen and completes the breakdown of stage 2 products, most of which are first converted to *acetyl CoA* (as′ĕ-til ko-a′). This process produces carbon dioxide and water and harvests large amounts of ATP.

The group of catabolic reactions collectively called **cellular respiration** consists of glycolysis, the citric acid cycle, and oxidative phosphorylation. As we will see shortly, these reactions take food fuels, particularly glucose, and break them down. Some of the energy released is captured to form ATP, the cells' energy currency that links energy-releasing catabolic reactions to cellular work.

Recall from Chapter 2 (◀ p. 55) that reactions driven by ATP are coupled. As ATP is hydrolyzed, enzymes shift its high-energy phosphate groups to other molecules, which are then said to be **phosphorylated** (fos″for′ĭ-la-ted). Phosphorylation primes a molecule, changing it in a way that increases its activity, produces motion, or does work. For example, phosphorylation activates many regulatory enzymes that catalyze key steps in metabolic pathways.

The body can also store energy in fuels, such as glycogen and fats, and mobilize these stores later to produce ATP for cellular use.

You do not need to memorize Figure 24.3, but you may want to refer to it often as a cohesive summary of nutrient processing and metabolism in the body.

Oxidation-Reduction Reactions and the Role of Coenzymes

Many of the reactions that take place within cells are **oxidation reactions**. *Oxidation* was originally defined as the combination of oxygen with other elements, seen in the rusting of iron (the slow formation of iron oxide) and the burning of wood. In burning, oxygen combines rapidly with carbon, releasing carbon dioxide, water, and an enormous amount of energy as heat and light.

However, oxidation also occurs when hydrogen atoms are *removed* from compounds. So *oxidation is the gain of oxygen or the loss of hydrogen*. As explained in Chapter 2 (◀ p. 37), whichever way oxidation occurs, the oxidized substance always *loses* (or nearly loses) electrons as they move to (or toward) a substance that more strongly attracts them.

To explain this loss of electrons, let's review the consequences of different electron-attracting abilities of atoms (◀ pp. 31–35). Consider a molecule made up of a hydrogen atom plus some other kinds of atoms. Hydrogen is very electropositive, so its lone electron usually spends more time orbiting the other atoms of the molecule. But when a hydrogen *atom* is removed, its electron goes with it, and the molecule as a whole loses that electron. Conversely, oxygen is very electron-hungry (electronegative), so when oxygen binds with other atoms the shared electrons spend more time in oxygen's vicinity. Again, the rest of the molecule loses electrons.

Essentially all oxidation of food fuels involves the step-by-step removal of pairs of hydrogen atoms (with their electrons) from the substrate molecules, eventually leaving only carbon dioxide (CO_2). Molecular oxygen (O_2) is the final electron acceptor. It combines with the removed hydrogen atoms at the very end of the process, to form water (H_2O).

Whenever one substance loses electrons (is oxidized), another substance gains them (is reduced). For this reason, oxidation and reduction are coupled reactions and we speak of **oxidation-reduction (redox) reactions**. The key understanding about redox reactions is that "oxidized" substances *lose* energy and "reduced" substances *gain* energy as energy-rich electrons are transferred from one substance to the next. Consequently, as food fuels are oxidized, their energy is transferred to a series of other molecules and ultimately to ADP to form energy-rich ATP.

Like all other chemical reactions in the body, redox reactions are catalyzed by enzymes. Those that catalyze redox reactions in which hydrogen atoms are removed are called **dehydrogenases** (de-hi′dro-jen-ās″ez), while enzymes catalyzing the transfer of oxygen are **oxidases**.

Most of these enzymes require the help of a specific coenzyme, typically derived from one of the B vitamins. Although

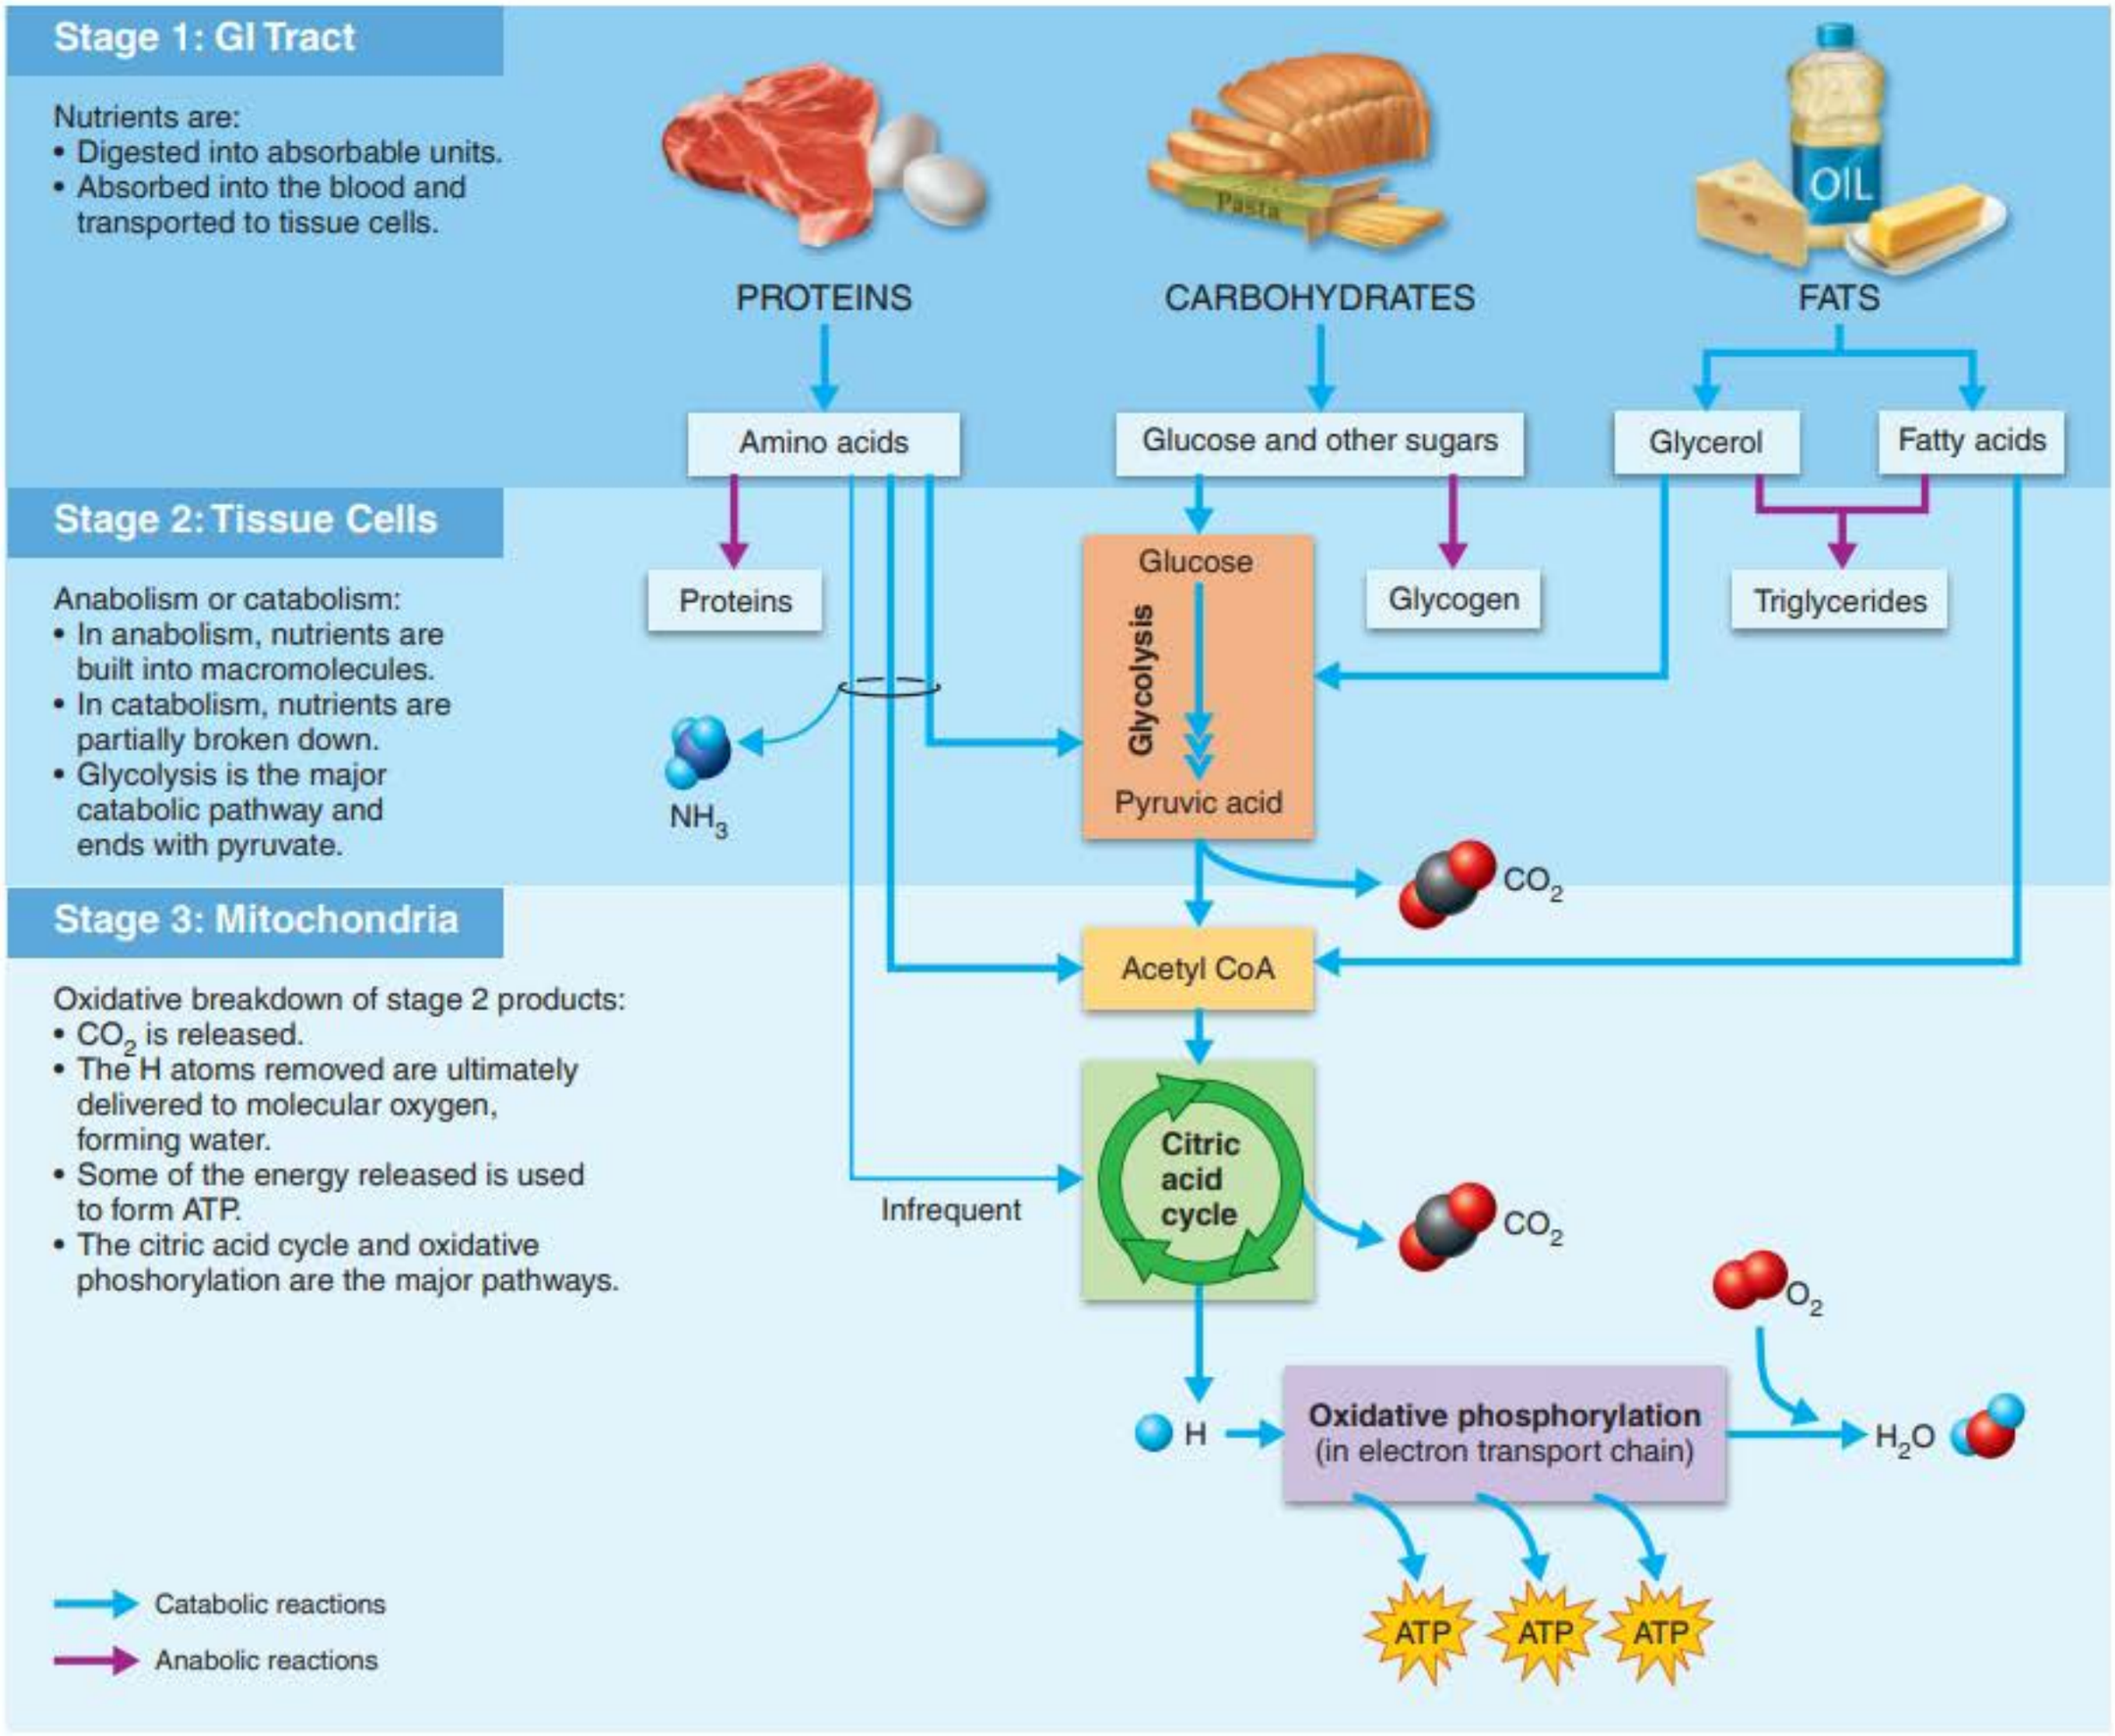

Figure 24.3 Three stages of metabolism of energy-containing nutrients.

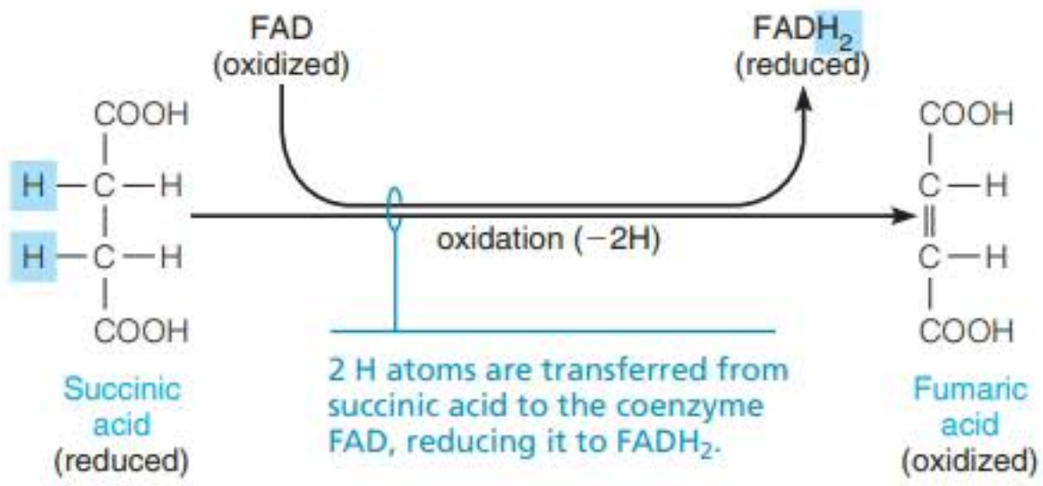
the enzymes catalyze the removal of hydrogen atoms to oxidize a substance, they cannot *accept* the hydrogen (hold on or bond to it). Their *coenzymes*, however, can act as hydrogen (or electron) acceptors, becoming reduced each time a substrate is oxidized.

Two very important coenzymes of the oxidative pathways are **nicotinamide adenine dinucleotide (NAD^+)** (nik″o-tin′ah-mīd), based on *niacin*, and **flavin adenine dinucleotide (FAD)**, derived from *riboflavin*. The oxidation of succinic acid to fumaric acid and the simultaneous reduction of FAD to $FADH_2$, an example of a coupled redox reaction, is shown on the right.



ATP Synthesis

How do our cells capture some of the energy liberated during cellular respiration to make ATP molecules? There are two mechanisms—substrate-level phosphorylation and oxidative phosphorylation.

Substrate-level phosphorylation occurs when high-energy phosphate groups are transferred directly from phosphorylated substrates (metabolic intermediates such as glyceraldehyde 3-phosphate) to ADP (**Figure 24.4a**). Essentially, this process occurs because the high-energy bonds attaching the phosphate groups to the substrates are even more unstable than those in ATP. ATP is synthesized by this route twice during glycolysis, and once during each turn of the citric acid cycle. The enzymes catalyzing substrate-level phosphorylations are located in both the cytosol (where glycolysis occurs) and in the watery matrix inside the mitochondria (where the citric acid cycle takes place) (**Figure 24.5**).

Oxidative phosphorylation is more complicated, but it releases most of the energy that is eventually captured in ATP bonds during cellular respiration. Oxidative phosphorylation, which is carried out by electron transport proteins embedded in the inner mitochondrial membranes, is an example of a chemiosmotic process. **Chemiosmotic processes** couple the movement of substances across membranes to chemical reactions.

In this case, some of the energy released during the oxidation of food fuels (the "chemi" part of chemiosmotic) is used to pump (*osmo* = push) protons (H^+) across the inner mitochondrial membrane into the intermembrane space (Figure 24.4b). This creates a steep concentration gradient for protons across the membrane. Then, when H^+ flows back across the membrane (through a membrane channel protein called *ATP synthase*), some of this gradient energy is captured and used to attach phosphate groups to ADP.

Check Your Understanding

8. What is a redox reaction?
9. How are anabolism and catabolism linked by ATP?
10. What is the energy source for the proton pumps of oxidative phosphorylation?
11. Briefly, how do substrate-level and oxidative phosphorylation differ?

For answers, see Answers Appendix.

24.4 Carbohydrate metabolism is the central player in ATP production

Learning Outcomes

- **Summarize important events and products of glycolysis, the citric acid cycle, and electron transport.**
- **Define glycogenesis, glycogenolysis, and gluconeogenesis.**

The story of carbohydrate metabolism is really a tale of glucose metabolism because all food carbohydrates are eventually transformed to glucose. Glucose enters tissue cells by facilitated

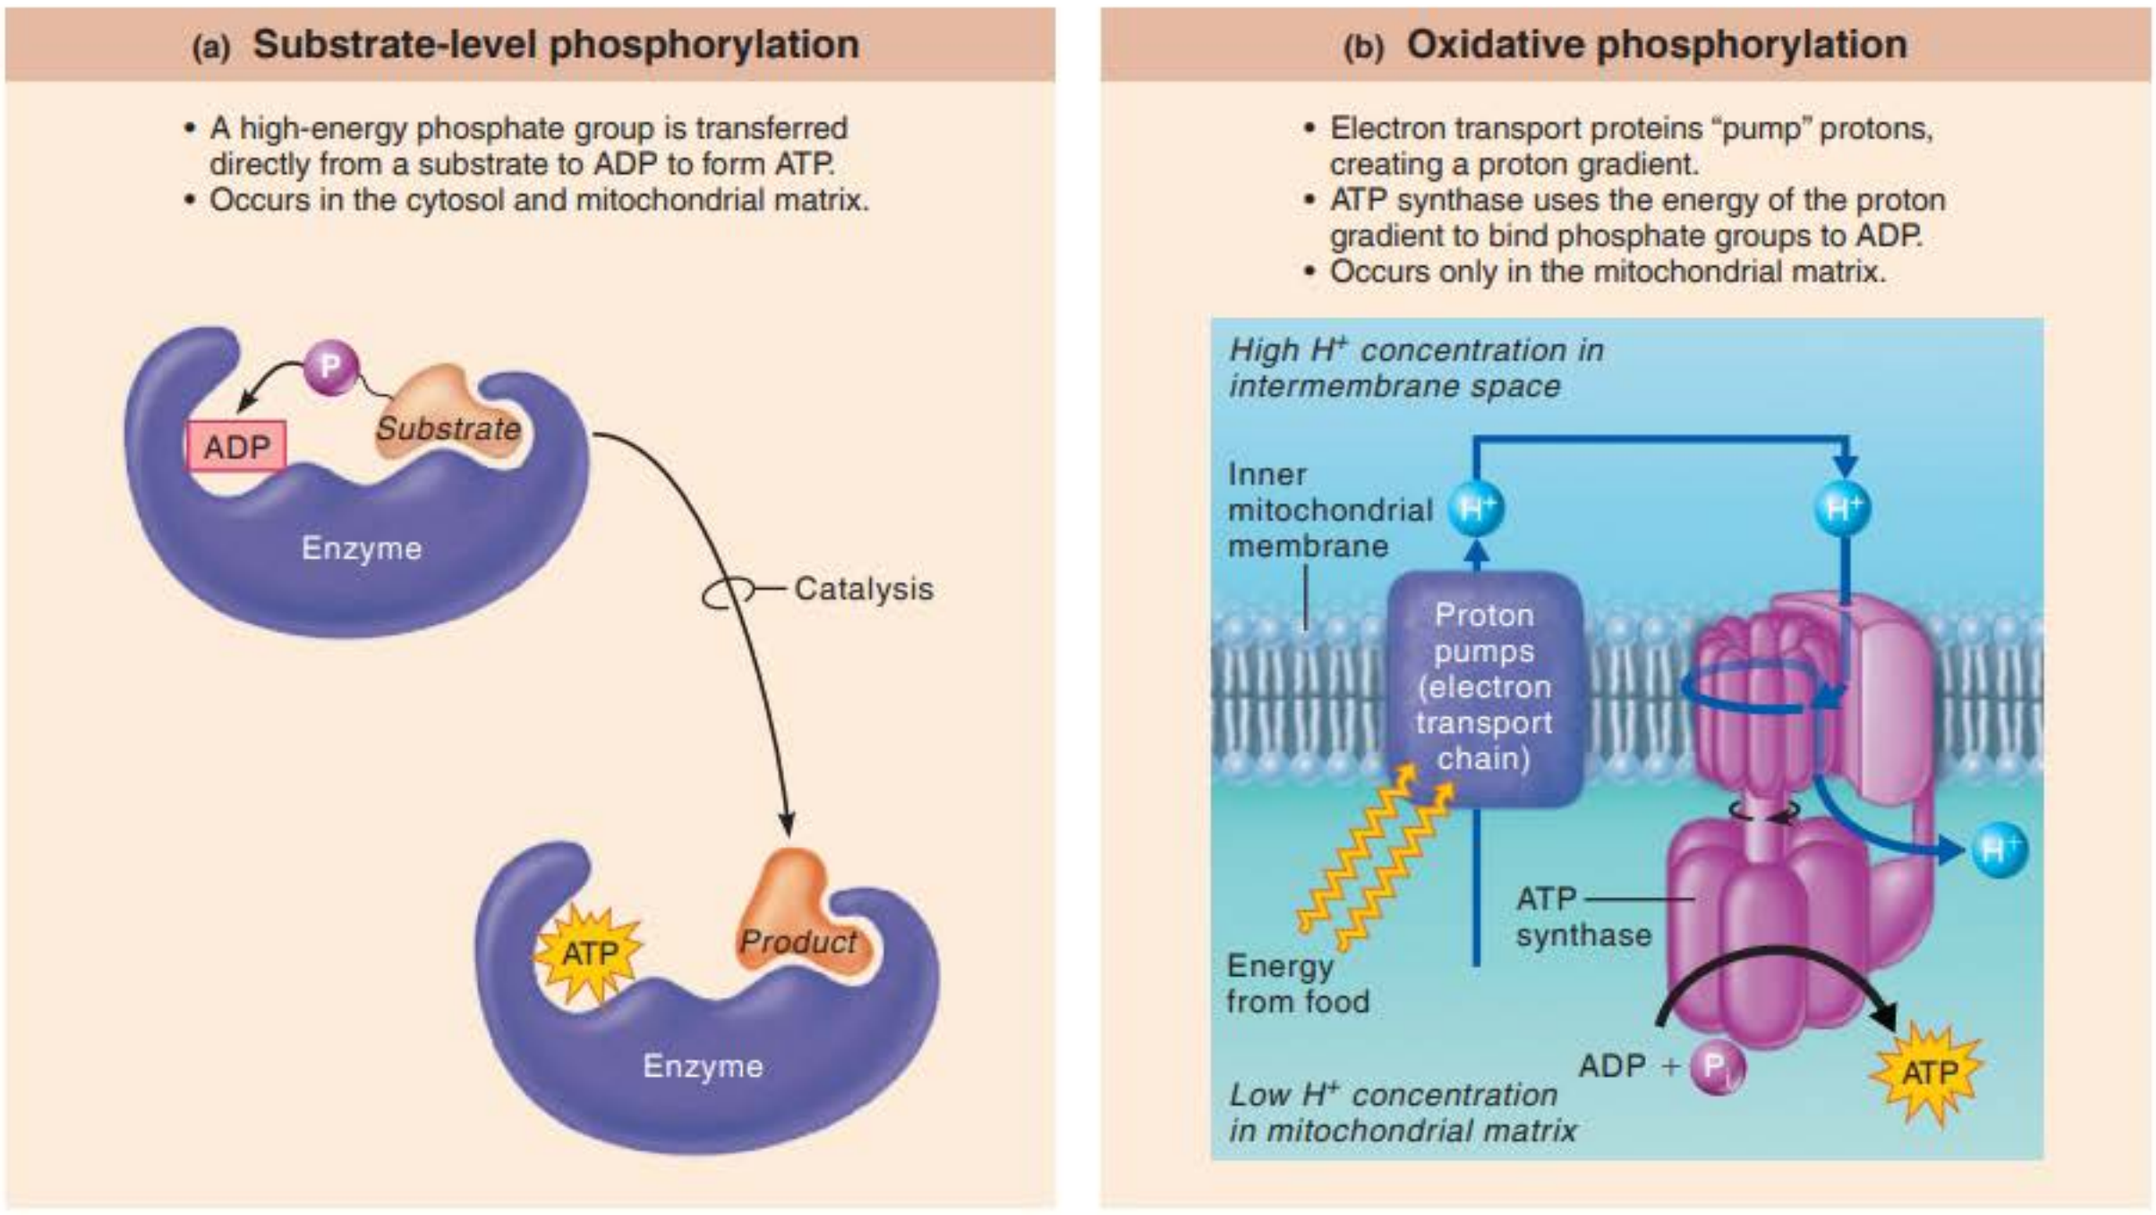


Figure 24.4 **Mechanisms of phosphorylation.**

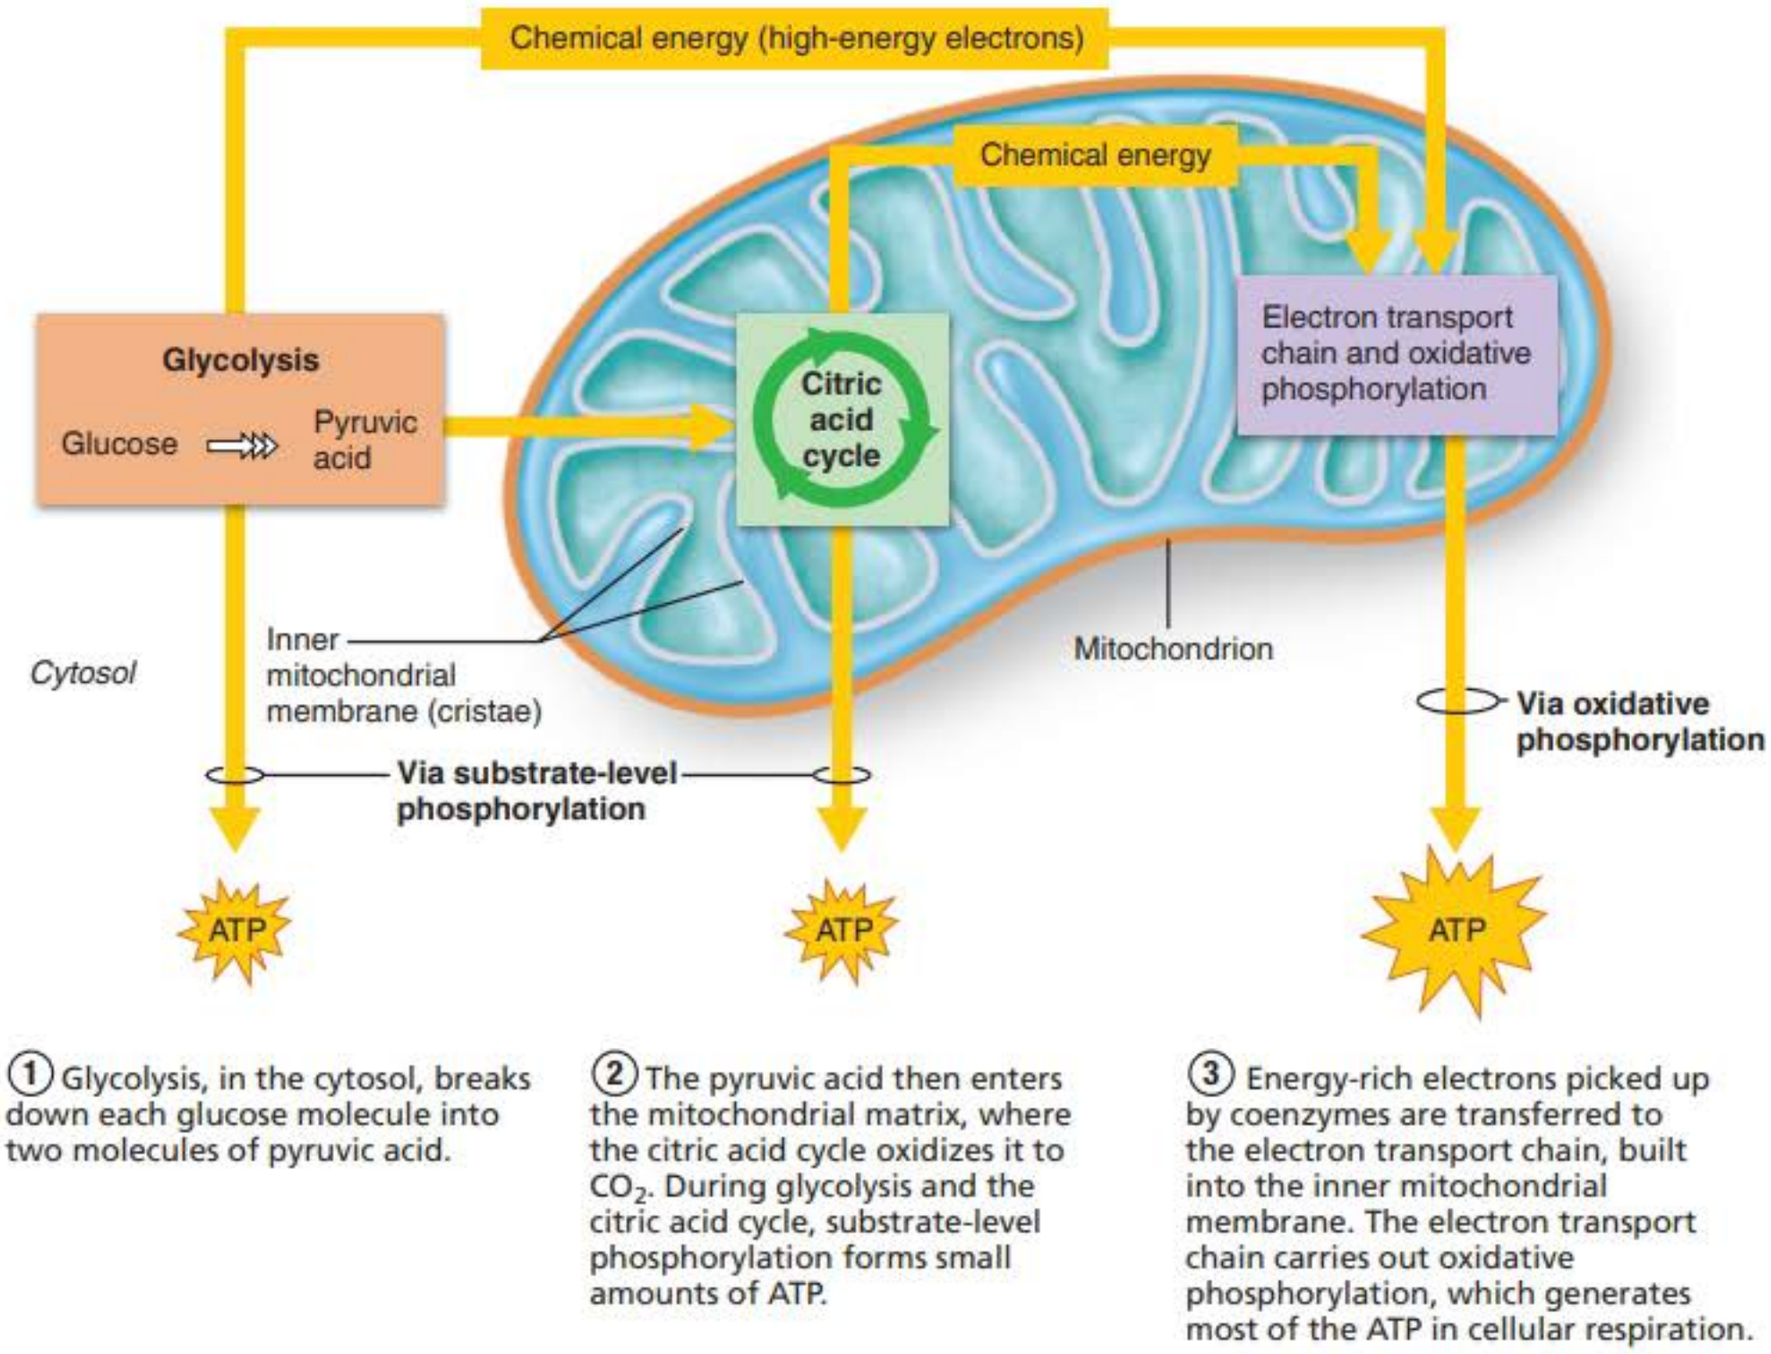

Figure 24.5 During cellular respiration, ATP is formed in the cytosol and in the mitochondria.

diffusion, a process that is greatly enhanced by insulin (◀ p. 630). Immediately after entering a cell, glucose is phosphorylated to *glucose-6-phosphate* by transfer of a phosphate group to its sixth carbon during a coupled reaction with ATP:

$$\text{Glucose} + \text{ATP} \rightarrow \text{glucose-6-PO}_4 + \text{ADP}$$

Phosphorylation effectively traps glucose inside the cell (it can't diffuse out) and most body cells lack the enzymes needed to reverse this reaction. Because glucose-6-phosphate is a *different* molecule from simple glucose, the reaction also keeps intracellular glucose levels low, maintaining a concentration gradient for glucose entry. Only intestinal epithelial cells, kidney tubule cells, and liver cells have the enzymes needed to reverse this phosphorylation reaction, which reflects their central roles in glucose uptake *and* release. The catabolic and anabolic pathways for carbohydrates all begin with glucose-6-phosphate.

Oxidation of Glucose

Glucose is the pivotal fuel molecule in the oxidative (ATP-producing) pathways. Glucose is catabolized via the reaction

$$\underset{\text{glucose}}{C_6H_{12}O_6} + \underset{\text{oxygen}}{6O_2} \rightarrow \underset{\text{water}}{6H_2O} + \underset{\text{carbon dioxide}}{6CO_2} + 32\,\text{ATP} + \text{heat}$$

This equation gives few hints that glucose breakdown is complex and involves three of the pathways featured in Figures 24.3 and 24.5:

1. Glycolysis (color-coded orange throughout the chapter)
2. The citric acid cycle (color-coded green)
3. The electron transport chain and oxidative phosphorylation (color-coded lavender)

These metabolic pathways occur sequentially.

Glycolysis

Also called the *glycolytic pathway*, **glycolysis** (gli-kol′ĭ-sis; "sugar splitting") occurs in the cytosol of cells. This pathway, a series of ten chemical steps, converts glucose to two *pyruvic acid* molecules. All steps are fully reversible except the first, during which glucose entering the cell is phosphorylated to glucose-6-phosphate.

Glycolysis is an *anaerobic process*. Although this term is sometimes mistakenly interpreted to mean the pathway occurs only in the absence of oxygen, it actually means that glycolysis *does not use oxygen and occurs whether or not oxygen is present.*

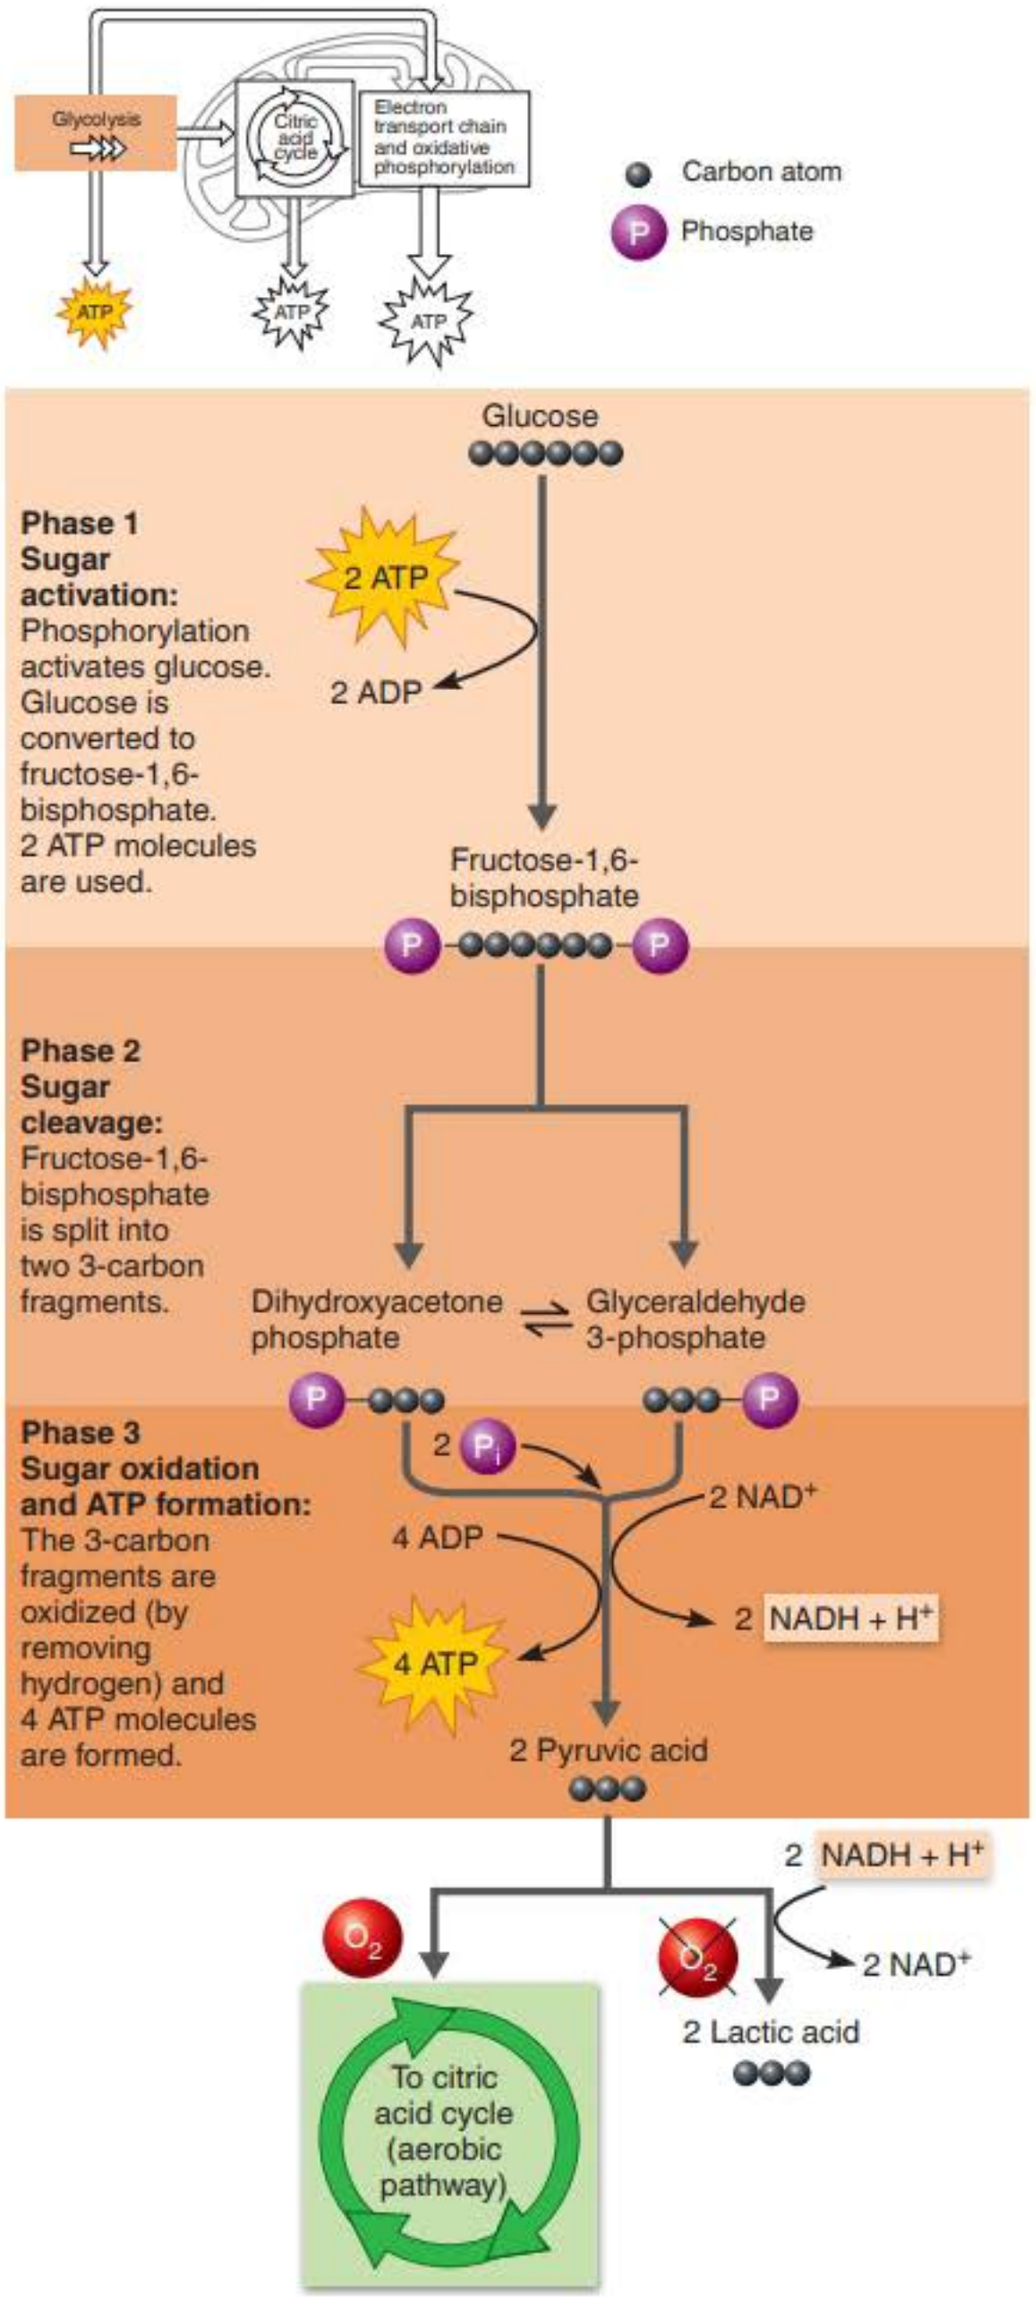

Figure 24.6 The three major phases of glycolysis. The fate of pyruvic acid depends on whether or not molecular O_2 is available.

The three major phases of glycolysis shown in **Figure 24.6** are described next. Appendix D shows the complete glycolytic pathway.

- **Phase 1. Sugar activation.** In phase 1, glucose is phosphorylated twice and converted to fructose-1,6-bisphosphate. These reactions use two ATP molecules (to be recouped later), which provide the *activation energy* needed to prime the later stages of the pathway. Phase 1 can be thought of as the *energy investment phase*.
- **Phase 2. Sugar cleavage.** During phase 2, fructose-1,6-bisphosphate is split into two 3-carbon fragments that exist (interconvertibly) as one of two isomers: glyceraldehyde (glis″er-al′dĕ-hīd) 3-phosphate or dihydroxyacetone (di″hi-drok″se-as′ĕ-tōn) phosphate.
- **Phase 3. Sugar oxidation and ATP formation.** In phase 3, two major events happen. First, the two 3-carbon fragments are oxidized by the removal of hydrogen, which NAD^+ picks up. In this way, some of glucose's energy is transferred to NAD^+. Second, inorganic phosphate groups (P_i) are attached to each oxidized fragment by high-energy bonds. Later, when these terminal phosphates are split off, enough energy is captured to form four ATP molecules. As we noted earlier, formation of ATP this way is called *substrate-level phosphorylation*.

The final products of glycolysis are two molecules of **pyruvic acid**, two molecules of reduced NAD^+ (NADH), and two H^+. There is a net gain of two ATP molecules per glucose molecule. Four ATPs are produced, but remember that two are consumed in phase 1 to activate the reactions. Each pyruvic acid molecule has the formula $C_3H_4O_3$, and glucose is $C_6H_{12}O_6$. Between them the two pyruvic acid molecules have lost four hydrogen atoms, whose electrons are now bound to two molecules of NAD^+. NAD carries a positive charge (NAD^+), so when it accepts a hydrogen pair, NADH + H^+ is the resulting reduced product. Although a small amount of ATP has been harvested, the other two products of glucose oxidation (H_2O and CO_2) have yet to appear.

The fate of pyruvic acid, which still contains most of glucose's chemical energy, depends on the availability of oxygen at the time the pyruvic acid is produced. Because the supply of NAD^+ is limited, glycolysis can continue only if the reduced coenzymes (NADH, together with its H^+) formed during glycolysis are relieved of their extra hydrogens. Only then can they continue to act as hydrogen acceptors.

When oxygen is readily available, this is no problem. NADH + H^+ delivers its burden of hydrogen atoms to the enzymes of the electron transport chain in the mitochondria, which deliver them to O_2, forming water. However, when oxygen is not present in sufficient amounts, as might occur during strenuous exercise, NADH + H^+ unloads its hydrogen atoms *back onto pyruvic acid*, reducing it. This addition of two hydrogen atoms to pyruvic acid yields **lactic acid** (see bottom right of Figure 24.6). Some of this lactic acid diffuses out of the cells and is transported to the liver for processing.

When oxygen is again available, lactic acid is oxidized back to pyruvic acid and enters the **aerobic pathways** (the oxygen-requiring citric acid cycle and electron transport chain within the mitochondria), and is completely oxidized to water and carbon dioxide. The liver may also convert lactic acid all the way back to glucose-6-phosphate (reverse glycolysis). Glucose-6-phosphate

can be either stored as glycogen or freed of its phosphate and released to the blood if blood sugar levels are low.

Except for red blood cells (which typically carry out *only* glycolysis), prolonged anaerobic metabolism ultimately results in acid-base problems. Consequently, *totally* anaerobic conditions resulting in lactic acid formation provide only a temporary route for rapid ATP production. Totally anaerobic conditions can go on without tissue damage for the longest periods in skeletal muscle, for much shorter periods in cardiac muscle, and almost not at all in the brain. Although glycolysis generates ATP rapidly, each glucose molecule yields only 2 ATP as compared to the 30 to 32 ATP when a glucose molecule is completely oxidized.

Citric Acid Cycle

The **citric acid cycle** (or Krebs cycle) is the next stage of glucose oxidation and is named for its first substrate. The citric acid cycle occurs in the mitochondrial matrix and is fueled largely by pyruvic acid produced during glycolysis and by fatty acids resulting from fat breakdown.

Because pyruvic acid is a charged molecule, it must enter the mitochondrion by active transport with the help of a transport protein. Once in the mitochondrion, the first order of business is a **transitional phase** that converts pyruvic acid to acetyl CoA. This occurs via a three-step process (**Figure 24.7**, top):

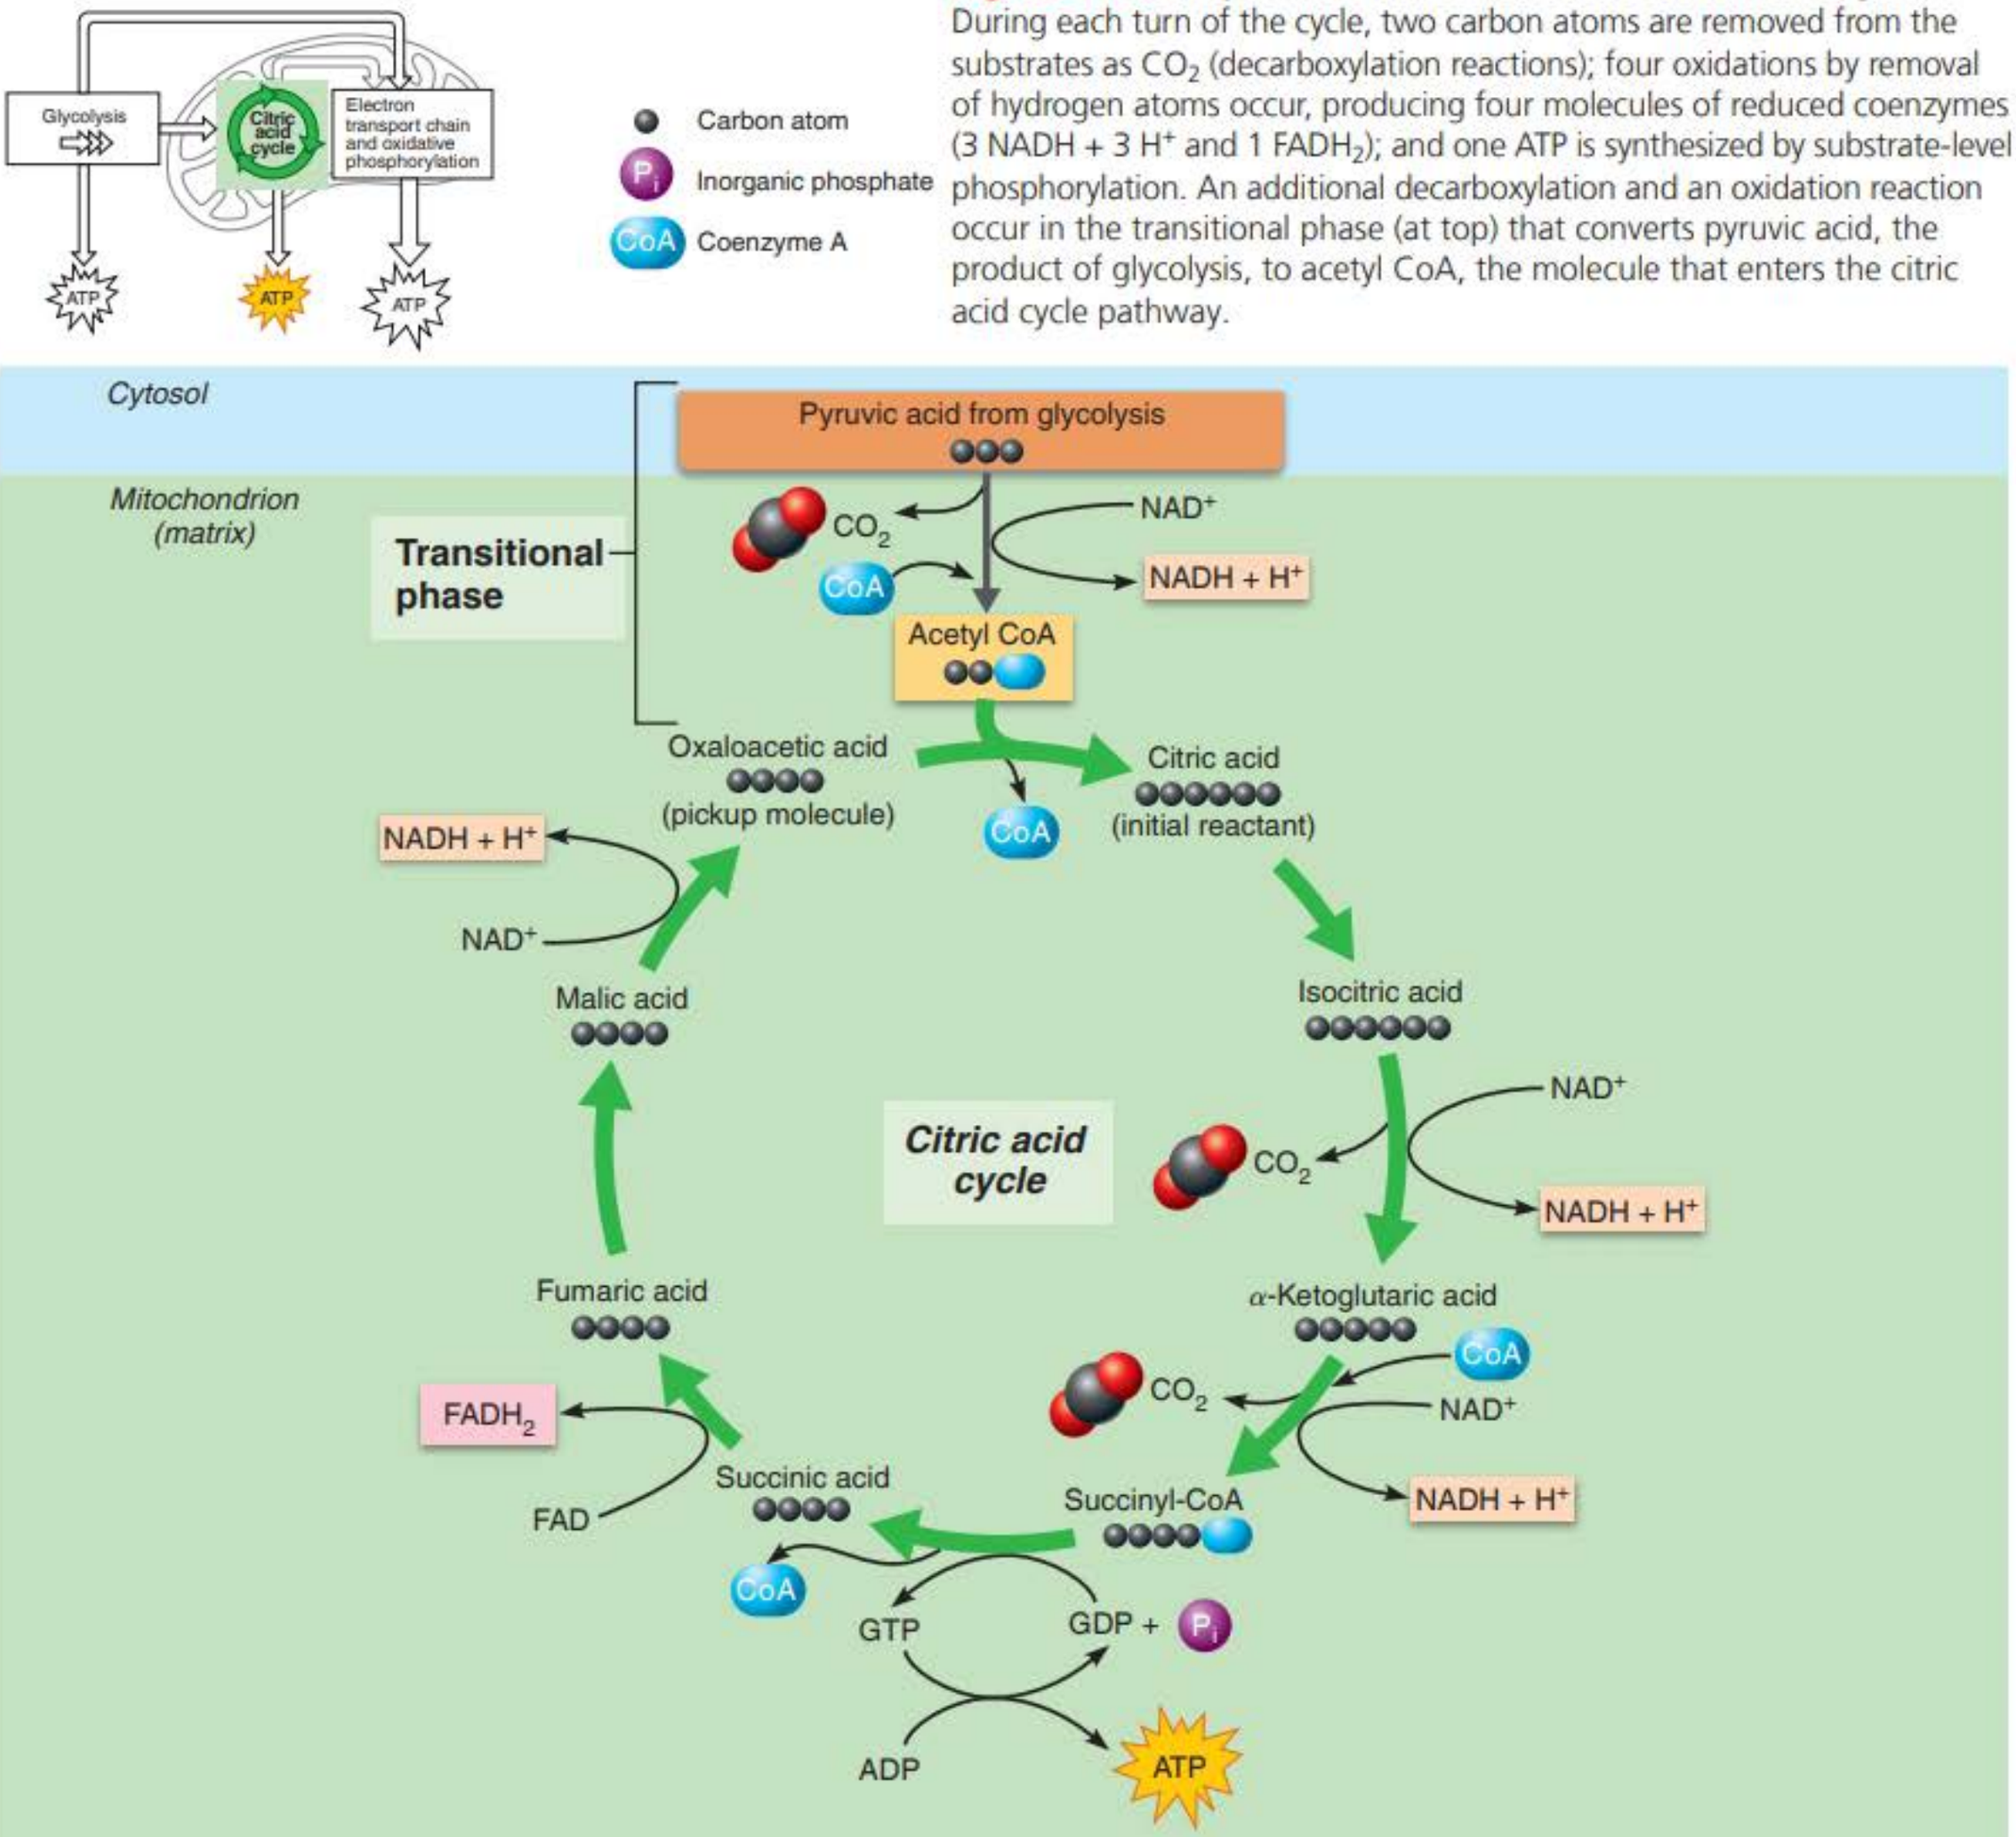

Figure 24.7 Simplified version of the citric acid (Krebs) cycle. During each turn of the cycle, two carbon atoms are removed from the substrates as CO_2 (decarboxylation reactions); four oxidations by removal of hydrogen atoms occur, producing four molecules of reduced coenzymes (3 NADH + 3 H^+ and 1 $FADH_2$); and one ATP is synthesized by substrate-level phosphorylation. An additional decarboxylation and an oxidation reaction occur in the transitional phase (at top) that converts pyruvic acid, the product of glycolysis, to acetyl CoA, the molecule that enters the citric acid cycle pathway.

1. **Decarboxylation.** In this step, one of pyruvic acid's carbons is removed and released as carbon dioxide gas, a process called **decarboxylation**. CO_2 diffuses out of the cells into the blood to be expelled by the lungs. This is the first time that CO_2 is released during cellular respiration.
2. **Oxidation.** The remaining 2-carbon fragment is oxidized to acetic acid by removing hydrogen atoms, which are picked up by NAD^+.
3. **Formation of acetyl CoA.** Acetic acid is combined with *coenzyme A* to produce the reactive final product, **acetyl coenzyme A (acetyl CoA)**. Coenzyme A is a sulfur-containing coenzyme derived from vitamin B_5.

Acetyl CoA is now ready to enter the citric acid cycle and be broken down completely by mitochondrial enzymes. Coenzyme A shuttles the 2-carbon acetic acid to an enzyme that joins it to a 4-carbon acid called **oxaloacetic acid** (ok″sah-lo″ah-sēt′ik) to produce the 6-carbon **citric acid**.

As the cycle moves through its eight successive steps, the atoms of citric acid are rearranged to produce different intermediate molecules, most called **keto acids** (Figure 24.7). The acetic acid that enters the cycle is broken apart carbon by carbon (decarboxylated) and oxidized, generating NADH + H^+ and $FADH_2$. At the end of the cycle, acetic acid has been totally disposed of and oxaloacetic acid, the *pickup molecule*, is regenerated.

For each turn of the cycle, we get:

- Two CO_2 molecules that come from two *decarboxylations*.
- Four molecules of reduced coenzymes (3 NADH + 3 H^+ and 1 $FADH_2$). The addition of water at certain steps accounts for some of the released hydrogen.
- One molecule of ATP (via substrate-level phosphorylation).

The detailed events of each of the eight steps of the citric acid cycle are described in Appendix D.

Now let's back up and account for the pyruvic acid molecules entering the mitochondria. We need to consider the products of both the transitional phase and the citric acid cycle itself. Altogether, each pyruvic acid yields three CO_2 molecules and five molecules of reduced coenzymes—1 $FADH_2$ and 4 NADH + 4 H^+ (equal to removing 10 hydrogen atoms). The products of glucose oxidation in the citric acid cycle are twice that (remember 1 glucose = 2 pyruvic acids): six CO_2, ten molecules of reduced coenzymes, and two ATP molecules.

Notice that it is these citric acid cycle reactions that produce the CO_2 released during glucose oxidation. The reduced coenzymes, which carry their extra electrons in high-energy linkages, must now be oxidized if the citric acid cycle and glycolysis are to continue.

Although glycolysis is exclusive to carbohydrate oxidation, breakdown products of carbohydrates, fats, and proteins can feed into the citric acid cycle to be oxidized for energy. On the other hand, some citric acid cycle intermediates can be siphoned off to make fatty acids and nonessential amino acids. In this way, the citric acid cycle is a source of building materials for anabolic reactions, as well as the final common pathway for oxidizing food fuels.

Electron Transport Chain and Oxidative Phosphorylation

Like glycolysis, none of the reactions of the citric acid cycle use oxygen directly. This is the exclusive function of the **electron transport chain**, which carries out the final catabolic reactions that occur on the inner mitochondrial membrane. However, because the reduced coenzymes produced in the citric acid cycle are the substrates for the electron transport chain, these two pathways are coupled, and both are *aerobic*, meaning they require oxygen.

In the electron transport chain, the hydrogens removed during the oxidation of food fuels are combined with O_2 to form water, and the energy released during those reactions is harnessed to attach P_i groups to ADP, forming ATP. As we noted earlier, this type of phosphorylation process is called *oxidative phosphorylation*. Let's peek under the hood of a cell's power plant and see how this rather complicated process works.

Just as in a car, what we see is a complicated structure with many parts. Why are there so many parts? In a car engine, we burn fuel for energy. If released all at once, that energy would result in a big, hot explosion. All of the complex engine parts make it possible to capture some of this energy to do useful work. In the same way, the electron transport chain harvests the energy of food fuels a bit at a time in a step-by-step way so we can ultimately make ATP.

Most components of the electron transport chain are proteins that bind metal atoms (known as *cofactors*). These proteins vary in composition and form multiprotein complexes that are firmly embedded in the inner mitochondrial membrane as shown in *Focus on Oxidative Phosphorylation* (**Focus Figure 24.1**). For example, some of the proteins, the **flavins**, contain flavin mononucleotide (FMN) derived from the vitamin riboflavin, and others contain both sulfur (S) and iron (Fe). Most of these proteins, however, are brightly colored iron-containing pigments called **cytochromes** (si′to-krōmz; *cyto* = cell, *chrom* = color), including complexes III and IV depicted in Focus Figure 24.1. Neighboring carriers are clustered together to form four **respiratory enzyme complexes** that are alternately reduced and oxidized as they pick up electrons and pass them on to the next complex in the sequence.

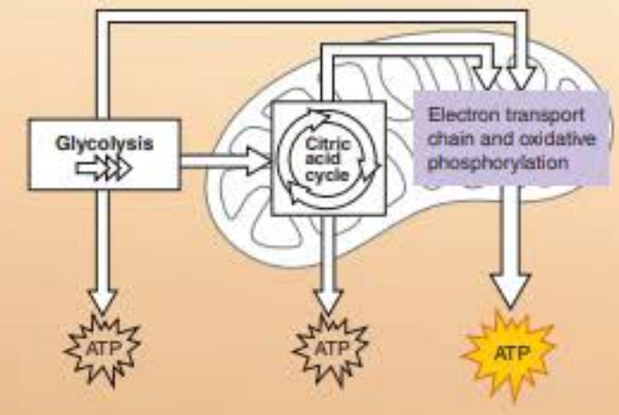
As Focus Figure 24.1 shows, the first such complex accepts hydrogen atoms from NADH + H^+, oxidizing it to NAD^+. $FADH_2$ transfers its hydrogen atoms slightly farther along the chain to the small complex II. The hydrogen atoms that the reduced coenzymes deliver to the electron transport chain are quickly split into protons (H^+) plus electrons (e^-). The electrons are shuttled along the inner mitochondrial membrane from one complex to the next, losing energy with each transfer. The protons escape into the watery matrix, only to be picked up and "pumped" across the inner mitochondrial membrane into the intermembrane space by one of the three major respiratory enzyme complexes (I, III, or IV).

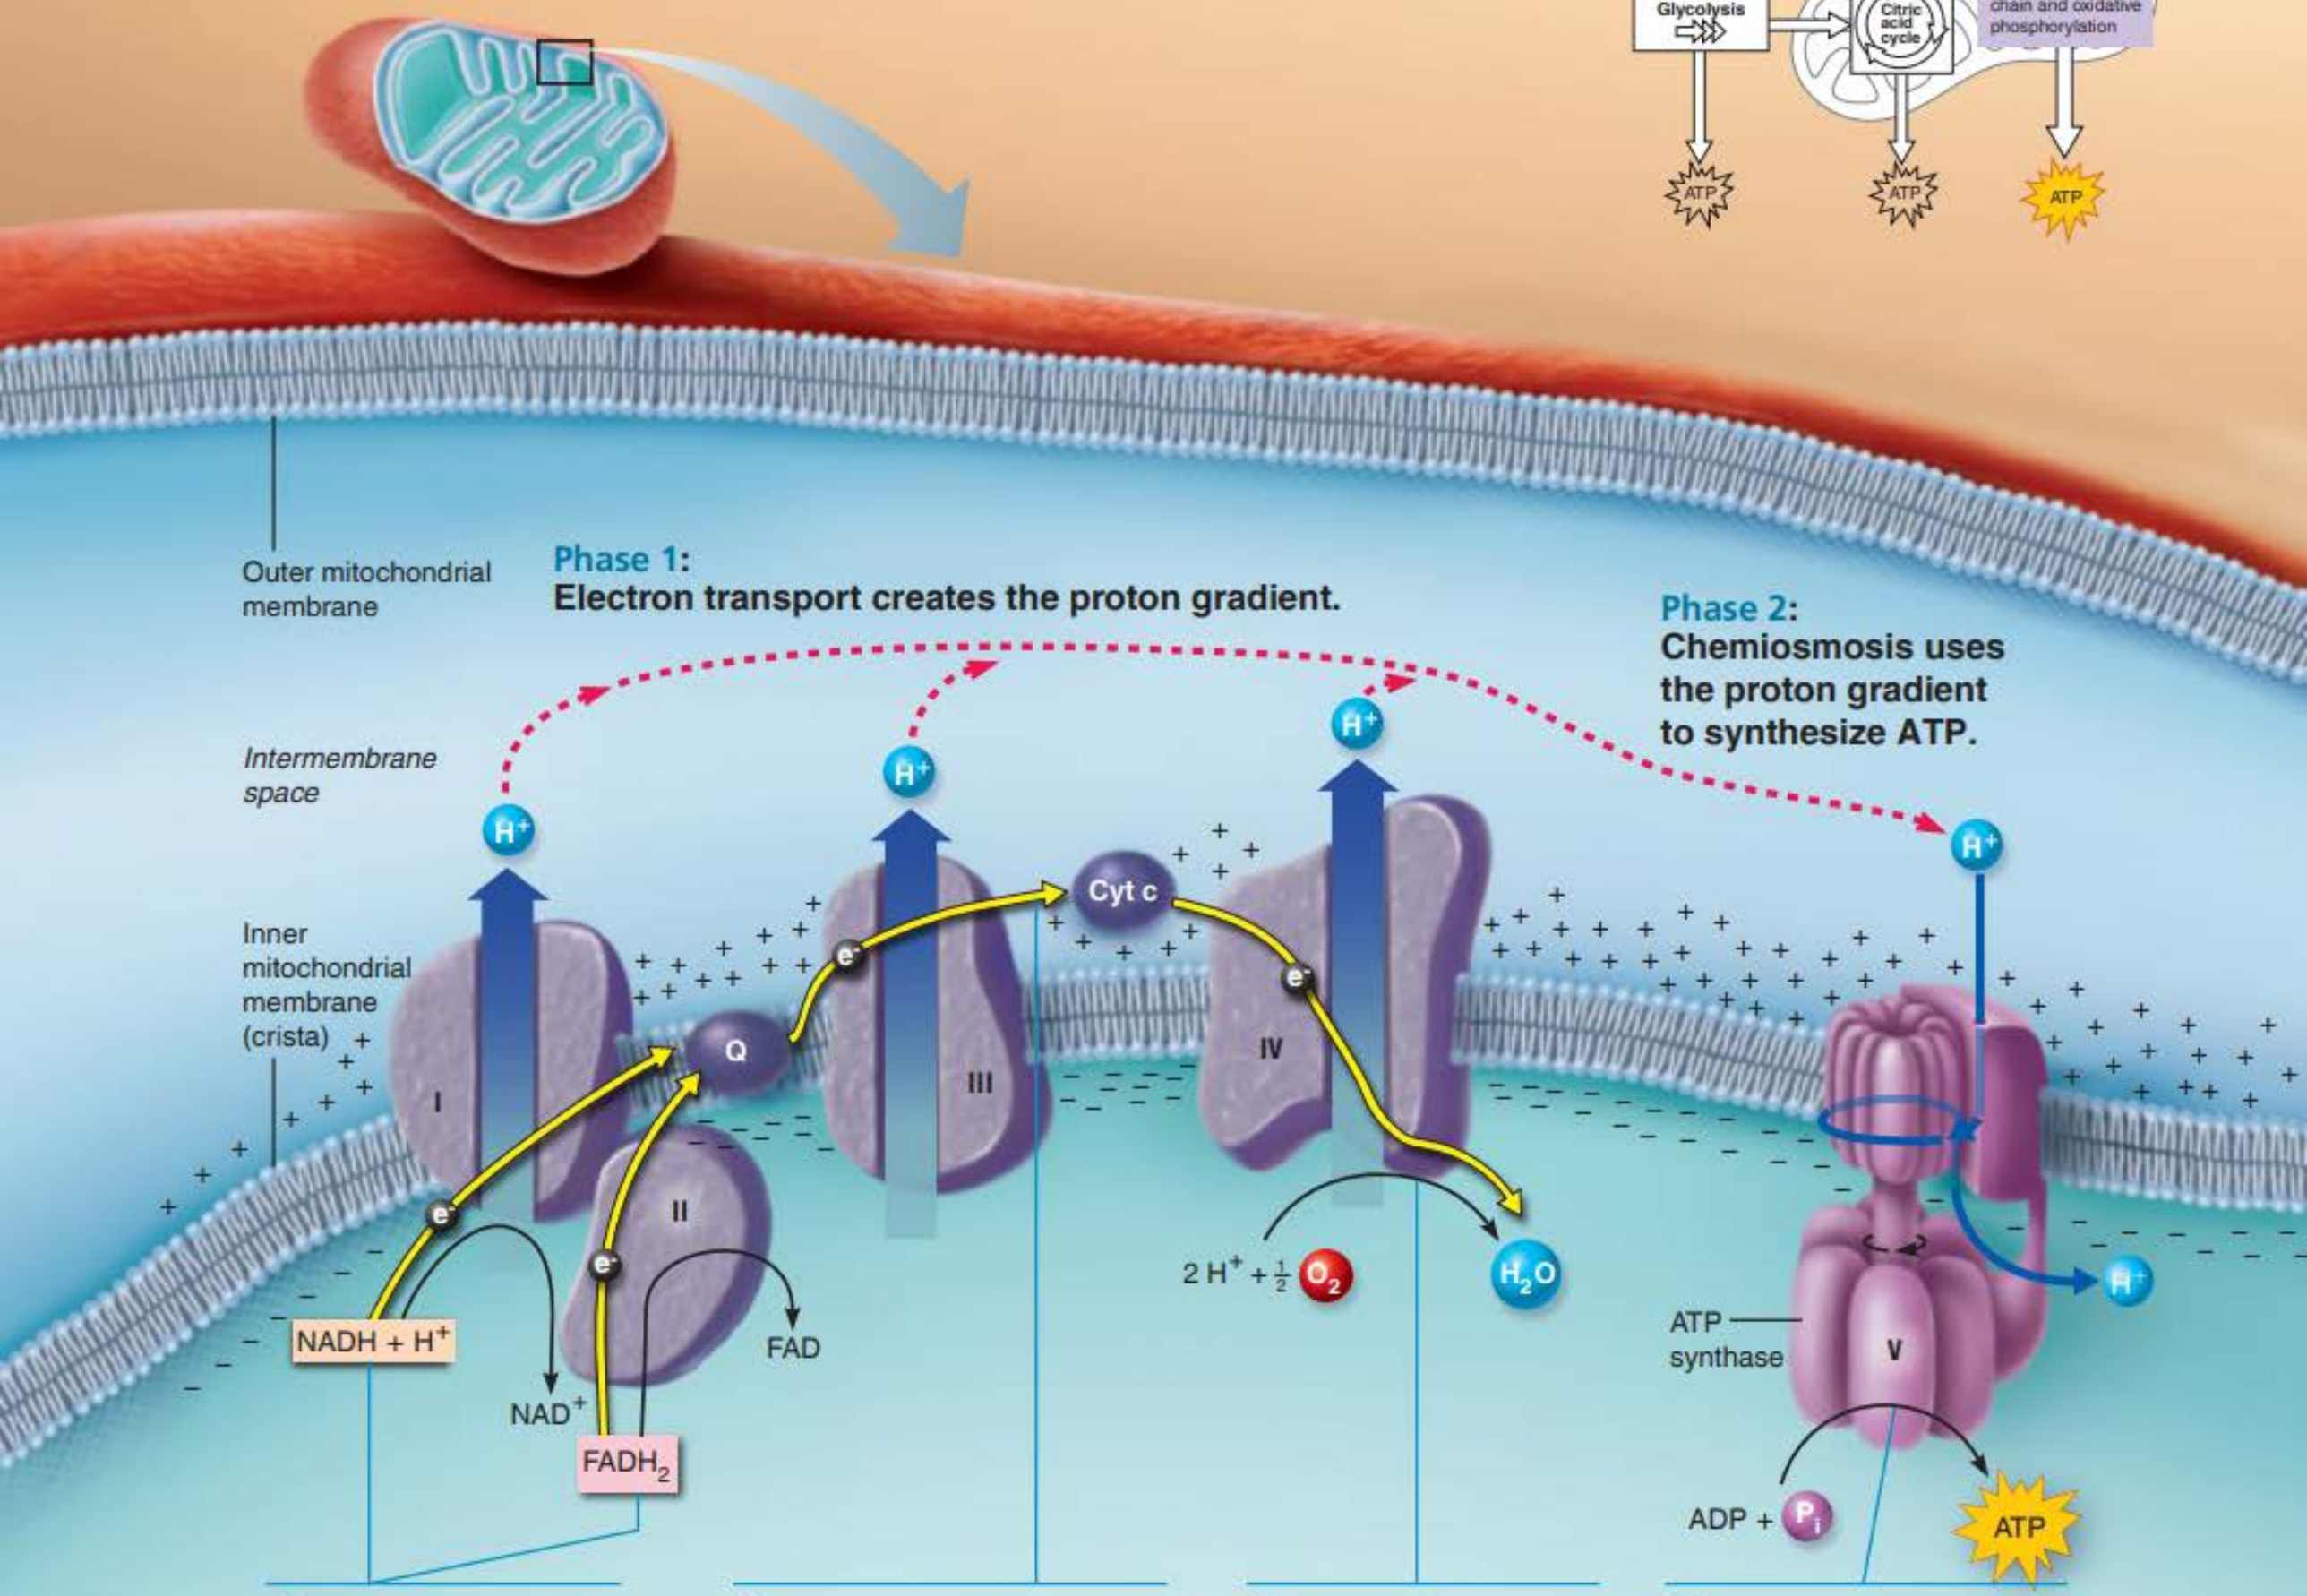
Ultimately two electrons are delivered to half a molecule of O_2 (in other words, to an oxygen atom), creating oxygen ions (O^-) that strongly attract H^+ and form water, as indicated by the reaction

$$2H^+ + 2e^- + \tfrac{1}{2}O_2 \rightarrow H_2O$$

FOCUS FIGURE 24.1 Oxidative Phosphorylation

Oxidative phosphorylation has two phases:
Phase 1: The electron transport chain creates a proton (H^+) gradient across the inner mitochondrial membrane using high-energy electrons (e^-) removed from food fuels.
Phase 2: Chemiosmosis uses the energy of the proton gradient to synthesize ATP.





(1) Reduced coenzymes ($NADH + H^+$ and $FADH_2$) deliver electrons to respiratory enzyme complexes I and II.

(2) The electrons are transferred from one complex to another in the membrane.
- Each complex is reduced and then oxidized.
- The energy released pumps H^+ into the intermembrane space, creating an electrochemical gradient between the matrix and the intermembrane space.
- Coenzyme Q (ubiquinone) and cytochrome c shuttle electrons between the larger complexes.

(3) At respiratory enzyme complex IV, two electrons combine with two protons (H^+) and a half molecule of O_2, forming water.

(4) ATP synthase (complex V) harnesses the energy of the proton gradient to synthesize ATP. As H^+ flows back across the membrane through ATP synthase, the synthase rotor spins, causing P_i to attach to ADP, forming ATP.

Virtually all the water resulting from glucose oxidation is formed during oxidative phosphorylation. Because NADH + H^+ and $FADH_2$ are oxidized as they release their cargo of hydrogen atoms, the net reaction for the electron transport chain is

$$\underset{\text{reduced coenzyme}}{\text{Coenzyme-2H}} + \tfrac{1}{2}O_2 \rightarrow \underset{\text{oxidized coenzyme}}{\text{coenzyme}} + H_2O$$

Each successive carrier has a greater affinity (binding strength, or "pull") for electrons than those preceding it. For this reason, the electrons cascade "downhill" from NADH + H^+ to progressively lower energy levels until they are finally delivered to oxygen, which has the greatest affinity of all for electrons. You could say that oxygen "pulls" the electrons down the chain (**Figure 24.8**).

The electron transport chain functions as an energy converter by using the stepwise release of electronic energy to pump protons from the matrix into the intermembrane space. Because the inner mitochondrial membrane is nearly impermeable to H^+, this chemiosmotic process creates an electrochemical **proton (H^+) gradient** across that membrane, a gradient that has potential energy and the capacity to do work.

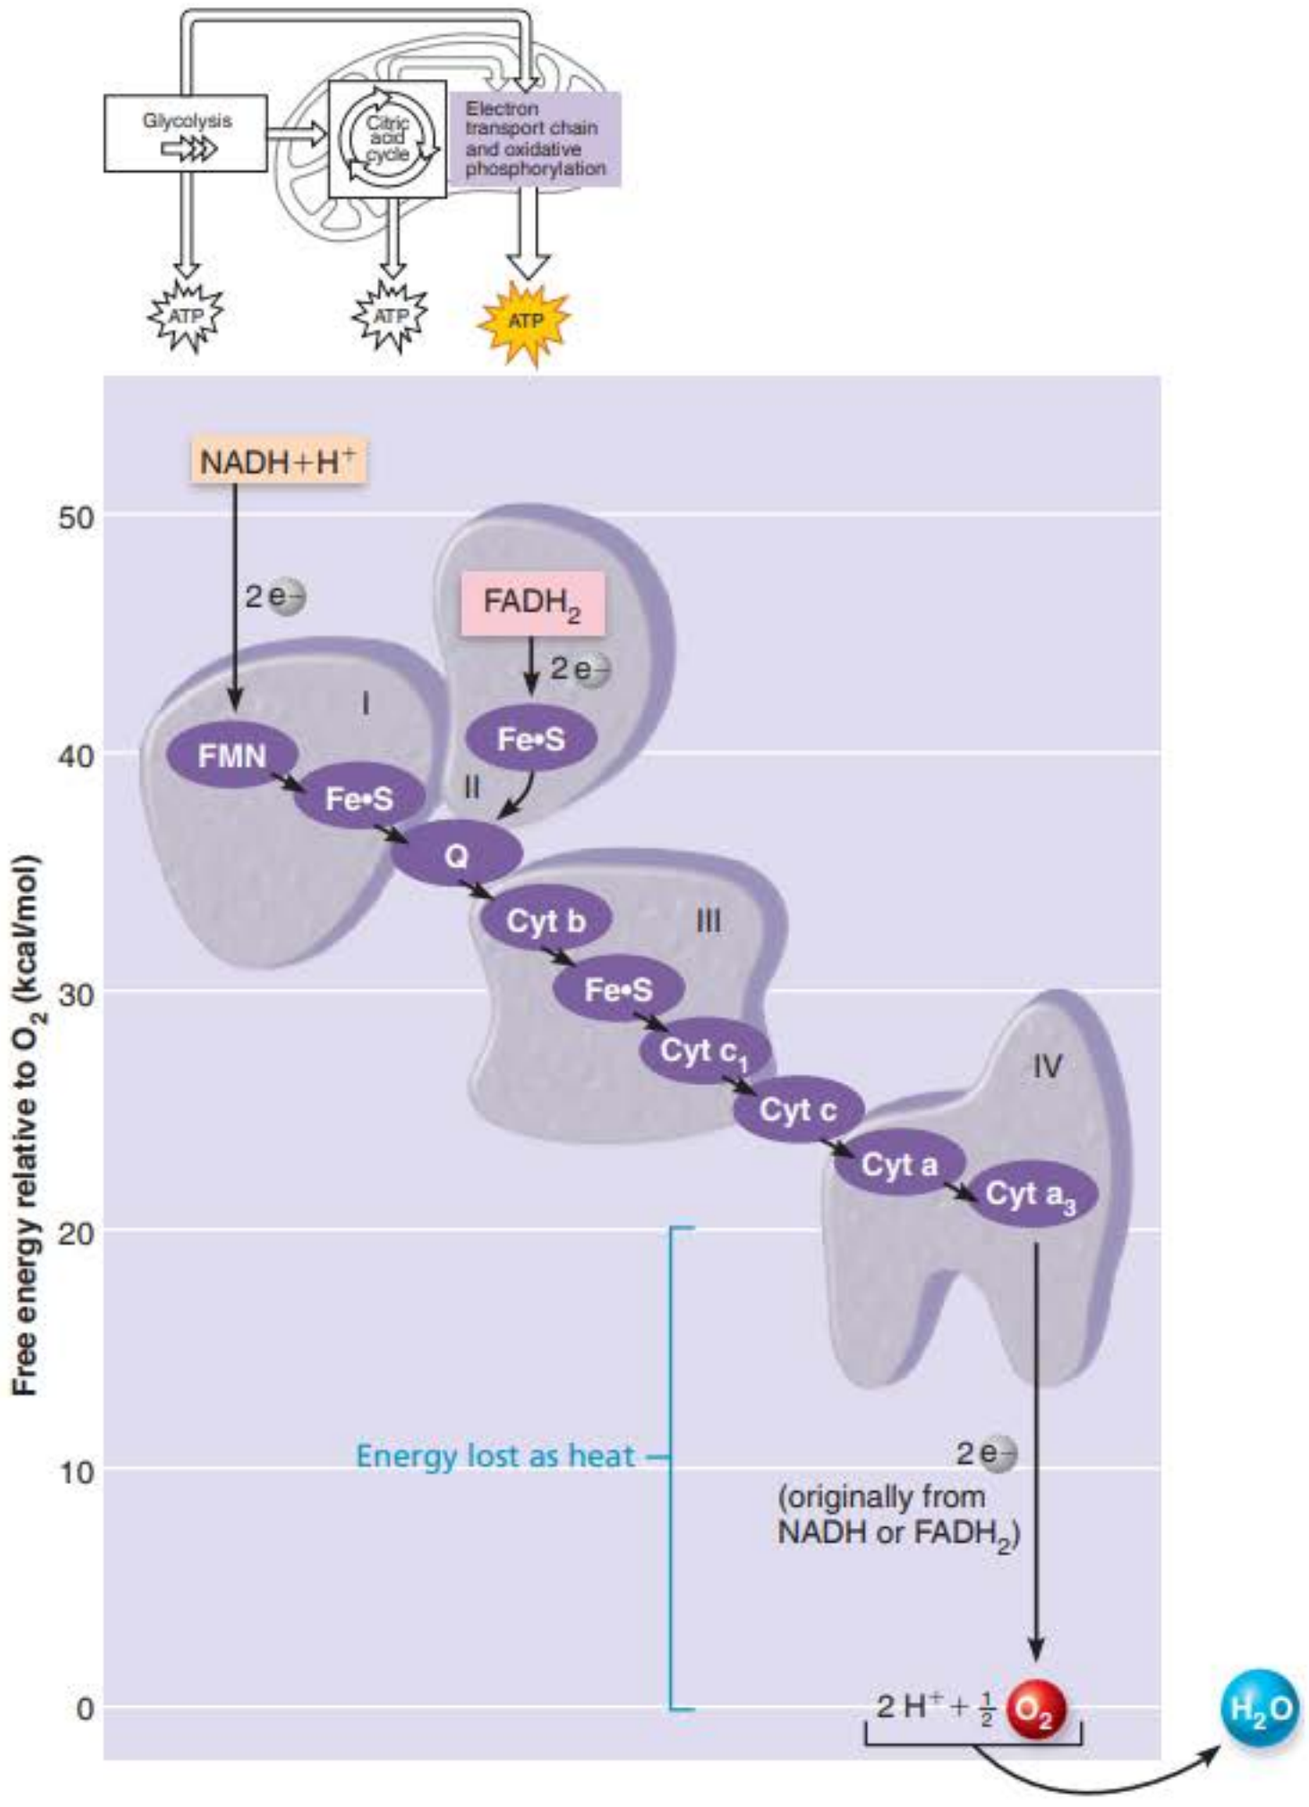


Figure 24.8 Energy is harvested at each step in the electron transport chain. The electron transport chain takes the large overall energy change between NADH + H^+ or $FADH_2$ (from food fuels) and oxygen and harvests smaller, more manageable amounts of energy at each step.

The proton gradient:

- Creates a pH gradient, with the H^+ concentration in the matrix much lower than that in the intermembrane space
- Generates a voltage across the membrane that is negative on the matrix side and positive between the mitochondrial membranes

Both conditions strongly attract H^+ back into the matrix. But how can they get there?

The only areas of the inner mitochondrial membrane freely permeable to H^+ are large enzyme-protein complexes (complex V) called **ATP synthases** (**Figure 24.9**). These complexes lay claim to being nature's smallest rotary motors. Each of these motors drives a molecular mill that fuses ADP and P_i together into ATP. How this molecular complex works is shown in **Figure 24.10**.

Notice something here: The ATP synthase works like an ion pump running in reverse. Recall from Chapter 3 (◀ p. 75) that ion pumps use ATP as their energy source to transport ions against an electrochemical gradient. Here we have ATP synthases using the energy of a proton gradient to power ATP synthesis.

The proton gradient also supplies energy to pump needed metabolites (ADP, pyruvic acid, inorganic phosphate) and calcium ions across the relatively impermeable inner mitochondrial membrane. The supply of energy from oxidation is not limitless, however, so when more of the gradient energy is used to drive these transport processes, less is available to make ATP.

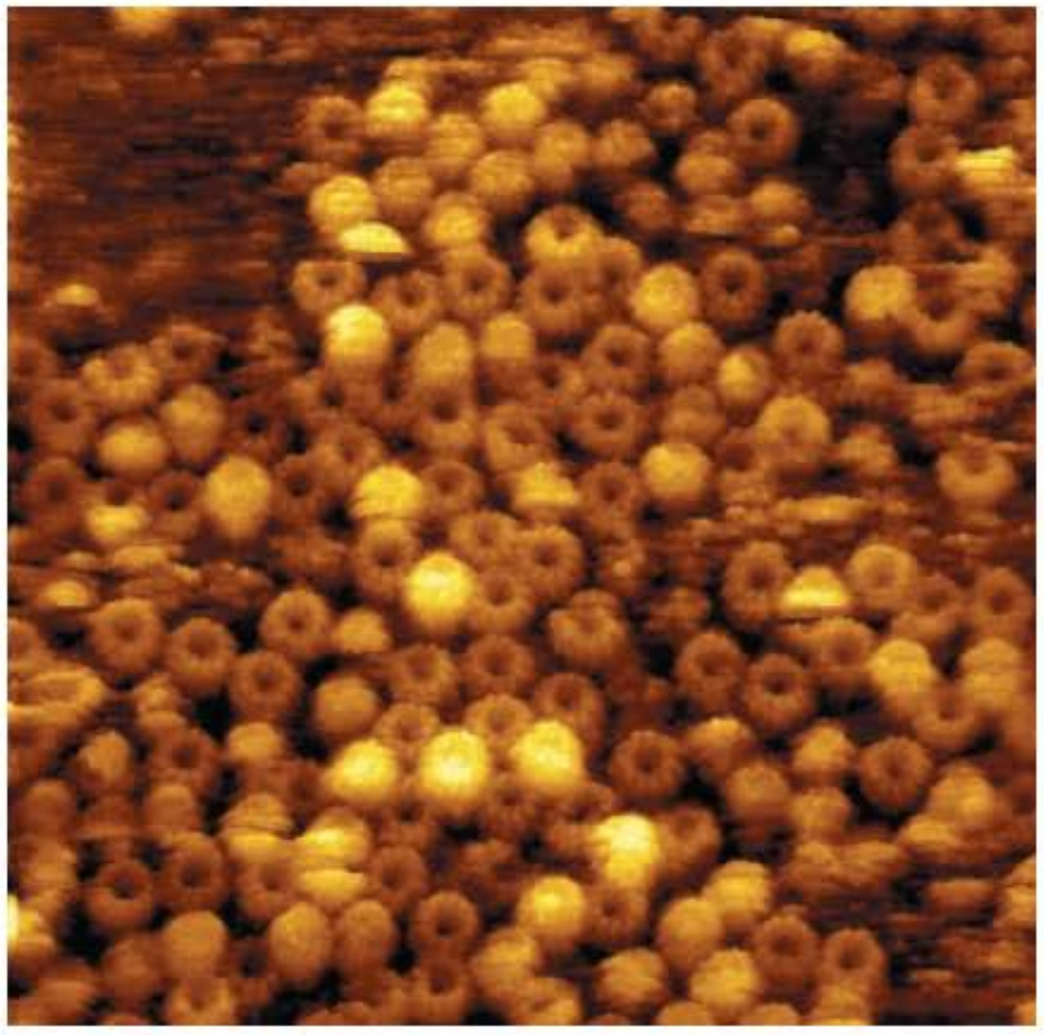

Figure 24.9 Atomic force microscopy reveals the structure of energy-converting ATP synthase rotor rings.

HOMEOSTATIC IMBALANCE 24.1 — CLINICAL

Studies of metabolic poisons support the chemiosmotic model of oxidative phosphorylation. For example, cyanide (the gas used in gas chambers) disrupts oxidative phosphorylation by binding to cytochrome oxidase and blocking electron flow from complex IV to oxygen (see Figure 24.8). Poisons called "uncouplers" abolish the proton gradient by making the inner mitochondrial membrane permeable to H^+. Consequently, although the electron transport chain continues to deliver electrons to oxygen at a furious pace and oxygen consumption rises, no ATP is made.

Summary of ATP Production

The average person at rest uses energy at the rate of roughly 100 kcal/hour, which is equal to 116 watts, or slightly more than an old-fashioned lightbulb. This may seem a tiny amount, but from a biochemical standpoint it places a staggering power demand on our mitochondria. Luckily, they are up to the task.

When O_2 is present, cellular respiration is remarkably efficient. Of the 686 kcal of energy present in 1 mole of glucose, as much as 262 kcal can be captured in ATP bonds. (The rest is liberated as heat.) This corresponds to an energy capture of about 38%, making cells far more efficient than any human-made machines, which capture only 10–30% of the energy available to them.

During cellular respiration, most energy flows in this sequence:

$$\text{Glucose} \rightarrow \text{NADH} + H^+ \rightarrow \text{electron transport chain} \rightarrow \text{proton gradient energy} \rightarrow \text{ATP}$$

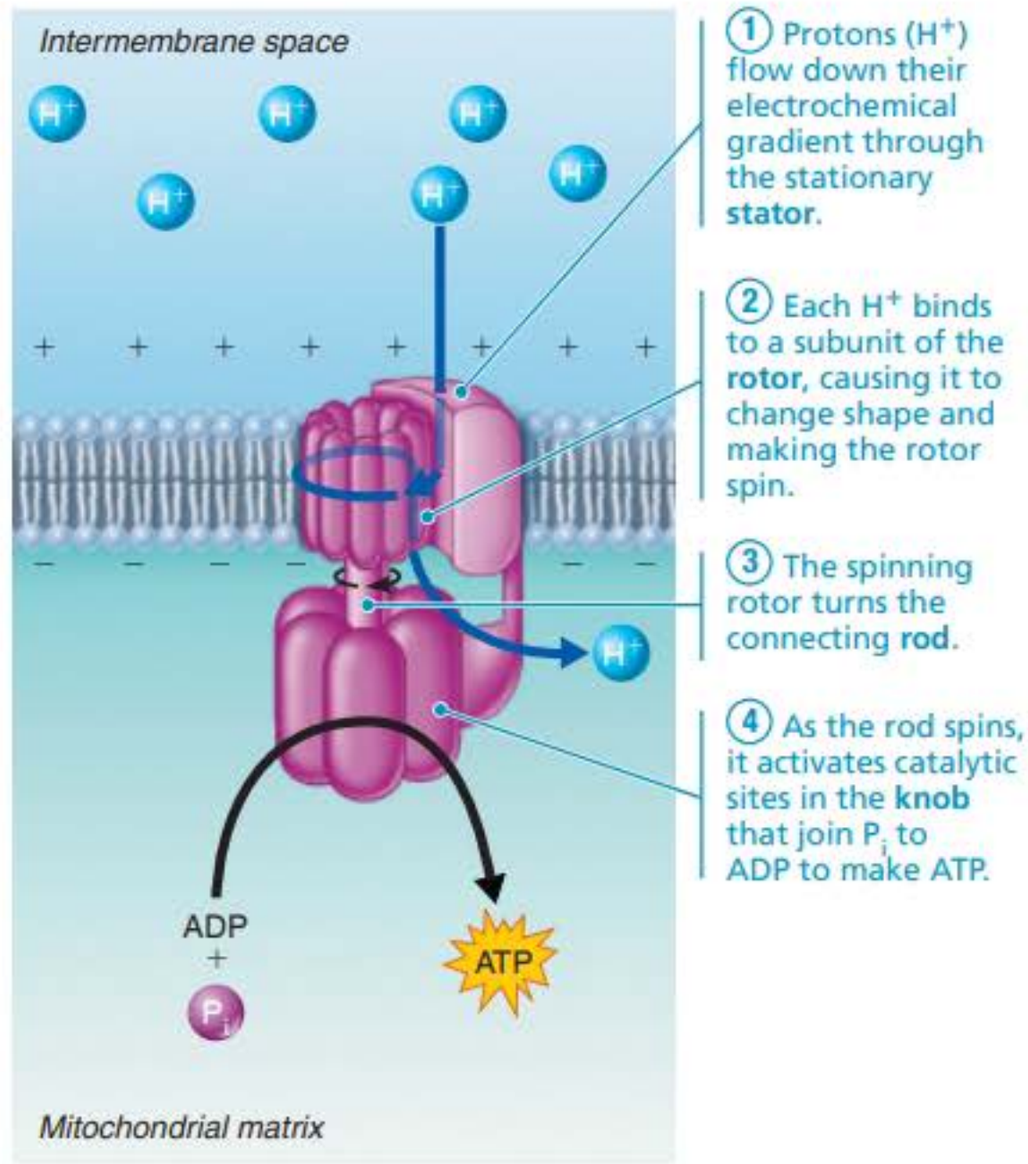

Figure 24.10 Structure and function of ATP synthase.

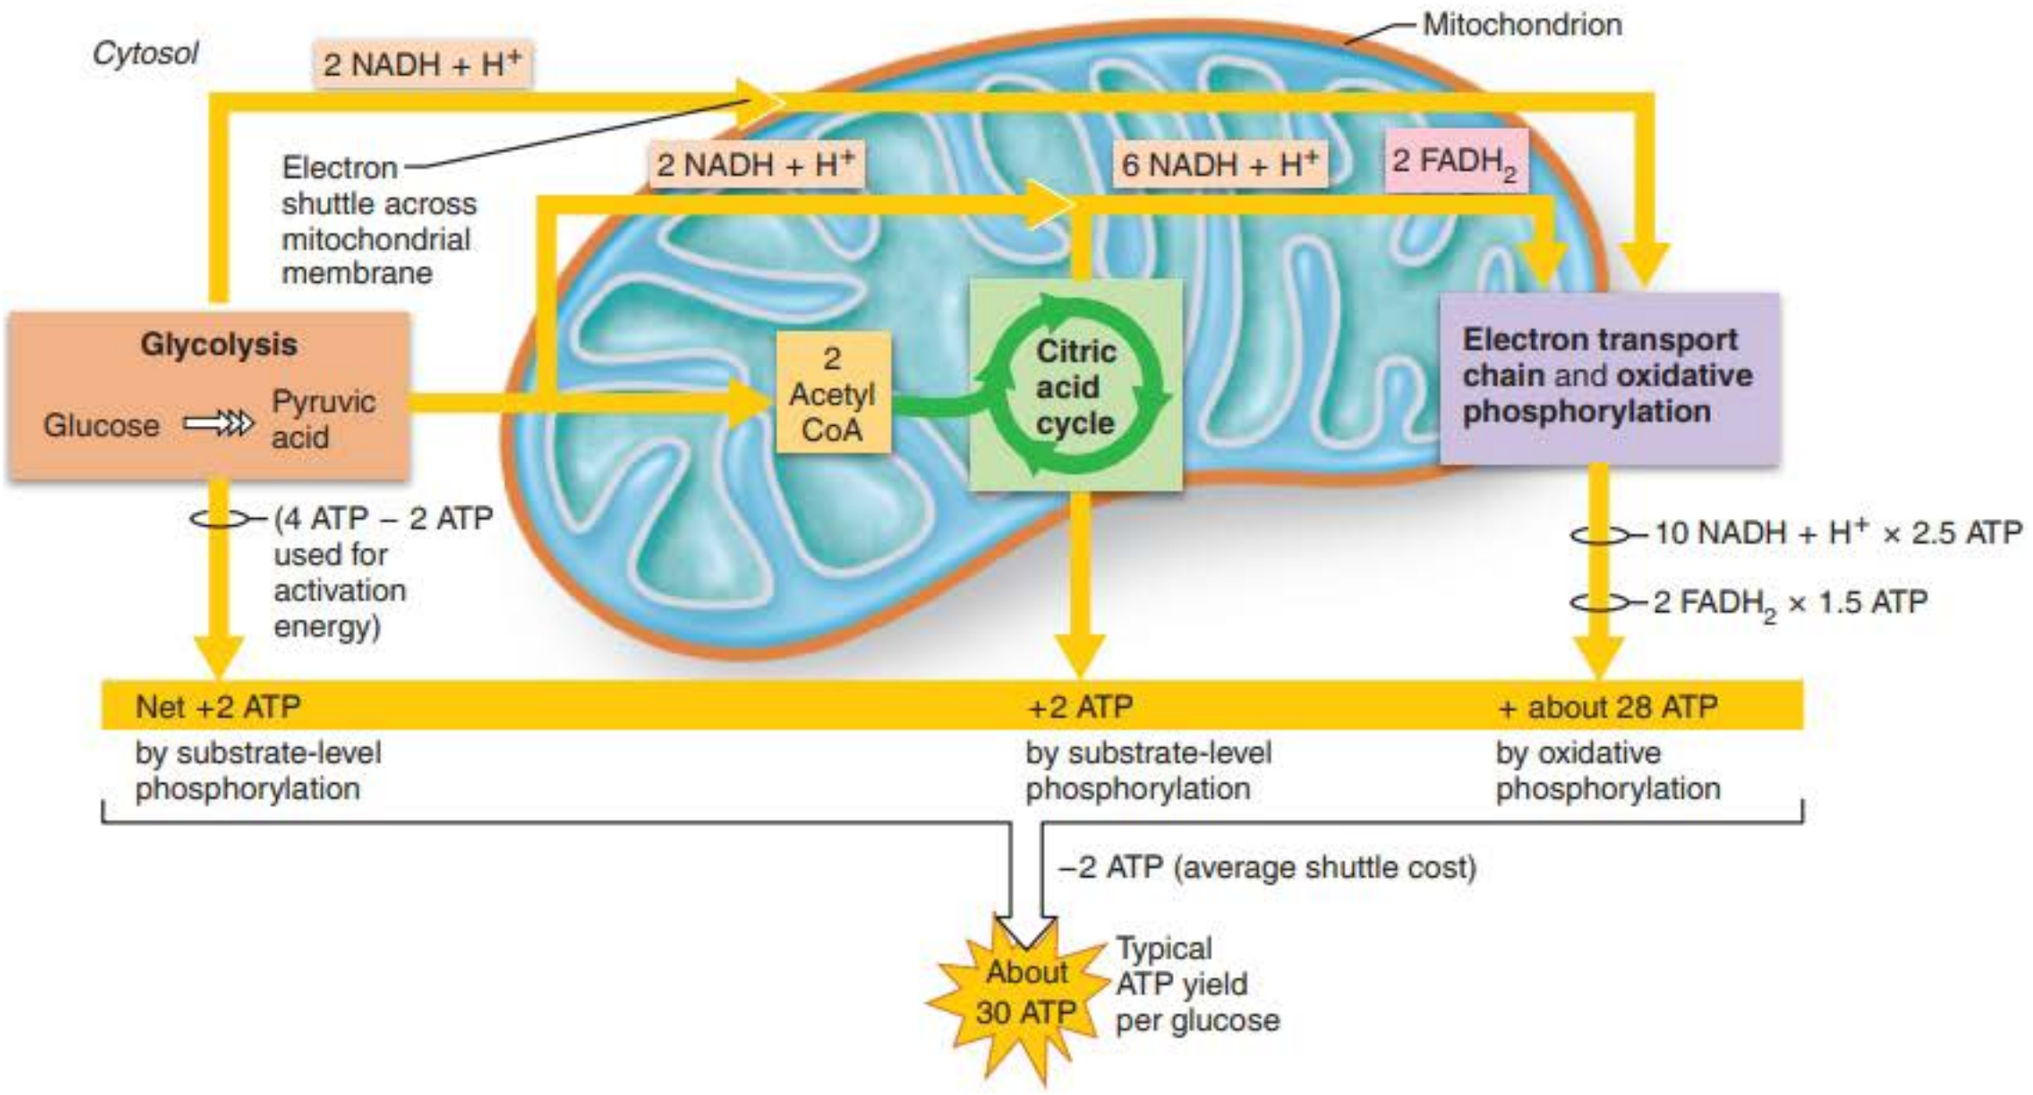

Figure 24.11 **Energy yield during cellular respiration.**

Let's do a little bookkeeping to summarize the net energy gain from one glucose molecule (**Figure 24.11**).

1. **Substrate-level phosphorylation.** Substrate-level phosphorylation gives us a net gain of 4 ATP (2 during glycolysis and 2 during the citric acid cycle).
2. **Oxidative phosphorylation.** NADH + H^+ and $FADH_2$ feeding into oxidative phosphorylation give us about 28 ATP.

   For each NADH + H^+, the proton gradient generates about 2½ ATP molecules. The 2 NADH + H^+ generated during glycolysis yield 5 ATP. The 8 NADH + H^+ produced during the transition reaction and citric acid cycle generate 20 ATP.

   The oxidation of $FADH_2$ is less efficient because it doesn't donate electrons to the "top" of the electron transport chain as does NADH + H^+, but to a lower energy level (at complex II). Each $FADH_2$ generates only about 1½ ATP, and so the 2 $FADH_2$ from the citric acid cycle are "worth" a total of 3 ATP.

Overall, complete oxidation of 1 glucose molecule to CO_2 and H_2O by both substrate-level phosphorylation and oxidative phosphorylation yields a maximum of 32 molecules of ATP. However, there is uncertainty about how much ATP is generated from the NADH + H^+ that comes from glycolysis that occurs *outside* the mitochondria. The inner mitochondrial membrane is not permeable to reduced NADH, so NADH + H^+ formed during glycolysis uses a *shuttle molecule* to deliver its electron pair to the electron transport chain. Some shuttles (for example, the glycerol phosphate shuttle) have an energy cost of 1 ATP per NADH, whereas other shuttles seem to provide a "free ride."

So, if we deduct 2 ATP to cover the average "fare" for the shuttle, our bookkeeping comes up with a grand total of 30 ATP per glucose as the typical energy yield. (Actually our figures are probably still too high because the proton gradient energy is also used to do other work and so the electron transport chain cannot recover all of the energy in a glucose molecule.)

Glycogenesis, Glycogenolysis, and Gluconeogenesis

Although most glucose is used to generate ATP molecules, unlimited amounts of glucose do *not* result in unlimited ATP synthesis, because cells cannot store large amounts of ATP. Aside from cellular respiration, the goal of carbohydrate metabolism is to make sure that just the right amount of glucose is present in the blood. Three processes with similar sounding names are required. **Figure 24.12** will help you keep them straight.

Glycolysis: Converts glucose to pyruvic acid
Glycogenesis: Polymerizes glucose to form glycogen
Glycogenolysis: Hydrolyzes glycogen to glucose monomers
Gluconeogenesis: Forms glucose from noncarbohydrate precursors

Figure 24.12 **Quick summary of carbohydrate reactions.**

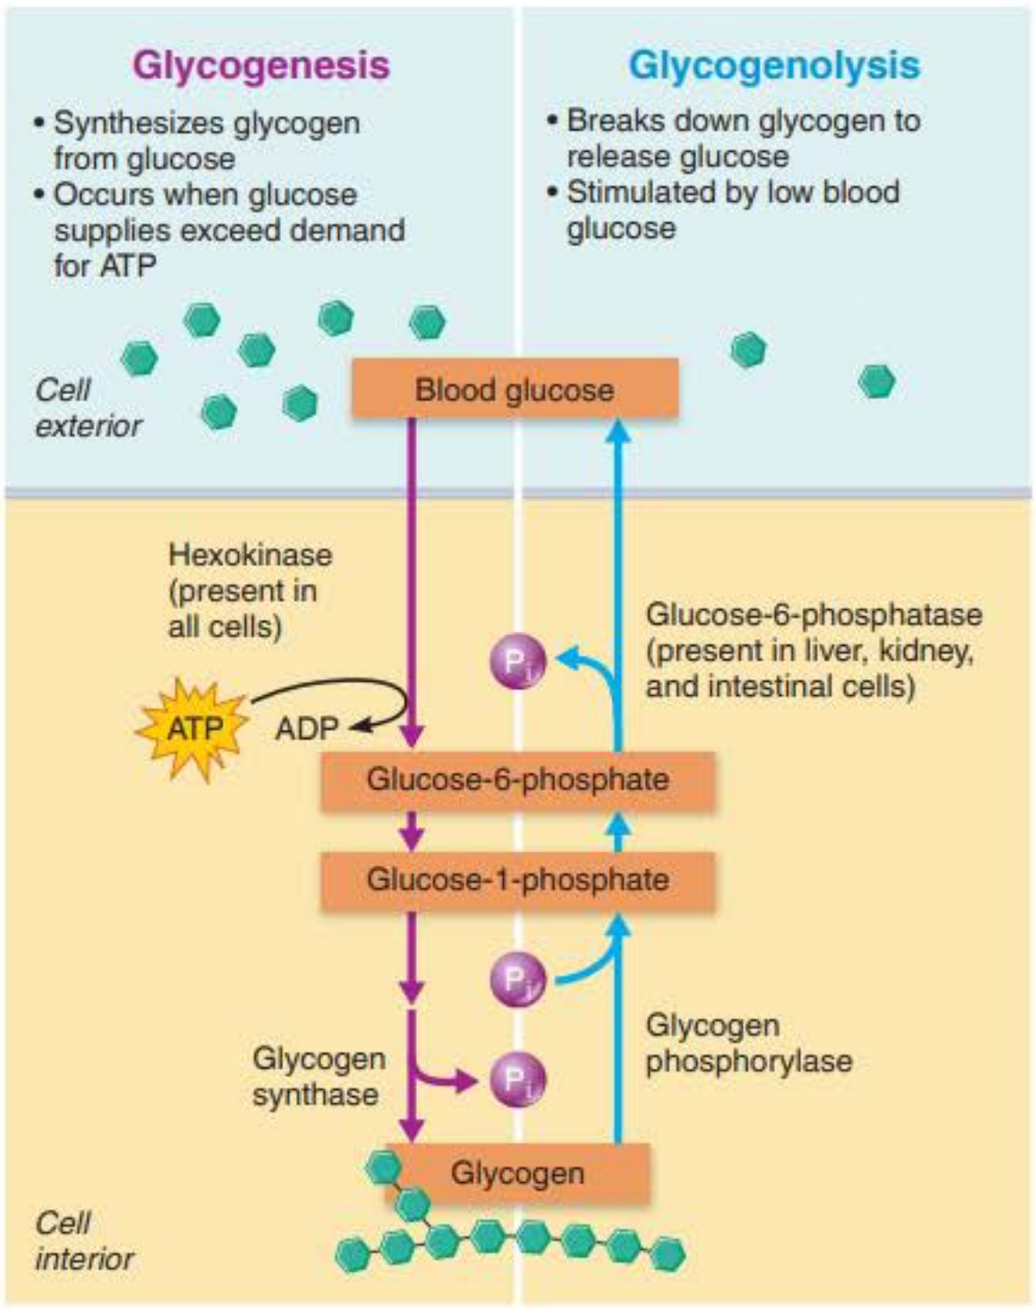

Figure 24.13 **Glycogenesis and glycogenolysis.**

When more glucose is available than can immediately be oxidized, rising intracellular ATP concentrations eventually inhibit glucose catabolism and cause glucose to be stored as glycogen or fat. Because the body can store much more fat than glycogen, fats account for 80–85% of stored energy.

Glycogenesis

When high ATP levels begin to "turn off" glycolysis, glucose molecules are combined in long chains to form glycogen, the animal carbohydrate storage product. This process is called **glycogenesis** (*glyco* = sugar; *genesis* = origin) (**Figure 24.13**, left side).

Glycogenesis begins as glucose entering cells is phosphorylated to glucose-6-phosphate and then converted to its isomer, *glucose-1-phosphate*. The terminal (last) phosphate group is split off as the enzyme *glycogen synthase* catalyzes the attachment of glucose to the growing glycogen chain. Liver and skeletal muscle cells are most active in glycogen synthesis and storage.

Glycogenolysis

On the other hand, when blood glucose levels drop, glycogen lysis (splitting) occurs. This process is known as **glycogenolysis** (gli″ko-jĕ-nol′ĭ-sis) (Figure 24.13, right side). The enzyme *glycogen phosphorylase* oversees phosphorylation and splitting of glycogen to release glucose-1-phosphate, which is then converted to glucose-6-phosphate, a form that can enter the glycolysis pathway to be oxidized for energy.

In muscle cells and most other cells, the glucose-6-phosphate resulting from glycogenolysis is trapped because it cannot cross the cell membrane. However, hepatocytes (and some kidney and intestinal cells) contain *glucose-6-phosphatase*, an enzyme that removes the terminal phosphate, producing free glucose. Because glucose can then readily diffuse from the cell into the blood, the liver can use its glycogen stores to provide blood sugar for other organs when blood glucose levels drop. Liver glycogen is also an important energy source for skeletal muscles that have depleted their own glycogen reserves.

Gluconeogenesis

When too little glucose is available to stoke the "metabolic furnace," glycerol and amino acids are converted to glucose. **Gluconeogenesis**, the process of forming new (*neo*) glucose from *noncarbohydrate* molecules, occurs in the liver.

Gluconeogenesis takes place when dietary sources and glucose reserves have been used up and blood glucose levels are beginning to drop. Gluconeogenesis protects the body, especially the nervous system, from the damaging effects of low blood sugar (*hypoglycemia*) by ensuring that ATP synthesis can continue.

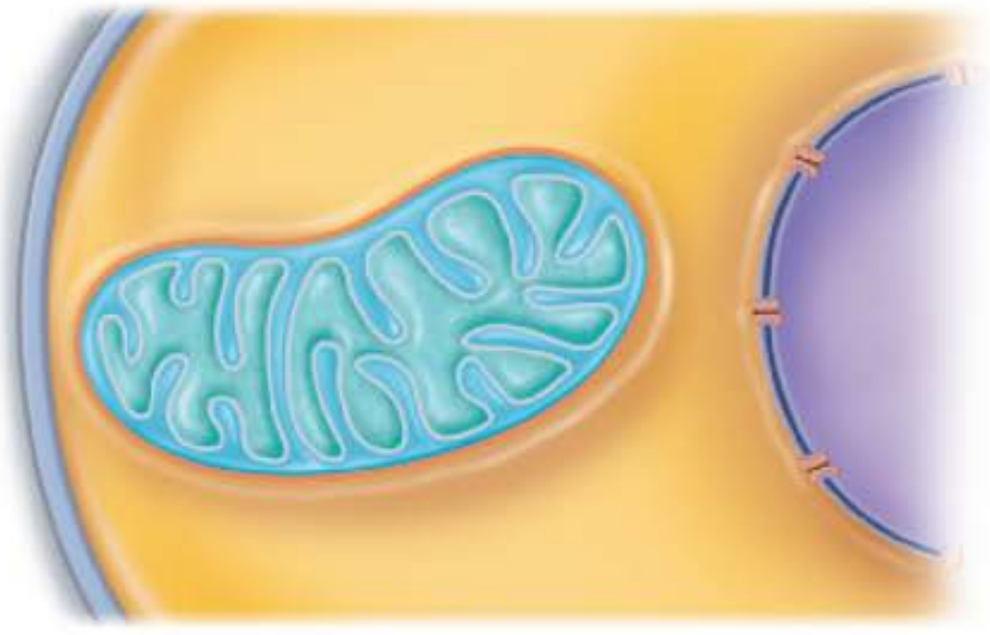
Check Your Understanding

12. What happens in glycolysis if oxygen and pyruvic acid are absent and NADH + H^+ cannot transfer its cargo of hydrogen to pyruvic acid?

13. What two major kinds of chemical reactions occur in the citric acid cycle, and how are these reactions indicated symbolically?

14. What name is given to the chemical reaction in which glycogen is broken down to its glucose subunits?

15. DRAW In the drawing of a cell and mitochondrion below, label the inner mitochondrial membrane, the outer mitochondrial membrane, the intermembrane space, and the matrix of the mitochondrion. Point to a location where each of the following processes takes place: glycolysis, citric acid cycle, oxidative phosphorylation. Identify the region where you would find the lowest pH.



For answers, seeAnswers Appendix.

24.5 Lipid metabolism is key for long-term energy storage and release

Learning Outcomes

- **Describe the process by which fatty acids are oxidized for energy.**
- **Define ketone bodies, and indicate the stimulus for their formation.**

Fats are the body's most concentrated source of energy. They contain very little water, and the energy yield from fat catabolism is more than twice that from either glucose or protein catabolism—9 kcal per gram of fat versus 4 kcal per gram of carbohydrate or protein. Most products of fat digestion are transported in lymph in the form of fatty-protein droplets called *chylomicrons* (see Chapter 23). Eventually, enzymes on capillary endothelium hydrolyze the lipids in the chylomicrons, and the resulting fatty acids and glycerol are taken up by body cells and processed in various ways. **Figure 24.14** summarizes the key metabolic reactions for lipids.

Oxidation of Glycerol and Fatty Acids

Of the various lipids, only triglycerides (◀ p. 45) are routinely oxidized for energy. Their catabolism involves the separate oxidation of their two different building blocks: glycerol and fatty acid chains (**Figure 24.15**).

Most body cells easily convert glycerol to glyceraldehyde 3-phosphate (a glycolysis intermediate) and eventually to acetyl CoA, which enters the citric acid cycle. Glyceraldehyde is equal to half a glucose molecule, and so the ATP energy harvest from its complete oxidation is approximately half that of glucose (15 ATP/glycerol).

Beta oxidation, the initial phase of fatty acid oxidation, occurs in the mitochondria. The net result is that the fatty acid chains are broken apart into two-carbon *acetic acid* fragments, and coenzymes (FAD and NAD^+) are reduced (Figure 24.15, right side). Each acetic acid molecule is fused to coenzyme A, forming acetyl CoA. The term "beta oxidation" reflects the fact that the carbon in the beta (third) position is oxidized each time a two-carbon fragment is broken off. Acetyl CoA then enters the citric acid cycle where it is oxidized to CO_2 and H_2O.

Beta oxidation: Converts fatty acids to acetyl CoA
Lipolysis: Breaks down lipids to fatty acids and glycerol
Lipogenesis: Forms lipids from acetyl CoA and glyceraldehyde 3-phosphate

Figure 24.14 Quick summary of lipid reactions.

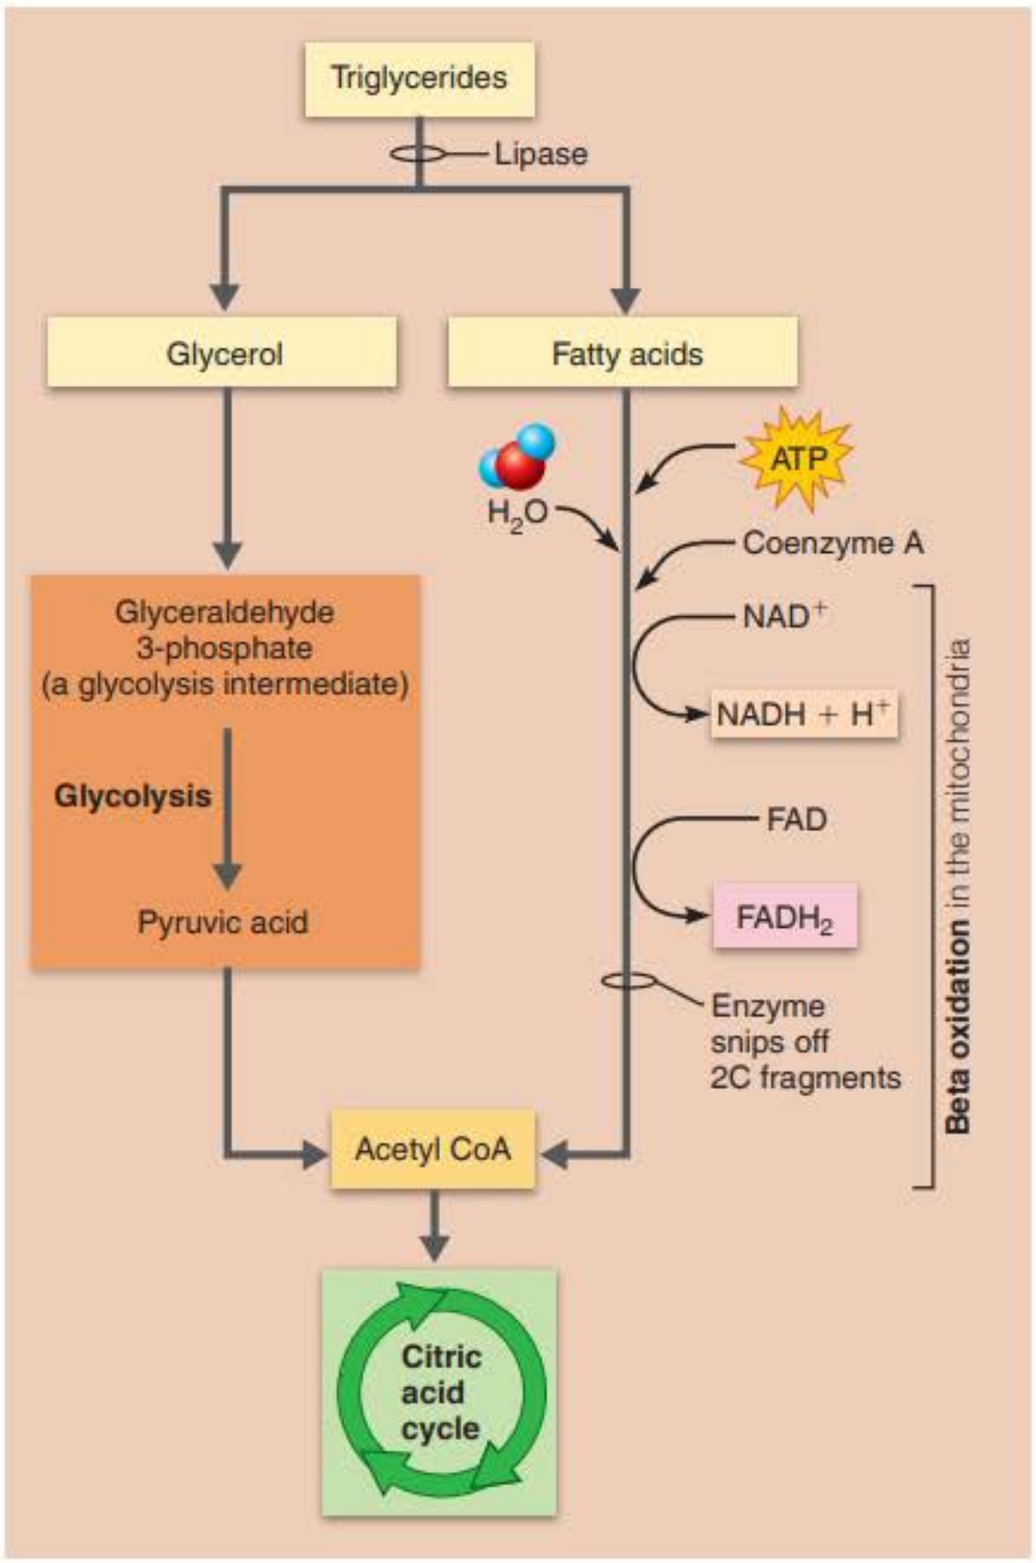


Figure 24.15 Lipid oxidation.

Lipogenesis

There is a continuous turnover of triglycerides in adipose tissue. New fats are stored for later use, and stored fats are broken down and released to the blood. That bulge of fatty tissue you see today does *not* contain the same fat molecules it did a month ago.

Glycerol and fatty acids from dietary fats not immediately needed for energy are recombined into triglycerides and stored. About 50% ends up in subcutaneous tissue, and the balance is stockpiled in other fat depots of the body.

Triglyceride synthesis, or **lipogenesis**, occurs when cellular ATP and glucose levels are high (**Figure 24.16**, magenta arrows). Excess ATP leads to an accumulation of acetyl CoA and glyceraldehyde 3-phosphate, two intermediates of glucose metabolism that would otherwise feed into the citric acid cycle. When these two metabolites are present in excess, they are channeled into triglyceride synthesis pathways.

Acetyl CoA molecules are joined together, forming fatty acid chains that grow two carbons at a time. (This accounts for

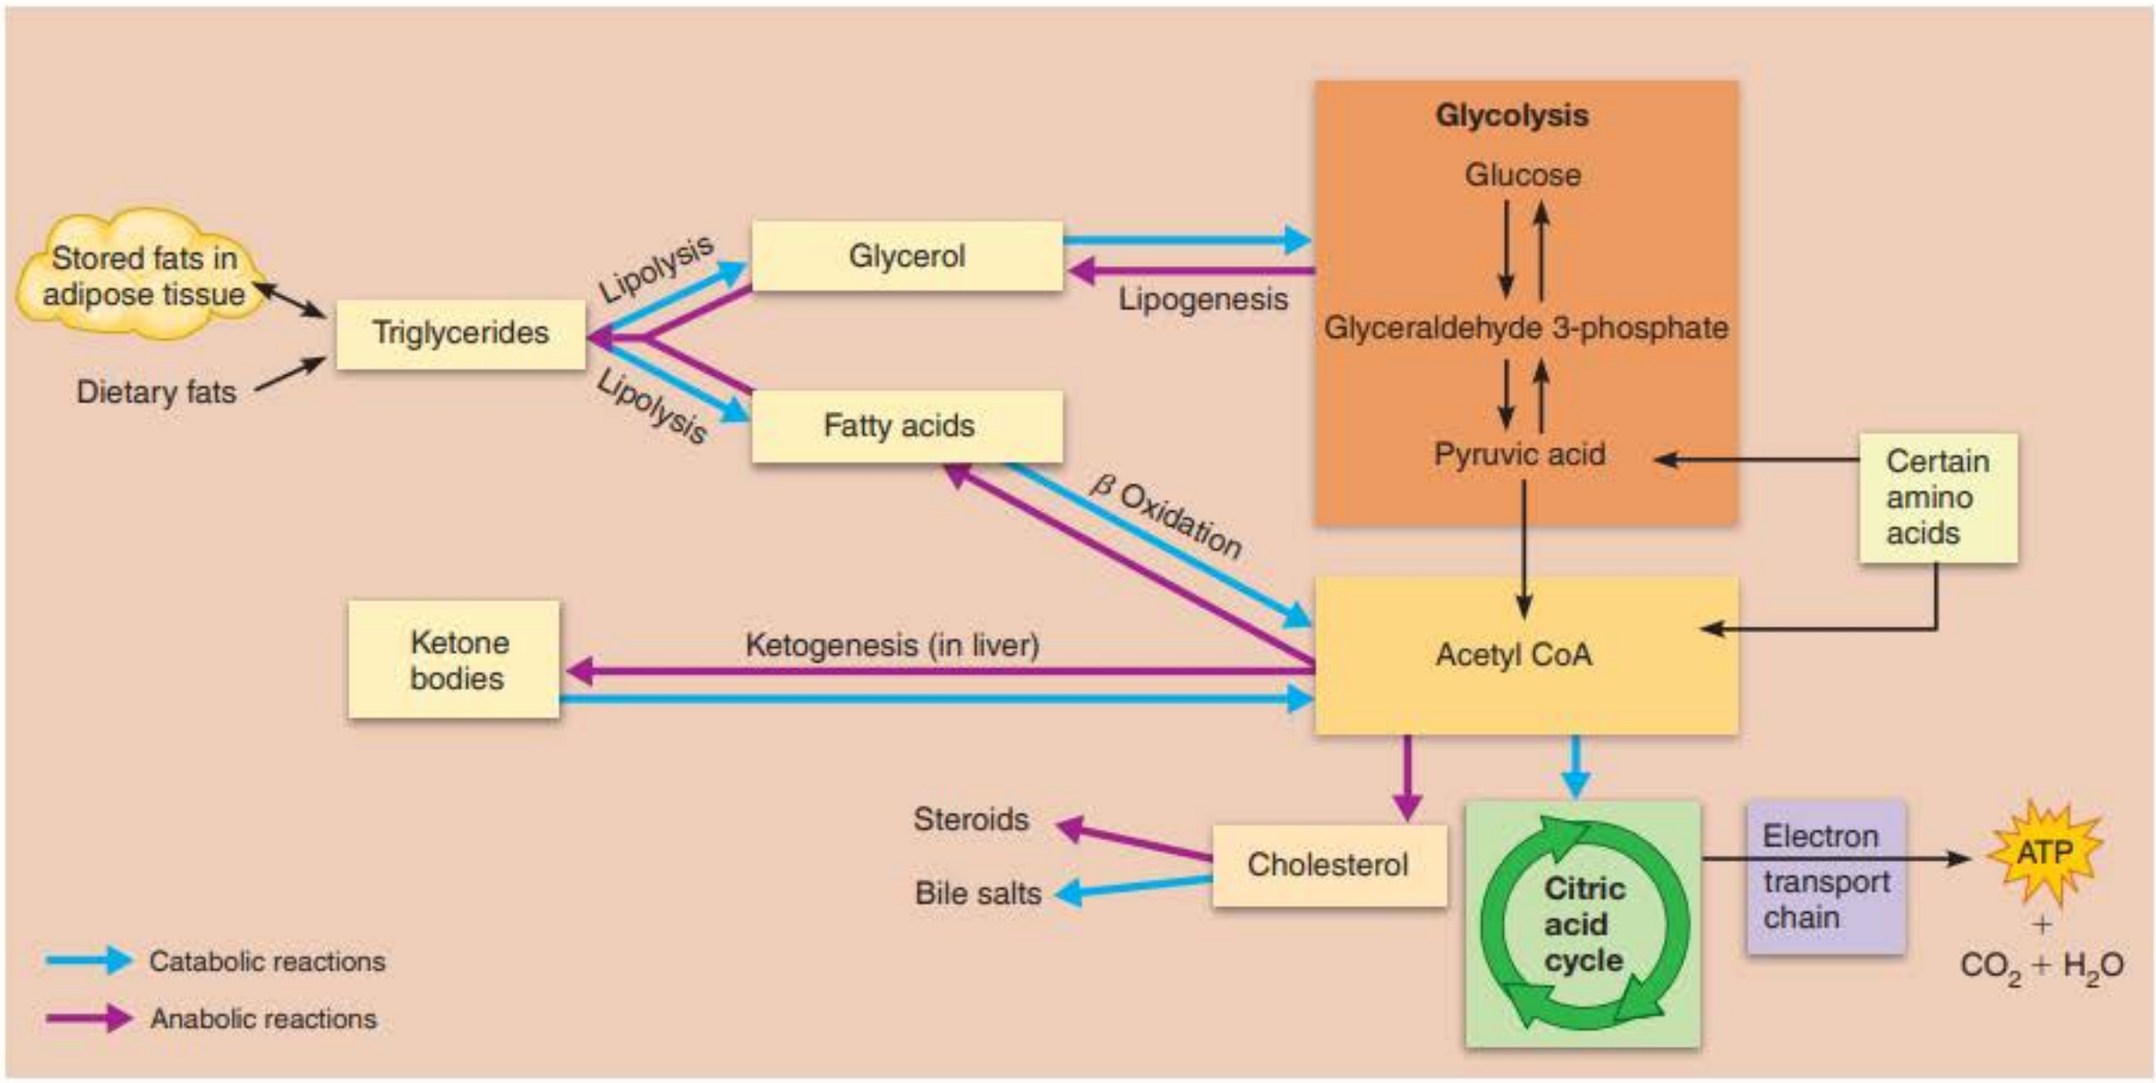

Figure 24.16 Lipid metabolism. When needed for energy, fats enter catabolic pathways (lipolysis). Excessive amounts of carbohydrates and amino acids are converted to triglycerides (lipogenesis) and stored.

the fact that almost all fatty acids in the body contain an even number of carbon atoms.) Because acetyl CoA, an intermediate in glucose catabolism, is also the *starting point* for fatty acid synthesis, glucose is easily converted to fat. Glyceraldehyde 3-phosphate is converted to glycerol, which is joined with fatty acids to form triglycerides. Consequently, even with a low-fat diet, carbohydrate intake can provide *all the raw materials* needed to make triglycerides. When blood sugar is high, lipogenesis is the major activity in adipose tissues and is also an important liver function.

Lipolysis

Lipolysis (lĭ-pol′ĭ-sis; "fat splitting"), the breakdown of stored fats into glycerol and fatty acids, is essentially lipogenesis in reverse (Figure 24.16, blue arrows). The fatty acids and glycerol are released to the blood, helping to ensure that body organs have continuous access to fat fuels for aerobic respiration. (The liver, cardiac muscle, and resting skeletal muscles actually prefer fatty acids as an energy fuel.)

The adage "Fats burn in the flame of carbohydrates" becomes clear when carbohydrate intake is inadequate. Under such conditions, lipolysis accelerates as the body attempts to fill the fuel gap with fats. However, the ability of acetyl CoA to enter the citric acid cycle depends on having sufficient carbohydrate intermediate molecules (see Figure 24.7). When carbohydrates are deficient, these intermediates are converted to glucose (to fuel the brain). Without them, fat oxidation is incomplete, and acetyl CoA accumulates.

Via a process called **ketogenesis**, the liver converts acetyl CoA molecules to **ketone bodies**, or **ketones**, which are released into the blood. Ketone bodies include acetoacetic acid, β-hydroxybutyric acid, and acetone. (The *keto acids* cycling through the citric acid cycle and the *ketone bodies* resulting from fat metabolism are quite different and should not be confused.)

HOMEOSTATIC IMBALANCE 24.2 — CLINICAL

When ketone bodies accumulate in the blood, *ketosis* results and large amounts of ketone bodies are excreted in the urine. Ketosis is a common consequence of starvation and diabetes mellitus, and also occurs during carbohydrate restriction.

Because most ketone bodies are organic acids, ketosis leads to *metabolic acidosis*. The body's buffer systems cannot tie up the acids (ketones) fast enough, and blood pH drops to dangerously low levels. The person's breath smells fruity as acetone vaporizes from the lungs, and breathing becomes more rapid as the respiratory system tries to reduce blood carbonic acid by blowing off CO_2 to force the blood pH up. In severe untreated cases, the person may become comatose or even die as the acid pH depresses the nervous system.

Synthesis of Structural Materials

All body cells use phospholipids and cholesterol to build their membranes. Phospholipids are important components of the myelin sheaths of neurons, and the ovaries, testes, and adrenal

cortex use cholesterol to synthesize their steroid hormones. In addition, the liver:

- Synthesizes lipoproteins to transport cholesterol, fats, and other substances in the blood (see pp. 956–957)
- Synthesizes cholesterol from acetyl CoA
- Uses cholesterol to form bile salts (◀ p. 897)

Check Your Understanding

16. Which part of triglyceride molecules enters glycolysis?
17. What is the central molecule in fat metabolism?
18. What are the products of beta oxidation?

For answers, see Answers Appendix.

24.6 Amino acids are used to build proteins or for energy

Learning Outcomes

- **Describe how amino acids are metabolized for energy.**
- **Describe the need for protein synthesis in body cells.**

Like all other biological molecules, proteins have a limited life span and must be broken down and replaced before they deteriorate. As proteins are broken down, their amino acids are recycled and used to build new proteins or modified to form a different N-containing compound. Cells actively take up newly ingested amino acids from the blood and use them to *replace* tissue proteins at the rate of about 100 grams each day.

Although popular opinion has it that excess protein can be stored by the body, nothing is farther from the truth. When more protein is available than is needed for anabolic purposes,

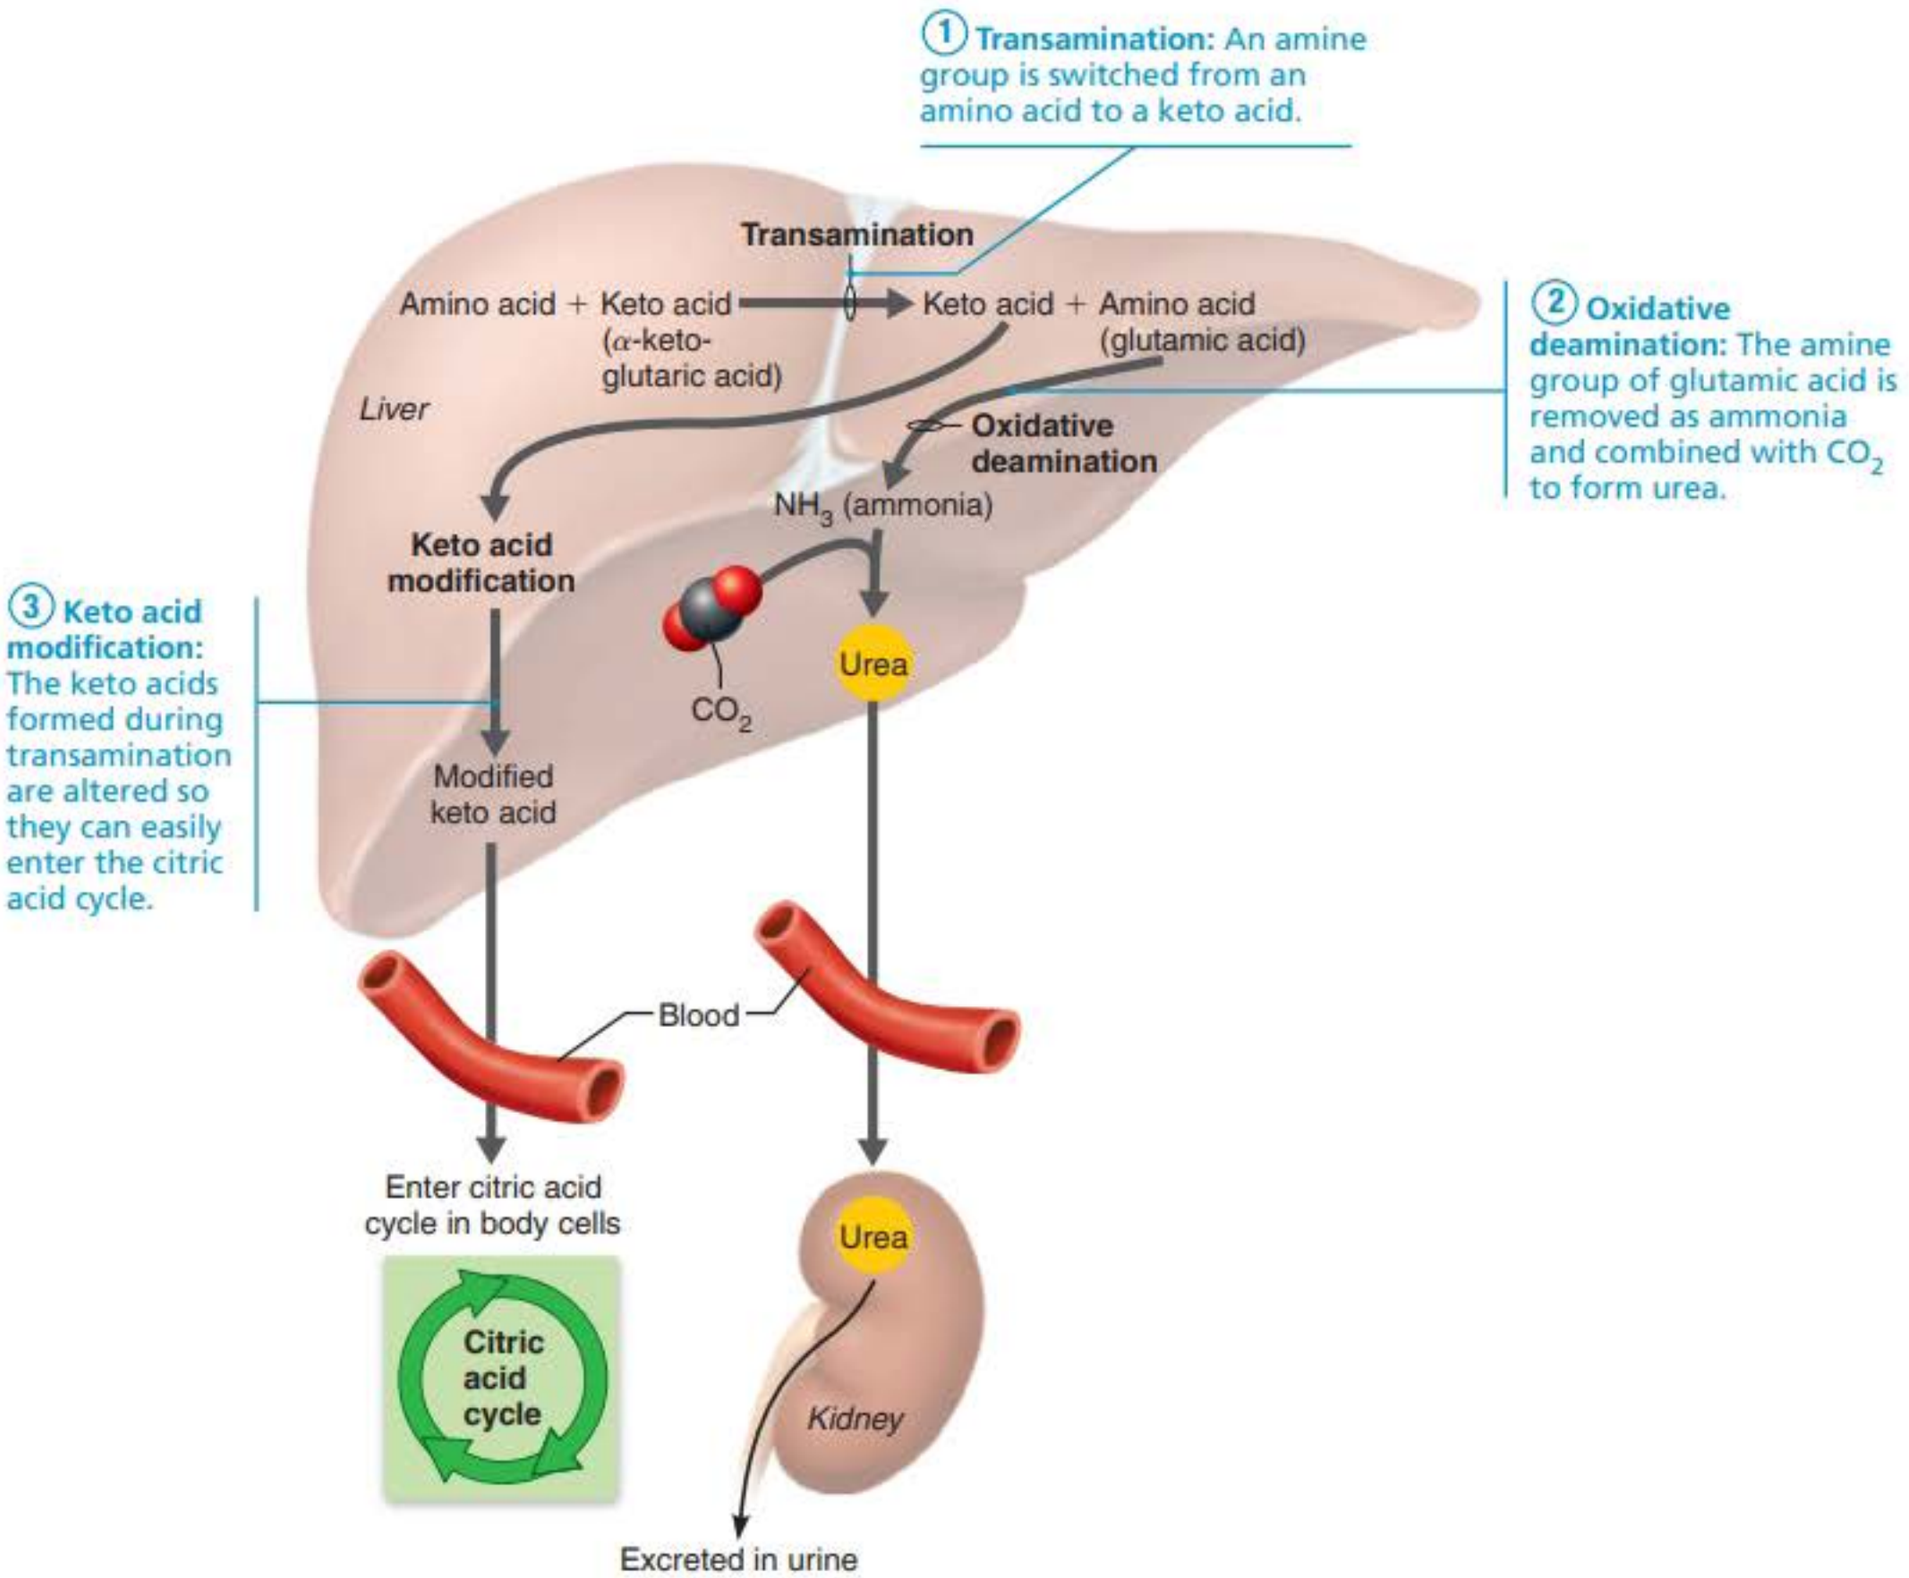

Figure 24.17 Processes that occur when amino acids are utilized for energy.

amino acids are oxidized for energy or converted to fat for future energy needs.

Degradation of Amino Acids

The goal of amino acid degradation is to produce molecules that can be oxidized for energy in the citric acid cycle or converted to glucose. Before amino acids can be oxidized or converted, they must be *deaminated*, that is, their amine group (NH_2) must be removed. (In sulfur-containing amino acids, such as methionine and cysteine, sulfur must also be removed.) The resulting molecule is then converted to pyruvic acid or to one of the keto acid intermediates in the citric acid cycle.

The key molecule in these conversions is the amino acid *glutamic acid* (gloo-tam′ik). As **Figure 24.17** shows, the following events occur:

1. **Transamination** (trans″am-ĭ-na′shun). A number of amino acids can transfer their amine group to α-ketoglutaric acid (a citric acid cycle keto acid), thereby transforming α-ketoglutaric acid to glutamic acid. In the process, the original amino acid becomes a keto acid (that is, it has an oxygen atom where the amine group formerly was). This reaction is fully reversible.
2. **Oxidative deamination.** In the liver, the amine group of glutamic acid is removed as **ammonia (NH_3)**, and α-ketoglutaric acid is regenerated. The liberated NH_3 molecules are combined with CO_2, yielding **urea** and water. The urea is released to the blood and excreted from the body in urine. Because ammonia is toxic to body cells, the ease with which glutamic acid funnels amine groups into the **urea cycle** is extremely important. This cycle rids the body not only of NH_3 produced during oxidative deamination, but also of bloodborne NH_3 produced by intestinal bacteria.
3. **Keto acid modification.** Keto acids resulting from transamination are altered as necessary to produce metabolites that can enter the citric acid cycle. The most important of these metabolites are pyruvic acid, acetyl CoA, α-ketoglutaric acid, and oxaloacetic acid (see Figure 24.7). Because the reactions of glycolysis are reversible, deaminated amino acids that are converted to pyruvic acid can be reconverted to glucose and contribute to gluconeogenesis.

A quick summary of the key reactions is shown in **Figure 24.18**.

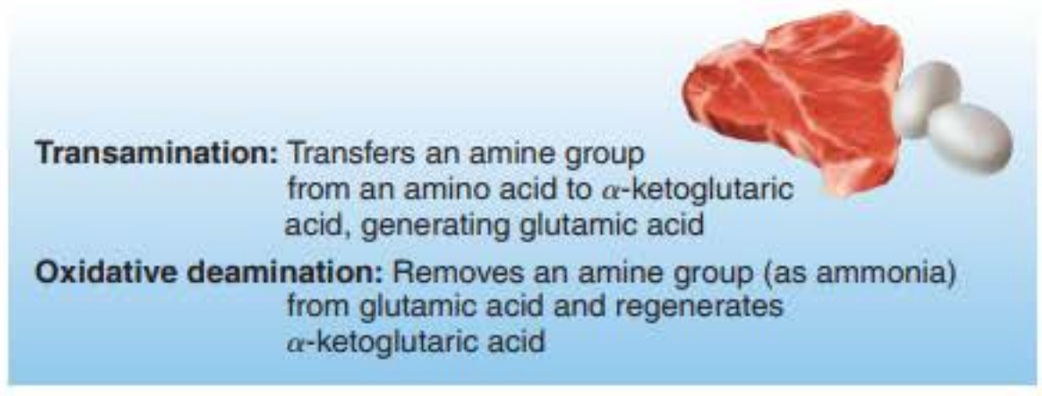

Figure 24.18 Quick summary of amino acid catabolism.

Protein Synthesis

Amino acids are the most important anabolic nutrients. Not only do they form all structural proteins, but they form most of the body's functional molecules as well. As we described in Chapter 3 (◀ pp. 104–107), protein synthesis occurs on ribosomes, where ribosomal enzymes oversee the formation of peptide bonds linking the amino acids together into protein polymers. Hormones (growth hormone, thyroxine, sex hormones, and others) precisely control the amount and type of protein synthesized. The rate of protein anabolism changes as we age and our balance of hormones changes.

During your lifetime, your cells will synthesize 225–450 kg (about 500–1000 lb) of proteins, depending on your size. However, you do not need to consume anywhere near that amount of protein because the body easily forms nonessential amino acids by siphoning keto acids from the citric acid cycle and transferring amine groups to them. Most of these transformations occur in the liver, which provides nearly all the nonessential amino acids needed to produce the relatively small amount of protein that the body synthesizes each day.

However, a complete set of amino acids must be present for protein synthesis to take place, so the diet must provide all essential amino acids. If some are lacking, the rest are oxidized for energy even though they may be needed for anabolism. In such cases, body protein is broken down to supply the essential amino acids needed, and negative nitrogen balance results.

Check Your Understanding

19. What does the liver use as its substrates when it synthesizes nonessential amino acids?

20. What happens to the ammonia removed from amino acids when the amino acids are used for energy fuel?

For answers, see Answers Appendix.

24.7 Energy is stored in the absorptive state and released in the postabsorptive state

Learning Outcomes

- **Explain the concept of amino acid or carbohydrate-fat pools, and describe pathways by which substances in these pools can be interconverted.**
- **Summarize important events of the absorptive and postabsorptive states, and explain how these events are regulated.**

Catabolic-Anabolic Balance of the Body

Now that we have examined metabolism at cellular levels, let's step back to look at the body as a system that deploys metabolic processes to provide fuel. Your body exists in a *dynamic catabolic-anabolic balance*, that is, its organic molecules are continuously broken down and rebuilt—frequently at a head-spinning rate.

The body draws on its **nutrient pools**—the current stocks of amino acids, carbohydrates, and fats—to meet its varying needs

(**Figure 24.19**). These pools are interconvertible because their pathways are linked by key intermediates. The liver, adipose tissue, and skeletal muscles are the primary effector organs or tissues determining the amounts and direction of the conversions shown in the figure.

The **amino acid pool** is the body's total supply of free amino acids. Our bodies lose small amounts of amino acids and proteins daily in urine and in sloughed hairs and skin cells. Typically, we replace these lost molecules via our diet. Otherwise, amino acids arising from tissue breakdown return to the pool. This pool is the source of amino acids used to synthesize proteins and form amino acid derivatives. In addition, as we described above, gluconeogenesis can convert deaminated amino acids to glucose. Not all events of amino acid metabolism occur in all cells. For example, *only* the liver forms urea. Nonetheless, the concept of a common amino acid pool is valid because all cells are connected by the blood.

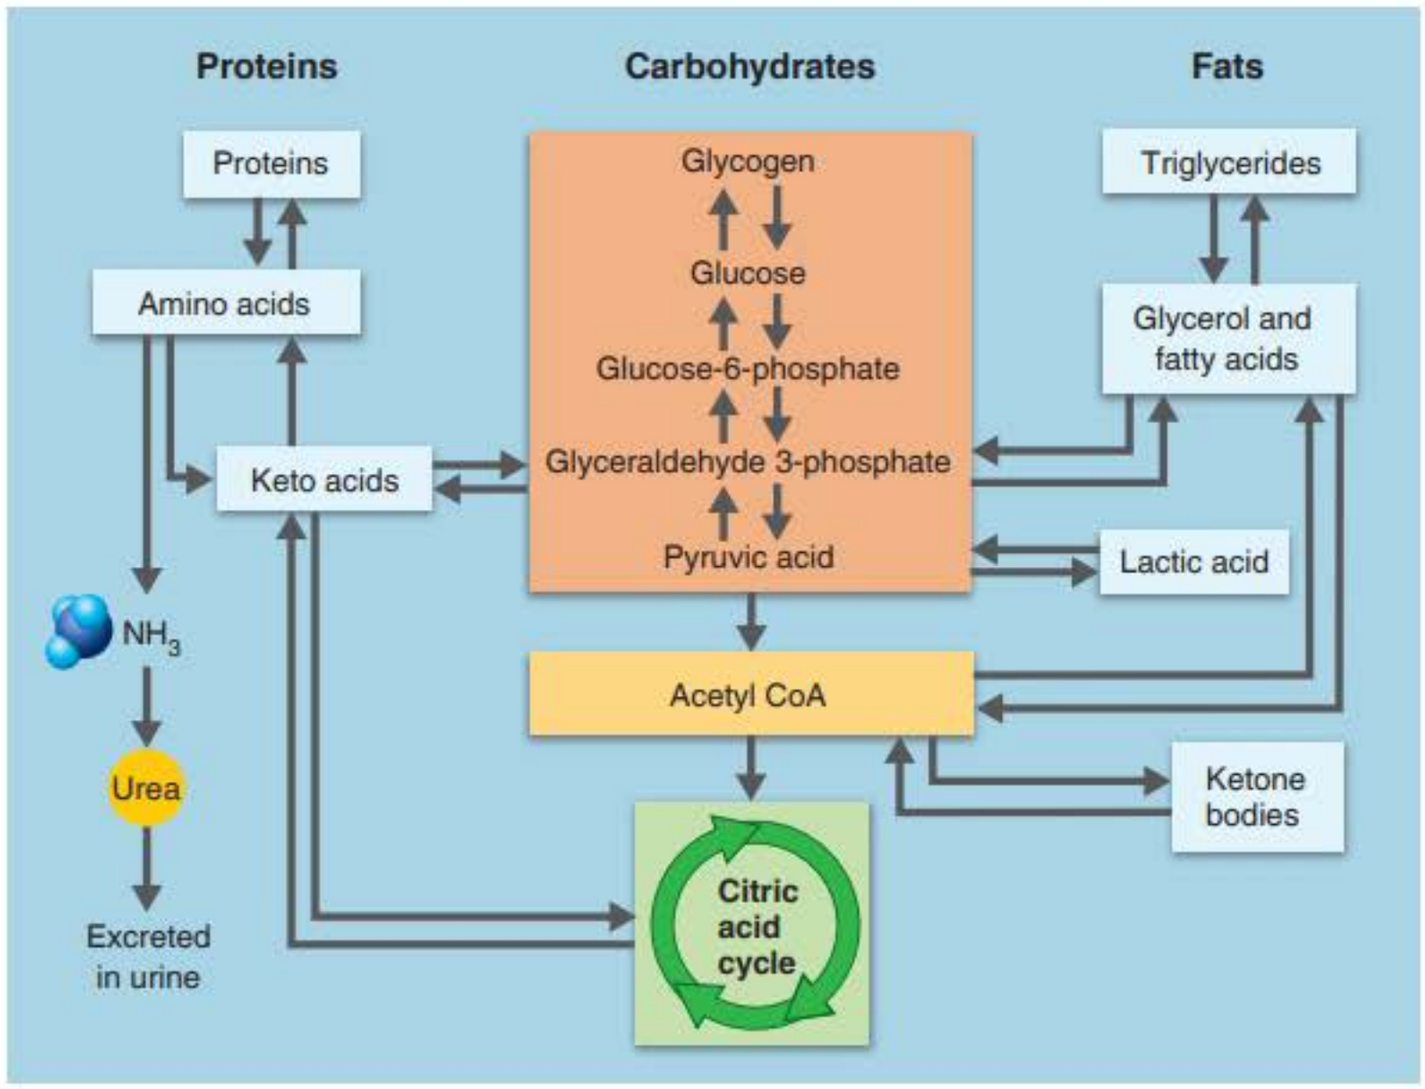

Figure 24.19 Interconversion of carbohydrates, fats, and proteins. These interconversions primarily occur in the liver, adipose tissue, and skeletal muscle.

Because carbohydrates are easily and frequently converted to fats, the **carbohydrate** and **fat pools** are usually considered together. There are two major differences between the carbohydrate-fat pool and the amino acid pool:

- Fats and carbohydrates are oxidized directly to produce cellular energy, whereas amino acids can be used to supply energy *only after being converted to a citric acid cycle intermediate* (a keto acid).
- Excess carbohydrate and fat can be stored as such, whereas excess amino acids are *not* stored as protein. Instead, they are oxidized for energy or converted to fat or glycogen for storage.

Metabolic controls act to equalize blood concentrations of energy sources between two nutritional states—the *absorptive state* and the *postabsorptive state*.

Absorptive State

The absorptive state, or *fed state,* lasts about four hours after eating begins, when nutrients are flushing into the blood from the GI tract. During the absorptive state, anabolism exceeds catabolism and nutrients are stored (**Figure 24.20**). Glucose is the major energy fuel. Dietary amino acids and fats are used to remake degraded body protein or fat, and small amounts are oxidized to provide ATP. Excess metabolites, regardless of source, are transformed to fat if not used for anabolism. Let's look at the fate and hormonal control of each nutrient group during this phase.

Carbohydrates

Absorbed monosaccharides are delivered directly to the liver, where fructose and galactose are converted to glucose. Glucose, in turn, is released to the blood or converted to glycogen and fat. Glycogen formed in the liver is stored there, but most fat synthesized there is packaged with proteins as *very low-density lipoproteins* (*VLDLs*; see p. 956) and released to the blood to be picked up by adipose tissues for storage.

Bloodborne glucose not sequestered by the liver enters body cells to be metabolized for energy. Excess glucose is stored in skeletal muscle cells as glycogen or in adipose cells as fat.

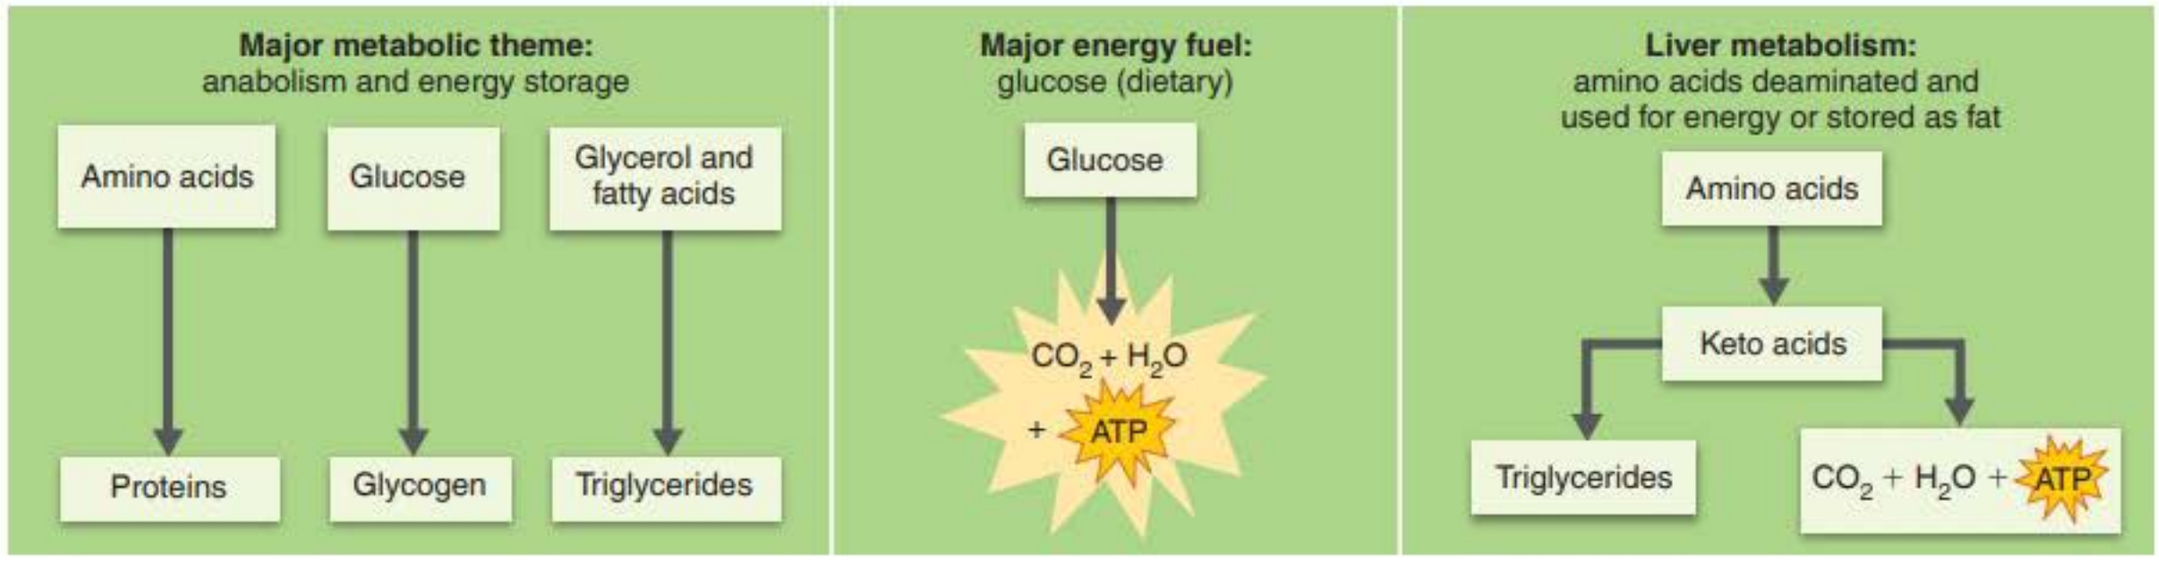
Triglycerides

Nearly all products of fat digestion enter the lymph in the form of chylomicrons (◀ p. 916). Triglycerides are hydrolyzed to fatty acids and glycerol, which can then pass through the capillary walls. *Lipoprotein lipase*, the enzyme that catalyzes fat hydrolysis, is particularly active in the capillaries of muscle and fat tissues (◀ p. 917).

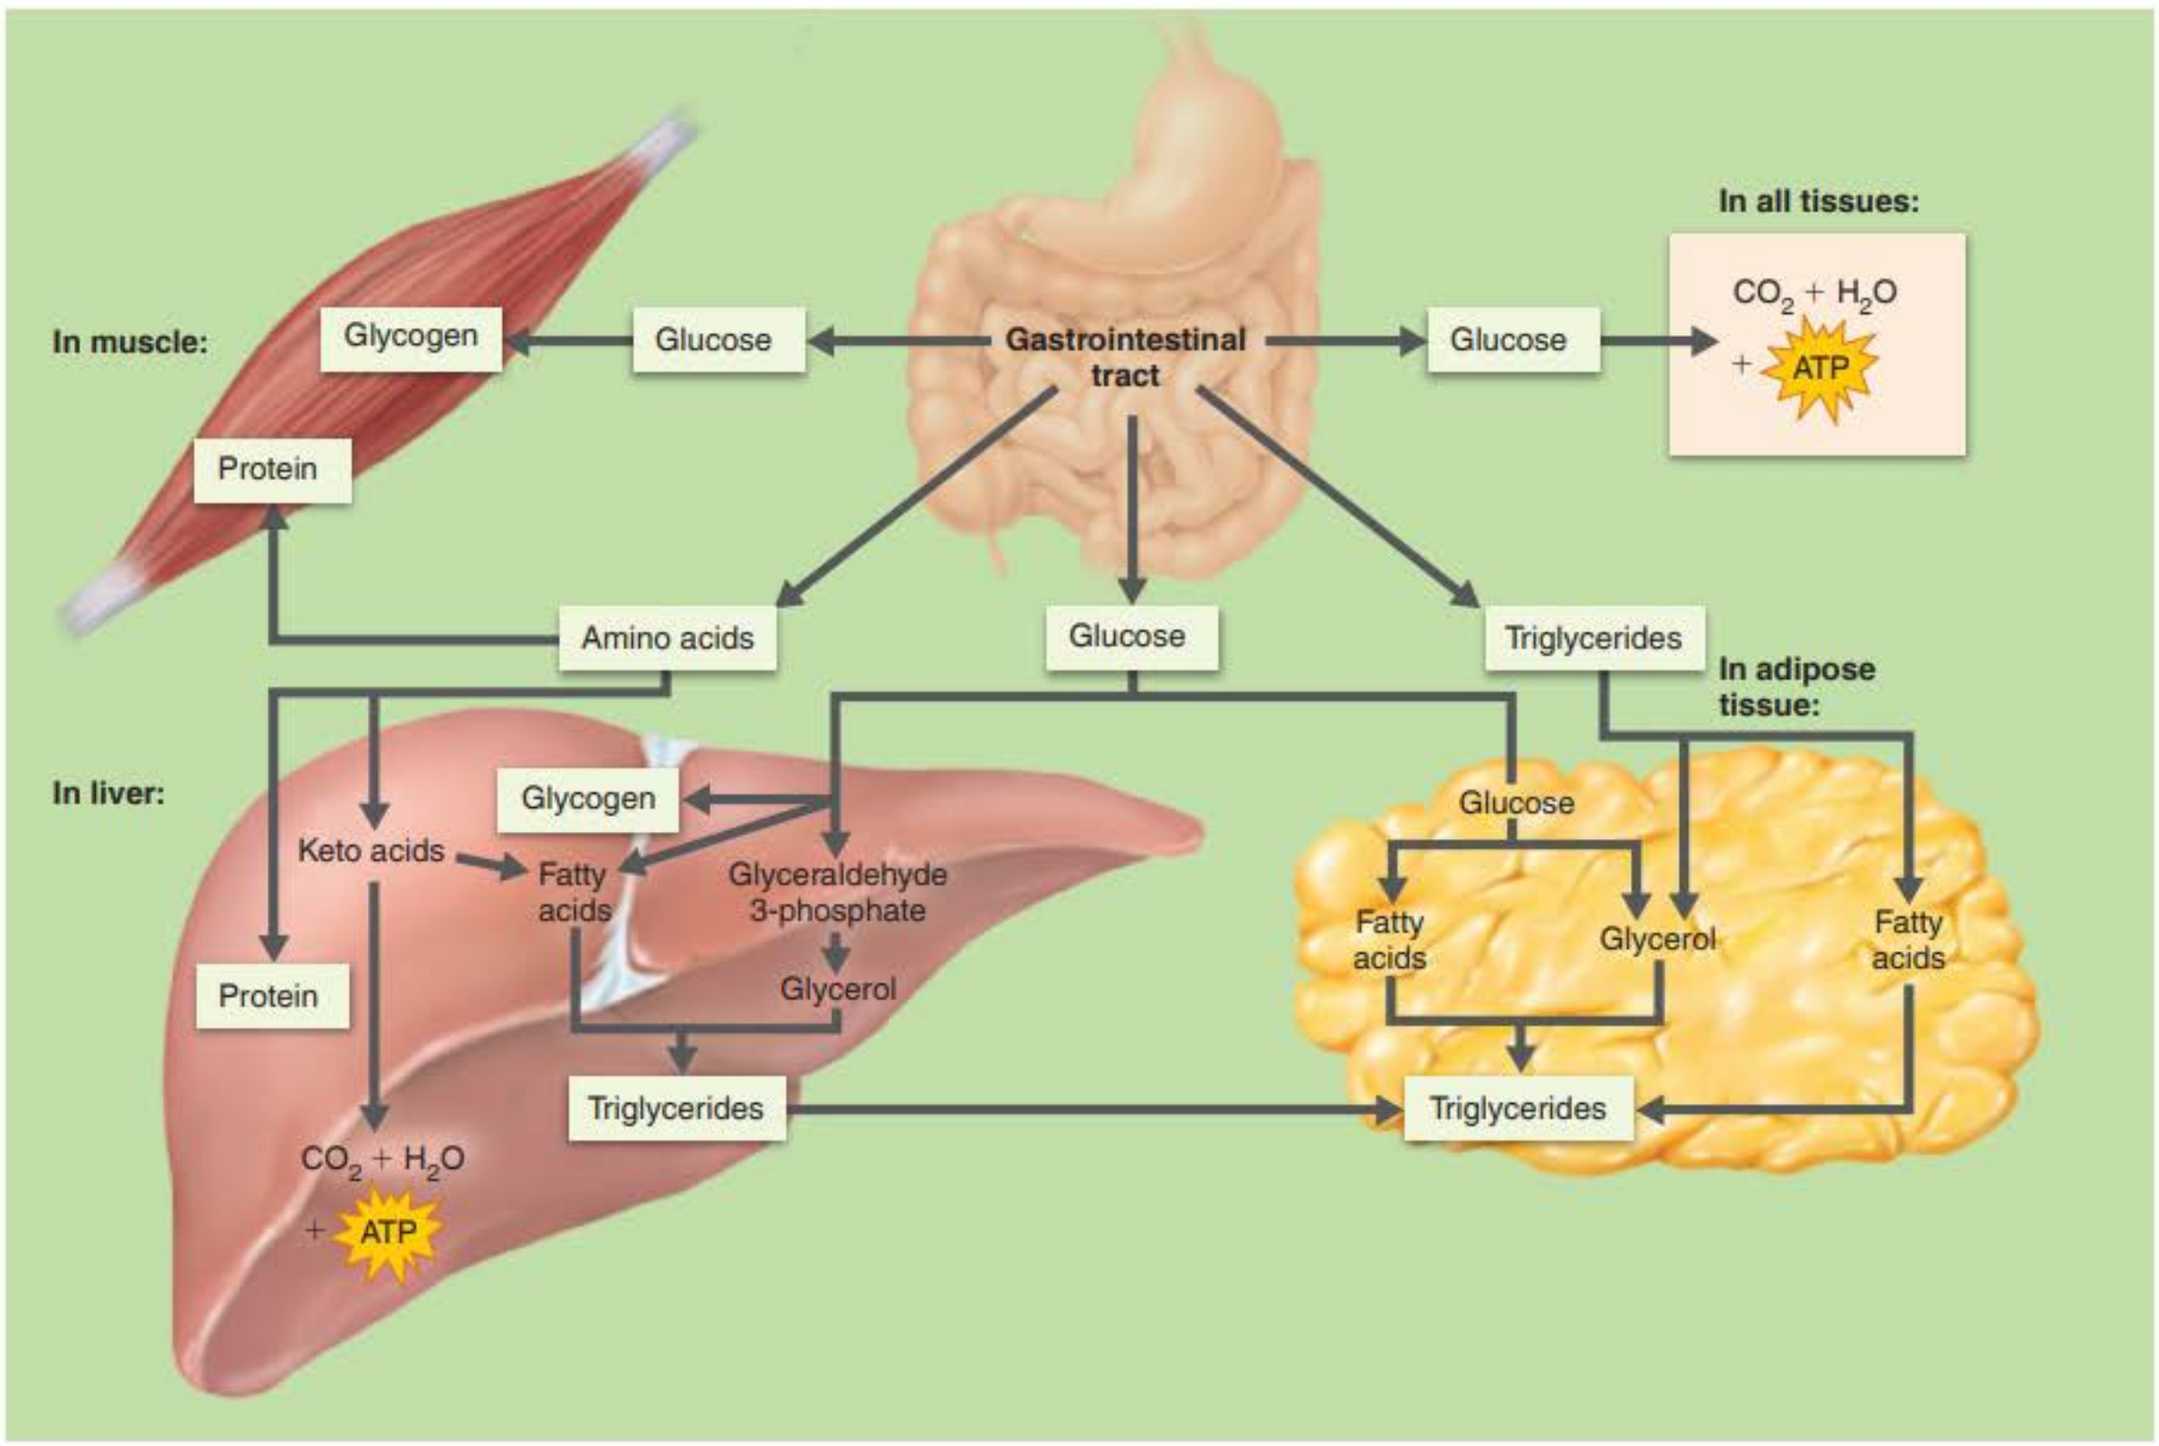
Adipose cells, skeletal and cardiac muscle cells, and liver cells use triglycerides as their primary energy source, but other cells also begin to oxidize more fat for energy when dietary carbohydrates are limited. Although some fatty acids and glycerol are used for anabolic purposes by tissue cells, most enter adipose tissue to be reconverted to triglycerides and stored.

Amino Acids

Absorbed amino acids are delivered to the liver, which deaminates some of them to keto acids. The keto acids may flow into the citric acid cycle to be used for ATP synthesis, or they may be converted to liver fat stores. The liver also uses some



(a) Major events of the absorptive state



(b) Principal pathways of the absorptive state

Figure 24.20 Major events and principal metabolic pathways of the absorptive state.
Although not indicated in (b), amino acids are also taken up by tissue cells and used for protein synthesis, and fats (triglycerides) are the primary energy fuel of muscle, liver cells, and adipose tissue.

of the amino acids to synthesize plasma proteins, including albumin, clotting proteins, and transport proteins. However, most amino acids flushing through the liver sinusoids remain in the blood for uptake by other body cells, where they are used to synthesize proteins.

Hormonal Control of the Absorptive State

Insulin directs essentially all events of the absorptive state (**Figure 24.21**). After a meal, rising blood glucose and amino acid levels stimulate the beta cells of the pancreatic islets to secrete more insulin (◀ **Figure 16.17, p. 631**). The GI tract hormone *glucose-dependent insulinotropic peptide* (*GIP*) and parasympathetic stimulation also promote the release of insulin.

Insulin binds to membrane receptors of its target cells. This stimulates the shuttling of glucose transporters to the plasma membrane, which enhances the carrier-mediated facilitated diffusion of glucose into those cells. Within minutes, the rate of glucose entry into tissue cells (particularly muscle and adipose cells) increases about 20-fold. The exception is brain and liver cells, which take up glucose whether or not insulin is present.

Once glucose enters tissue cells, insulin enhances glucose oxidation for energy and stimulates its conversion to glycogen and, in adipose tissue, to triglycerides. Insulin also "revs up" the active transport of amino acids into cells, promotes protein synthesis, and inhibits liver export of glucose and virtually all liver enzymes that promote gluconeogenesis.

As you can see, insulin is a **hypoglycemic hormone** (hi″po-gli-se′mik). It sweeps glucose out of the blood into tissue cells, lowering blood glucose levels. It also enhances glucose oxidation or storage while inhibiting any process that might raise blood glucose levels.

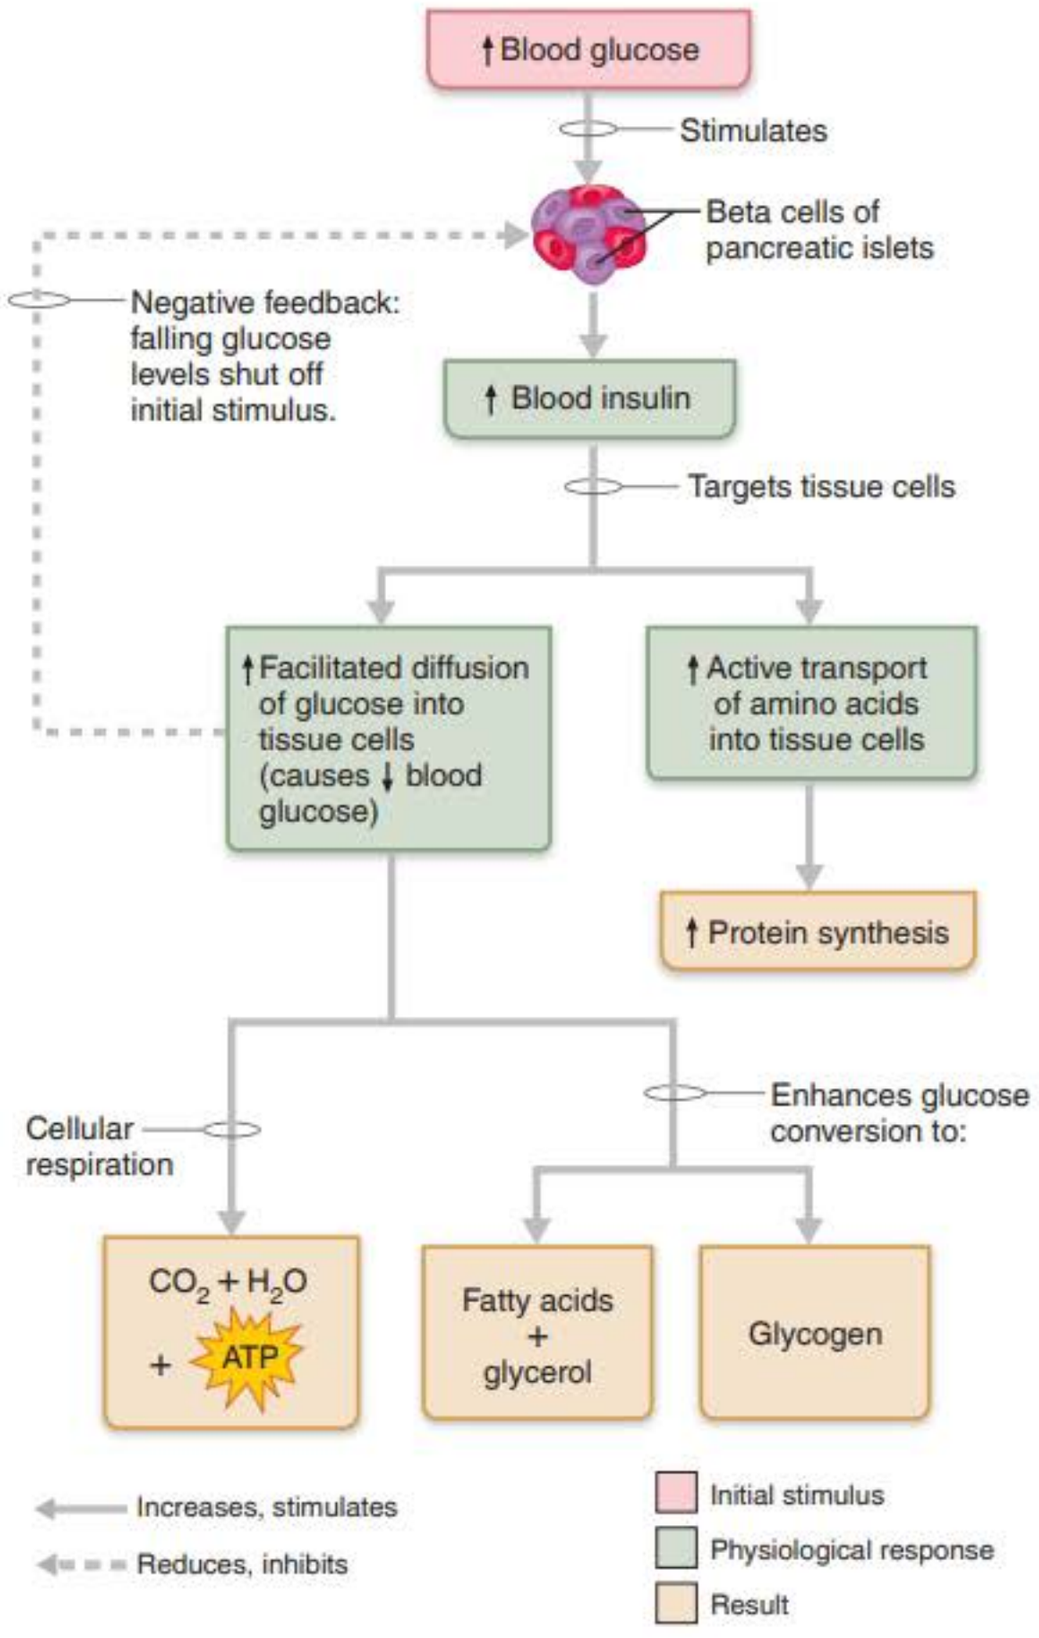


Figure 24.21 Insulin directs nearly all events of the absorptive state. (Note: Not all effects shown occur in all cells.)

HOMEOSTATIC IMBALANCE 24.3 CLINICAL

Diabetes mellitus is a disorder of inadequate insulin production or abnormal insulin receptors. Without insulin or receptors that "recognize" it, glucose is unavailable to most body cells. Blood glucose levels remain high, and large amounts of glucose are excreted in urine. Metabolic acidosis, protein wasting, and weight loss occur as large amounts of fats and tissue proteins are used for energy. (Diabetes mellitus is described in more detail in Chapter 16, ◀ **pp. 632–634**.)

Postabsorptive State

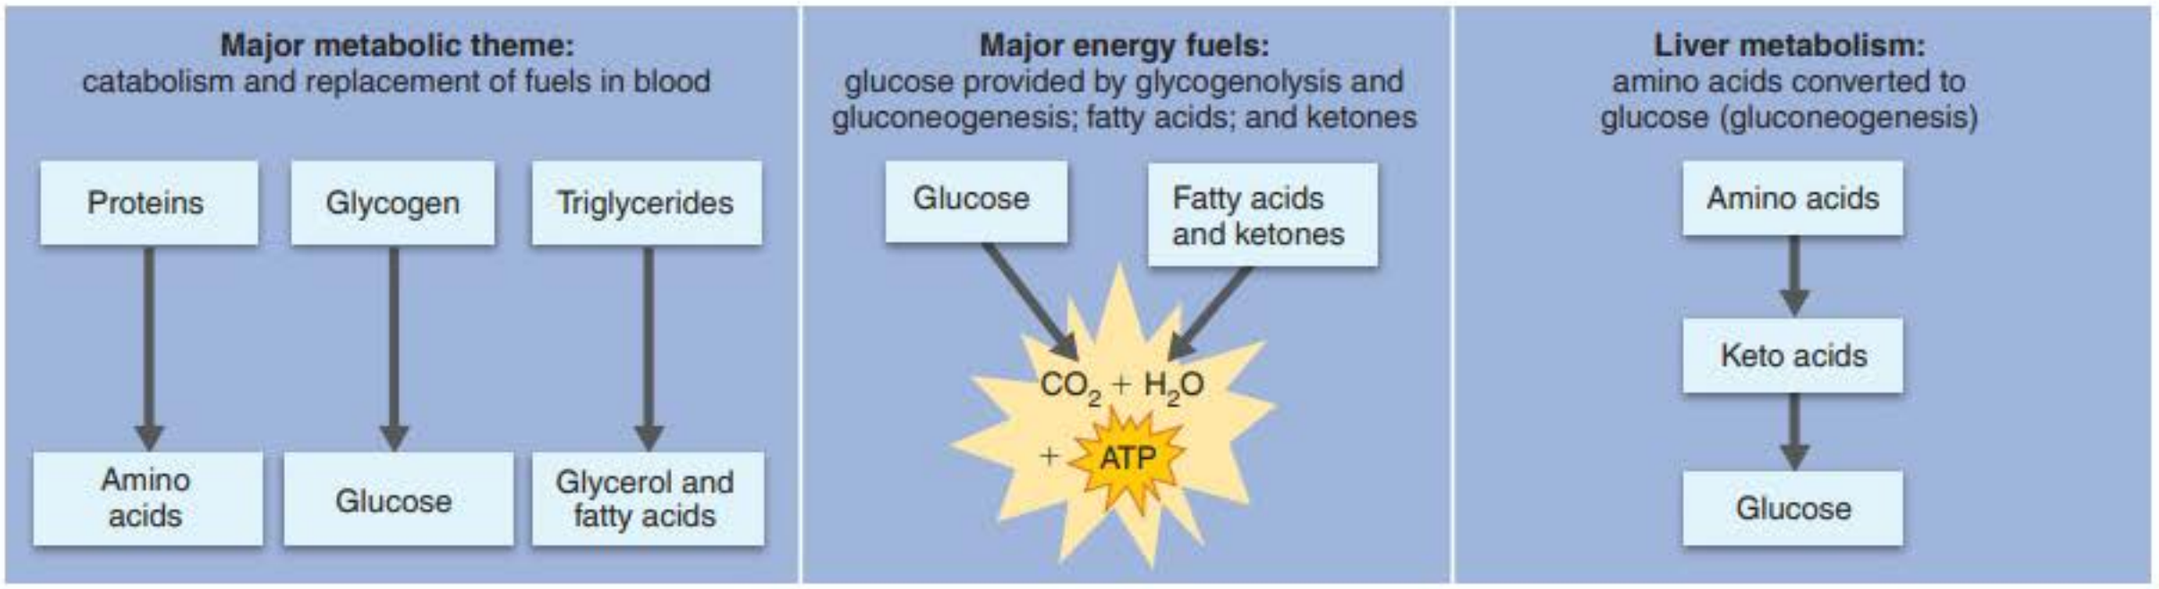
The postabsorptive state, or *fasting state*, is the period when the GI tract is empty and body reserves are broken down to supply energy. Net synthesis of fat, glycogen, and proteins ends, and catabolism of these substances begins (**Figure 24.22a**).

The primary goal during the postabsorptive state is to maintain blood glucose levels within the homeostatic range (70–110 mg of glucose per 100 ml). Remember that constant blood glucose is important because the brain almost always uses glucose as its energy source. Most events of the postabsorptive state either (1) make glucose available to the blood or (2) make certain organs (such as skeletal muscle) switch over to using fats instead of glucose to spare glucose for organs that can't use fats.

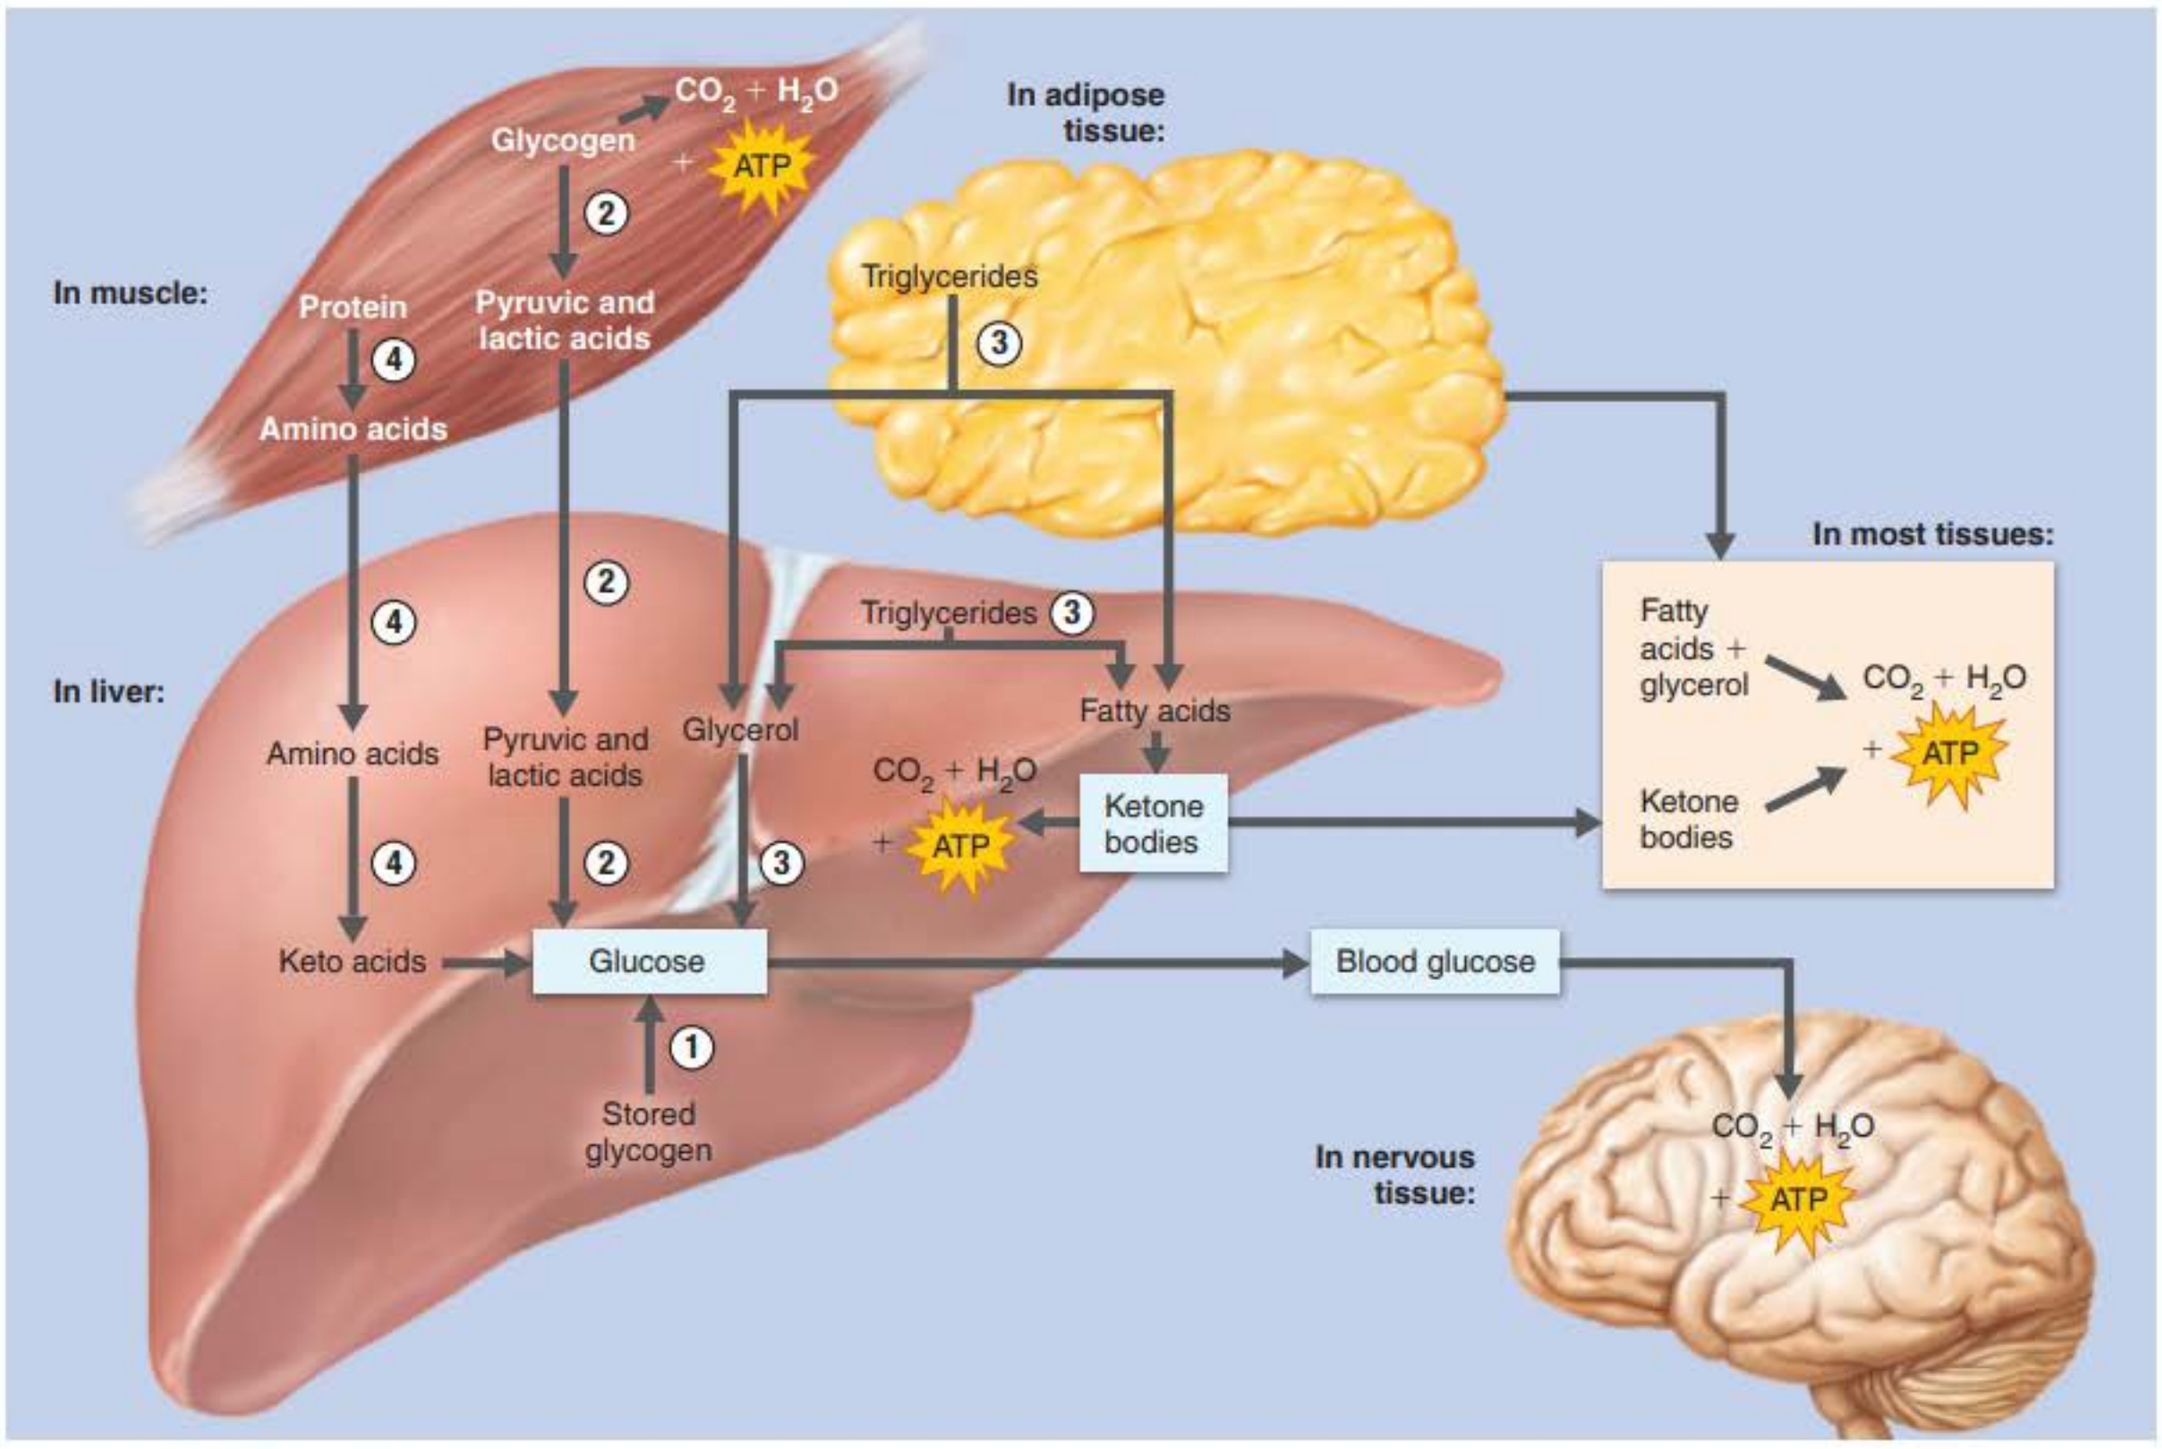
Sources of Blood Glucose

So where does blood glucose come from in the postabsorptive state? Sources include stored glycogen in the liver and skeletal muscles, tissue proteins, and, in limited amounts, fats (Figure 24.22b).

1. **Glycogenolysis in the liver.** The liver's glycogen stores (about 100 g) are the first line of glucose reserves. They are mobilized quickly and can maintain blood sugar levels for about four hours during the postabsorptive state.
2. **Glycogenolysis in skeletal muscle.** Glycogen stores in skeletal muscle are approximately equal to those of the liver. Before liver glycogen is exhausted, glycogenolysis begins in skeletal muscle (and to a lesser extent in other tissues). However, the glucose-6-phosphate produced is not released to the blood because, unlike the liver, skeletal muscle lacks the enzymes needed to dephosphorylate glucose. Instead, glucose is partly oxidized to pyruvic acid (or, during anaerobic conditions, lactic acid), which enters the blood, is reconverted to glucose by the liver, and is released to the blood again.



(a) Major events of the postabsorptive state



(b) Principal pathways of the postabsorptive state

Figure 24.22 Major events and principal metabolic pathways of the postabsorptive state.

③ **Lipolysis in adipose tissues and the liver.** Adipose and liver cells produce glycerol by lipolysis, and the liver converts the glycerol to glucose (gluconeogenesis) and releases it to the blood. Because acetyl CoA, a product of the beta oxidation of fatty acids, is produced beyond the *reversible* steps of glycolysis, fatty acids *cannot* be used to bolster blood glucose levels.

④ **Catabolism of cellular protein.** Tissue proteins become the major source of blood glucose during prolonged fasting when glycogen and fat stores are nearly exhausted. Cellular amino acids are deaminated and converted to glucose in the liver. During fasts lasting several weeks, the kidneys

also carry out gluconeogenesis and contribute as much glucose to the blood as the liver.

In these situations, the body sets priorities. Muscle proteins are the first to be catabolized. Movement is not nearly as important as maintaining wound healing and the immune response. Of course there are limits to the amount of tissue protein that can be catabolized before the body stops functioning. The heart is almost entirely muscle protein, and when it is severely catabolized, the result is death. In general, the amount of fat the body contains determines the time a person can survive without food.

Glucose Sparing

During prolonged periods without food, the body can adapt to burn more fats and proteins, which enter the citric acid cycle along with glucose breakdown products. The increased use of noncarbohydrate fuel molecules (especially triglycerides) to conserve glucose is called **glucose sparing**.

As the body progresses from the absorptive to the postabsorptive state, the brain continues to take its share of blood glucose, but virtually every other organ switches to fatty acids as its major energy source, sparing glucose for the brain. During this transition phase, lipolysis begins in adipose tissues. Tissue cells pick up released fatty acids and oxidize them for energy. In addition, the liver oxidizes fats to ketone bodies and releases them to the blood for use by tissue cells.

If fasting continues for longer than four or five days, the brain too begins to use large quantities of ketone bodies as well as glucose as its energy fuel. The brain's ability to use an alternative fuel source has survival value—much less tissue protein has to be ravaged to form glucose.

Hormonal and Neural Controls of the Postabsorptive State

Several hormones and the sympathetic nervous system together control events of the postabsorptive state. Consequently, regulation of this state is much more complex than that of the absorptive state when a single hormone, insulin, holds sway.

An important trigger for initiating postabsorptive events is reduced insulin release, which occurs as blood glucose levels drop. Falling insulin levels inhibit all insulin-induced cellular responses.

Glucagon Declining glucose levels also stimulate the alpha cells of the pancreatic islets to release the insulin antagonist **glucagon**. Like other hormones acting during the postabsorptive state, glucagon is a **hyperglycemic hormone**—it raises blood glucose levels.

Glucagon targets the liver and adipose tissue (**Figure 24.23**).

- Hepatocytes respond by accelerating glycogenolysis and gluconeogenesis.
- Adipose cells mobilize their fatty stores (lipolysis) and release fatty acids and glycerol to the blood. In this way, glucagon "refurbishes" blood energy sources by enhancing *both* glucose and fatty acid levels. Under certain hormonal conditions and persistent low glucose levels or prolonged fasting, most of the fat mobilized is converted to ketone bodies.

Glucagon release is inhibited after the next meal or whenever blood glucose levels rise and insulin secretion begins again.

So far, the picture is pretty straightforward. Increasing blood glucose levels trigger insulin release, which "pushes" glucose out of blood and into cells. This drop in blood glucose stimulates secretion of glucagon, which "pulls" glucose from the cells into blood. However, there is more than a push-pull mechanism here because rising amino acid levels in the blood stimulate the release of *both* insulin and glucagon.

This effect is insignificant when we eat a balanced meal, but it has an important adaptive role when we eat a high-protein, low-carbohydrate meal. In this instance, the stimulus for insulin release is strong, and if it were not counterbalanced, the brain might be damaged by the abrupt onset of hypoglycemia as glucose rushes out of the blood. Simultaneous release of glucagon modulates the effects of insulin and helps stabilize blood glucose levels.

Sympathetic Nervous System The sympathetic nervous system also plays a crucial role in supplying fuel quickly when

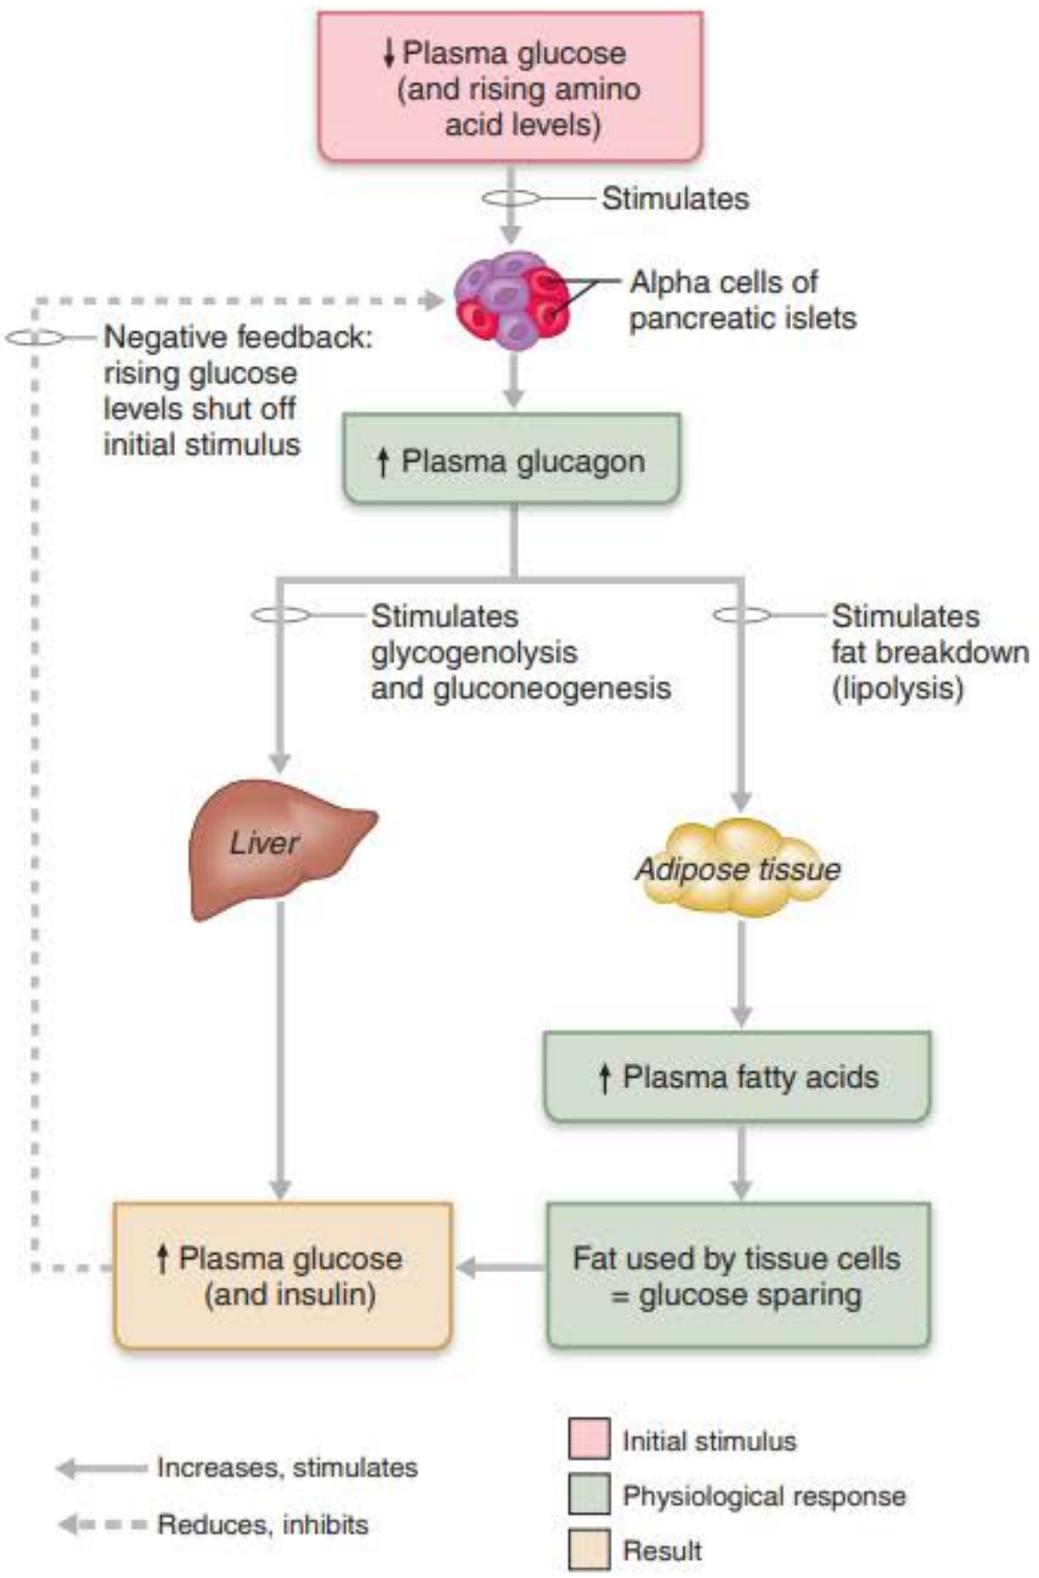


Figure 24.23 Glucagon is a hyperglycemic hormone that stimulates a rise in blood glucose levels.

Table 24.4 Summary of Normal Hormonal Influences on Metabolism

HORMONE'S EFFECTS	INSULIN	GLUCAGON	EPINEPHRINE	GROWTH HORMONE	THYROXINE	CORTISOL	TESTOSTERONE

Stimulates gluconeogenesis		✓	✓	✓		✓	
Stimulates protein breakdown (catabolic)						✓	

blood glucose levels drop suddenly. Adipose tissue is well supplied with sympathetic fibers, and epinephrine released by the adrenal medulla in response to sympathetic activation acts on the liver, skeletal muscle, and adipose tissues. Together, these stimuli mobilize fat and promote glycogenolysis—essentially the same effects prompted by glucagon.

Injury, anxiety, or any other stressor that mobilizes the fight-or-flight response will trigger this control pathway, as does exercise. During exercise, large amounts of fuels must be made available for muscles, and the metabolic profile is essentially the same as that of a fasting person when glucagon and the sympathetic nervous system are in control except that the facilitated diffusion of glucose into muscle is enhanced.

Other Hormones A number of other hormones—including growth hormone, thyroxine, sex hormones, and corticosteroids—influence metabolism and nutrient flow. Prolonged fasting or rapid declines in blood glucose levels enhance growth hormone secretion, which exerts important anti-insulin effects (◀ **Figure 16.5, p. 614**).

However, the release and activity of most of these hormones are not specifically related to absorptive or postabsorptive metabolic events. **Table 24.4** summarizes typical metabolic effects of various hormones.

Check Your Understanding

21. Which three organs or tissues are the primary effector organs determining the amounts and directions of interconversions in the nutrient pools?

22. Generally speaking, what kinds of reactions and events characterize the absorptive state? The postabsorptive state?

23. Which hormone is glucagon's main antagonist?

24. Which event increases both glucagon and insulin release?

24.8 The liver metabolizes, stores, and detoxifies

Learning Outcomes

- **Describe several metabolic functions of the liver.**
- **Differentiate between LDLs and HDLs relative to their structures and major roles in the body.**

The liver is one of the most biochemically complex organs in the body. It processes nearly every class of nutrients and plays a major role in regulating plasma cholesterol levels. In a pinch, mechanical contraptions can stand in for a failed heart, lungs, or kidney, but the only thing that can do the versatile liver's work is a hepatocyte.

The hepatocytes carry out some 500 or more intricate metabolic functions. A description of all of these functions is well beyond the scope of this text, but **Table 24.5** on p. 956 provides a brief summary.

Cholesterol Metabolism and Regulation of Blood Cholesterol Levels

Cholesterol has received little attention in this discussion so far, primarily because it is not used as an energy source. It serves instead as the structural basis of bile salts, steroid hormones, and vitamin D and is a major component of plasma membranes.

About 15% of blood cholesterol comes from the diet. The liver—and to a lesser extent other body cells, particularly intestinal cells—make the other 85% from acetyl CoA. Cholesterol

Table 24.5 Summary of Metabolic Functions of the Liver

METABOLIC PROCESSES TARGETED	FUNCTIONS
Carbohydrate Metabolism	
Particularly important in maintaining blood glucose homeostasis	• Converts galactose and fructose to glucose • Stores glucose as glycogen when blood glucose levels are high; in response to hormonal controls, performs glycogenolysis and releases glucose to blood • Gluconeogenesis: converts amino acids and glycerol to glucose when glycogen stores are exhausted and blood glucose levels are falling • Converts glucose to fats for storage
Fat Metabolism	
Although most cells are capable of some fat metabolism, liver bears the major responsibility	• Primary body site of beta oxidation (breakdown of fatty acids to acetyl CoA) • Converts excess acetyl CoA to ketone bodies for release to tissue cells • Stores fats • Synthesizes lipoproteins for transport of fatty acids, fats, and cholesterol in blood • Synthesizes cholesterol from acetyl CoA; catabolizes cholesterol to bile salts, which are secreted in bile (◀ p. 897)
Protein Metabolism	
Protein metabolism by the liver is essential for life (e.g., clotting protein synthesis, ammonia disposal)	• Synthesizes urea to remove ammonia from body; inability to perform this function (e.g., in cirrhosis or hepatitis) allows ammonia to accumulate in the blood • Synthesizes most plasma proteins (exceptions are antibodies and some hormones and enzymes); inability to perform this function (e.g., in cirrhosis) causes edema (◀ p. 734) • Deaminates amino acids for their conversion to glucose or for ATP synthesis (amount of deamination that occurs outside the liver is unimportant) • Transamination: interconversion of nonessential amino acids (amount that occurs outside liver is unimportant)
Vitamin/Mineral Storage	
	• Stores vitamin A (1–2 years' supply) • Stores sizable amounts of vitamins D and B_{12} (1–4 months' supply) • Stores iron; other than iron bound to hemoglobin, most of body's supply is stored in liver as ferritin
Biotransformation Functions	
	• Metabolizes alcohol, drugs, and other toxins by inactivating them for excretion by the kidneys, and performs reactions that may result in products which are more active, changed in activity, or less active • Processes bilirubin resulting from RBC breakdown and excretes bile pigments in bile (◀ p. 649) • Metabolizes bloodborne hormones to forms that can be excreted in urine

is lost from the body when it is catabolized and secreted in bile salts, which are eventually excreted in feces (◀ p. 897).

Cholesterol Transport

Because triglycerides and cholesterol are insoluble in water, they do not circulate free in the blood. Instead, they are transported to and from tissue cells bound to small lipid-protein complexes called **lipoproteins**. These complexes solubilize the hydrophobic lipids, and contain signals that regulate lipid entry and exit at specific target cells.

Lipoproteins vary in their relative fat-protein composition, but they all contain triglycerides, phospholipids, and cholesterol in addition to protein (**Figure 24.24**). In general, the higher the percentage of lipid in the lipoprotein, the lower its density; and the greater the proportion of protein, the higher its density. On this basis, there are **very low-density lipoproteins (VLDLs), low-density lipoproteins (LDLs),** and **high-density lipoproteins (HDLs)**. *Chylomicrons*, which transport absorbed lipids from the GI tract, have the lowest density of all.

The liver is the primary source of VLDLs, which transport triglycerides from the liver to peripheral (nonliver) tissues,

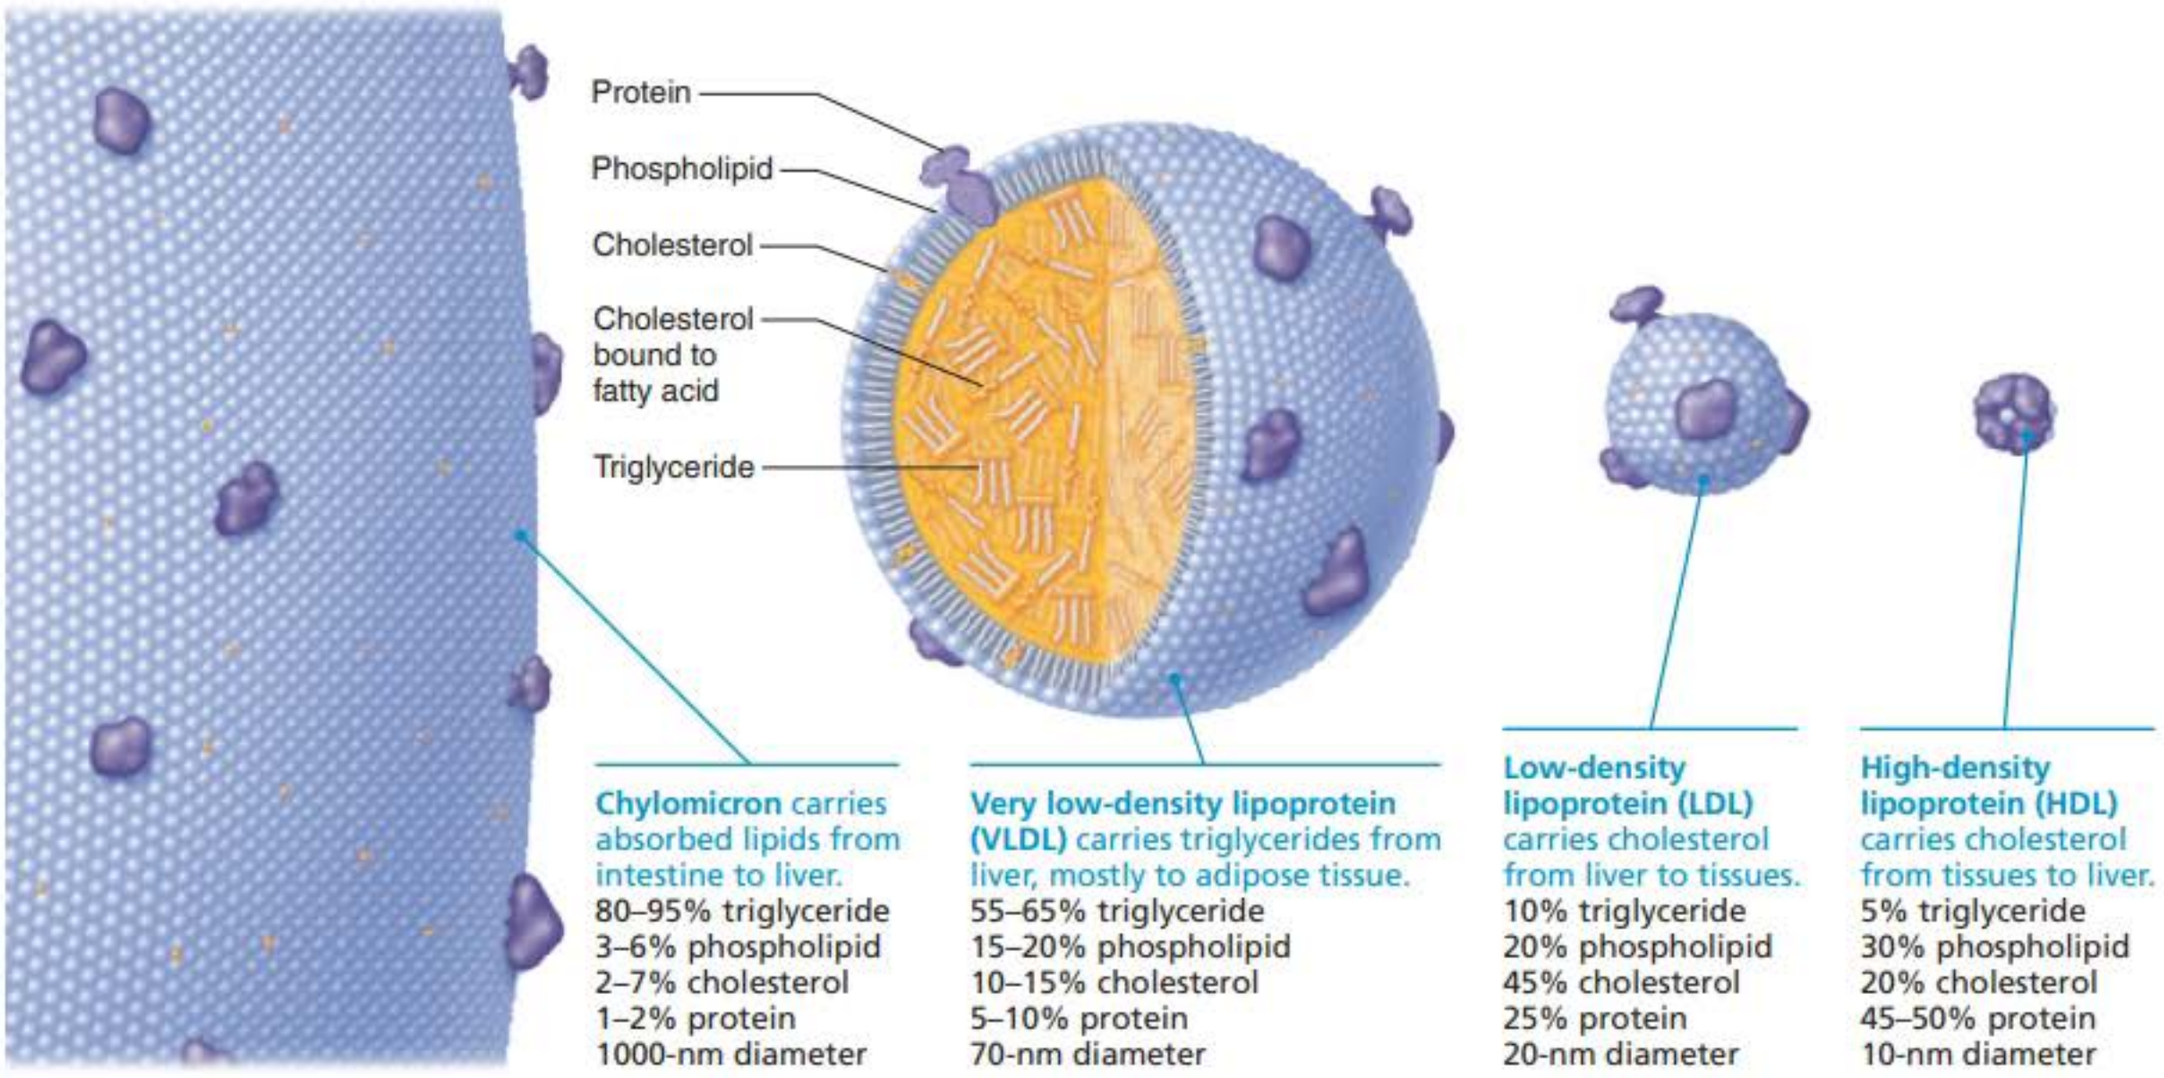

Figure 24.24 Composition and function of lipoproteins. The VLDL has been cut open to show its contents.

mostly to *adipose tissues*. Once the triglycerides are unloaded, the residues are called LDLs, which are cholesterol-rich. The job of the LDLs is to transport cholesterol *to peripheral tissues*, making it available to tissue cells to synthesize membranes or hormones, and to store it for later use.

Most cells other than liver and intestinal cells obtain the bulk of the cholesterol they need for membrane synthesis from the blood. When a cell needs cholesterol, it makes membrane receptor proteins for LDL. LDL binds to the receptors, is engulfed by endocytosis, and the endocytotic vesicles fuse with lysosomes, where the cholesterol is freed for use. When excessive cholesterol accumulates in a cell, it inhibits both the cell's own cholesterol synthesis and its synthesis of LDL receptors.

The major function of HDLs, which are particularly rich in phospholipids and proteins, is to scoop up and transport excess cholesterol *from peripheral tissues to the liver*, where it is broken down and becomes part of bile. The liver makes the protein envelopes of the HDL particles and then ejects them into the bloodstream in collapsed form, rather like deflated beach balls. Once in the blood, these still-incomplete HDL particles fill with cholesterol picked up from tissue cells and "pulled" from artery walls. Surprisingly, HDL also provides the steroid-producing organs, like the ovaries and adrenal glands, with their raw material (cholesterol).

Blood Levels of Total Cholesterol, HDL, and LDL

For adults, a total cholesterol level below 200 mg/dl of blood is generally considered desirable. Blood cholesterol levels above 200 mg/dl have been linked to atherosclerosis, which clogs the arteries and causes strokes and heart attacks (◀ p. 760). However, it is not enough to simply measure total cholesterol. How cholesterol is packaged for transport in the blood is more important clinically.

As a rule, high levels of HDLs are considered *good* because the transported cholesterol is destined for degradation (think H for healthy). HDL levels above 60 mg/dl are thought to protect against heart disease, and levels below 40 are considered undesirable. In the United States, HDL levels average 40–50 in males and 50–60 in women.

High LDL levels (160 mg/dl or above) are generally considered *bad* (think L for lousy) because when LDLs are excessive, potentially lethal cholesterol deposits are laid down in the artery walls. A good rule of thumb is that HDL levels can't be too high and LDL levels can't be too low.

Factors Regulating Blood Cholesterol Levels

A negative feedback loop partially adjusts the amount of cholesterol produced by the liver according to the amount of cholesterol in the diet. A high cholesterol intake inhibits its synthesis by the liver, but it is not a one-to-one relationship because the liver produces a basal amount of cholesterol even when dietary intake is high. Conversely, severely restricting dietary cholesterol, although helpful, does not markedly reduce blood cholesterol levels.

However, the relative amounts of saturated and unsaturated fatty acids in the diet do have an important effect on blood cholesterol levels. Saturated fatty acids *stimulate liver synthesis* of cholesterol and *inhibit its excretion* from the body. In contrast,

Obesity: Magical Solution Wanted

Fat—unwanted, unloved, and yet often overabundant. Besides the physical toll, the social stigma and economic disadvantages of obesity are legendary. A fat person pays higher insurance premiums, is discriminated against in the job market, has fewer clothing choices, and endures frequent humiliation throughout life.

What Causes Obesity?

It's a fair bet that few people choose to become obese, and yet too many of us are. So what causes it? Fundamentally, obesity is caused by consuming more calories than you use. With easy access to large amounts of calorie-dense foods and less physical activity, our waistlines have expanded. However, it is much more complicated than that. Some of the other factors involved are:

1. **Obese people are more fuel efficient and more effective "fat storers."** Although it is often assumed that people who are obese eat more, this is not necessarily true—many actually eat less than people of normal weight. When yo-yo dieters lose weight, their metabolic rate falls sharply. But when they subsequently gain weight, their metabolic rate temporarily increases like a furnace being stoked. Each successive weight loss occurs more slowly, but they regain weight faster.

   To make matters worse, "fat" fat cells of overweight people:

   - Sprout more alpha-adrenergic receptors, which favor fat accumulation.
   - Send different molecular messages than "thin" fat cells. They spew out inflammatory cytokines that can promote insulin resistance and they release less adiponectin, a hormone that improves the action of insulin in glucose uptake and storage.
   - Have exceptionally efficient lipoprotein lipases, which unload fat from the blood (usually to fat cells).

2. **Genetic predisposition.** A true genetic predisposition for "fatness" appears to account for only about 5% of obese Americans. For these people, extra calories are always laid down as fat, as opposed to people who lay down more muscle with some of the excess.
3. **Gut bacteria.** New evidence suggests that the kinds and proportions of the various bacteria that live in the gut can have a profound influence on the development and maintenance of obesity. The gut bacteria of obese individuals are less diverse, leading to higher levels of inflammation. In addition, evidence suggests that the gut bacteria of obese individuals generate fewer short-chain fatty acids. Since short-chain fatty acids inhibit fat deposition and enhance satiety hormones, obese individuals lay down more fat. The good news is that you may be able to change your gut bacteria through changes in your diet.
4. **Environmental chemicals.** A number of environmental contaminants such as pesticides, fungicides, and chemicals found in plastics interact with hormonal pathways. In animal models, these chemicals cause obesity. While it has been much more difficult to establish a link in humans, environmental chemicals may well play a role in the increased prevalence of obesity.

Treatments—The Bad and the Good

Some so-called treatments for obesity are almost more dangerous than the disease itself. Unfortunate strategies include the following.

1. **"Water pills."** Diuretics prompt the kidneys to excrete more water and may cause a few pounds of weight loss for a few hours. They can also cause serious dehydration and electrolyte imbalance.
2. **Liposuction.** Liposuction reshapes the body by suctioning off fat deposits, but it is not a good choice for losing weight. It carries all the risks of surgery, and

unsaturated fatty acids (found in olive and most other vegetable oils) *enhance excretion* of cholesterol and its catabolism to bile salts, thereby reducing total cholesterol levels.

Trans fats are made from "healthy" oils that have been hydrogenated. This makes them more solid, such as some margarines. Trans fats have a worse effect on blood cholesterol levels than saturated fats do. The trans fatty acids spark a greater increase in LDLs and a greater reduction in HDLs, producing the unhealthiest combination.

The unsaturated omega-3 fatty acids found in especially large amounts in some cold-water fish (such as salmon) lower the proportions of both saturated fats and cholesterol. The omega-3 fatty acids also make blood platelets less sticky, thus helping prevent spontaneous clotting that can block blood vessels. In addition, they appear to lower blood pressure.

Factors other than diet also influence blood cholesterol levels. For example, cigarette smoking and stress lower HDL levels, whereas regular aerobic exercise and estrogen lower LDL levels and increase HDL levels. Interestingly, body shape provides clues to risky blood levels of cholesterol and fats. "Apples" (people with upper body and abdominal fat, seen more often in men) tend to have higher levels of cholesterol and LDLs than "pears" (whose fat is localized in the hips and thighs, a pattern more common in women).

unless eating habits change, fat deposits elsewhere in the body overfill.

3. **Diet drugs and weight-loss supplements.** Older weight-loss drugs (e.g., phentermine) are generally amphetamine-like stimulants that decrease hunger but also increase blood pressure and heart rate.

Another drug, orlistat, interferes with pancreatic lipase so that part of the fat eaten is not digested or absorbed. This also interferes with the absorption of fat-soluble vitamins. It is effective as a weight-loss agent, but its side effects (diarrhea and anal leakage) are unpleasant to say the least. It also carries the risk of severe liver injury.

Several over-the-counter weight-loss supplements that claim to increase metabolism and burn calories have proved to be very dangerous. For example:

- Capsules containing usnic acid damage hepatocytes and have led to liver failure in a few cases.
- Ephedra-containing supplements are notorious—over 100 deaths and 16,000 cases of problems including strokes, seizures, and headaches have been reported.

When it comes to supplements, the burden of proof is on the U.S. FDA to show that the product is unsafe. For this reason, the true extent of problems caused by weight-loss supplements is not known—while the worst cases attract attention, less serious ones go unreported or undiagnosed.

Unfortunately, there is no quick and easy solution, no "magic pill." For most of us who want to lose weight, diet is where we begin. But which diet?

There is a long-standing duel between those promoting low-carbohydrate (high-protein and -fat) regimens such as the Atkins Diet™ and South Beach Diet®, and those espousing the traditional low-fat (high–complex carbohydrates) diet.

Clinical studies show that people on the low-carbohydrate diets lose weight more quickly at first, but plateau at 6 months. When dieting continued for a year, those on the low-fat diets lost just as much weight as did those on the low-carbohydrate diets. Although there was concern that the low-carbohydrate diets would promote undesirable plasma cholesterol and lipid values, for the most part this has not been the case.

The oldie-but-goodie Weight Watchers® diet, which has dieters counting points, still works and allows virtually any food choice as long as the allowed point count isn't exceeded.

For some of us, more extreme measures may be required.

1. **New drugs.** Several new diet drugs have recently been approved by the FDA. These drugs are not a panacea, however. Their side effects limit their use to only the very obese, and weight loss (even with diet and exercise) tends to be moderate.
2. **Surgery.** For the severely obese, there are surgical solutions: reducing stomach volume by banding, and gastric bypass surgery.

The most common type of gastric bypass surgery (Roux-en-Y) rearranges the digestive tract. The surgeon forms a small pouch from the upper part of the stomach and attaches the jejunum. The duodenum is attached farther down the jejunum, allowing pancreatic enzymes to act on chyme. However, bypassing chyme around the duodenum reduces nutrient absorption.

These surgical procedures have been remarkably effective at promoting weight loss and restoring health by reducing the effects of the *metabolic syndrome* (see p. 968). Blood pressure returns to normal in many who were originally hypertensive, and sleep apnea is reduced. Additionally, up to 86% of patients with long-standing type 2 diabetes mellitus find they are suddenly diabetes free or demonstrate a dramatic improvement in their regulation of the disease within weeks after the procedure. This result may prove to be the single greatest benefit.

New treatments are always on the horizon. For example, animal studies have shown that activating brown adipose tissue counteracts weight gain and type 2 diabetes. (Brown adipose tissue is a special kind of adipose tissue that uses energy to generate heat.) The possibility that activated brown adipose tissue could deter or reverse obesity is definitely worth exploring. Can we find a way to activate this pathway in humans?

At present, the only realistic way to lose weight is to take in fewer calories and increase physical activity. Fidgeting helps and so does resistance exercise, which increases muscle mass. Physical exercise suppresses appetite and increases metabolic rate not only during activity but also for some time after. The only way to keep the weight off is to make dietary and exercise changes lifelong habits.

HOMEOSTATIC IMBALANCE 24.4 CLINICAL

Previously, high cholesterol and LDL:HDL ratios were considered the most valid predictors of risk for atherosclerosis, cardiovascular disease, and heart attack. However, almost half of those who get heart disease have normal cholesterol levels, while others with poor lipid profiles remain free of heart problems. Presently, LDL levels and assessments of other cardiovascular disease risk factors are believed to be more accurate indicators of whether treatment is needed, and many physicians recommend dietary changes regardless of total cholesterol or HDL levels.

Cholesterol-lowering drugs such as *statins* are routinely prescribed for people with elevated LDL levels. It is estimated that more than 10 million Americans are now taking statins.

Check Your Understanding

25. If you had your choice, would you prefer to have high blood levels of HDLs or LDLs? Explain your answer.
26. What are trans fats and how do they affect LDL and HDL levels?

For answers, see Answers Appendix.

PART 3

ENERGY BALANCE

Learning Outcome

▶ **Explain what is meant by body energy balance.**

When any fuel is burned, it consumes oxygen and liberates heat. The "burning" of food fuels by our cells is no exception. As we described in Chapter 2 (◀ pp. 24–25), energy can be neither created nor destroyed—only converted from one form to another. If we apply this principle (actually the *first law of thermodynamics*) to cell metabolism, it means that bond energy released when foods are catabolized (energy input) must be precisely balanced by the total energy output of the body. A dynamic balance exists between the body's energy intake and energy output:

Energy intake = energy output
(heat + work + energy storage)

Energy intake is the energy liberated during food oxidation. **Energy output** includes energy (1) immediately lost as heat (about 60% of the total), (2) used to do work (driven by ATP), and (3) stored as fat or glycogen. Because losses of organic molecules in urine, feces, and sweat are very small in healthy people, they are usually ignored in calculating energy output.

Nearly all the energy derived from foodstuffs is eventually converted to heat. Heat is lost during every cellular activity—when ATP bonds are formed and when they are broken to do work, as muscles contract, and through friction as blood flows through blood vessels. Though cells cannot use this energy to do work, the heat warms the tissues and blood and helps maintain the homeostatic body temperature that allows metabolic reactions to occur efficiently. Energy storage is an important part of the equation only during periods of growth and net fat deposit.

24.9 Neural and hormonal factors regulate food intake

Learning Outcome

▶ **Describe several theories of food intake regulation.**

When energy intake and energy output are balanced, body weight remains stable. When they are not, weight is either gained or lost. Unhappily for many people, the body's weight-controlling systems appear to be designed more to protect us against weight loss than weight gain.

Obesity

How fat is too fat? What distinguishes a person who is obese from one who is merely overweight? Let's take a look.

The bathroom scale is an inaccurate guide because body weight tells little of body composition. Dense bones and well-developed muscles can make a fit, healthy person technically overweight. A competitive bodybuilder, for example, may tip the scales at a hefty 250 lb.

Body mass index (BMI) is a formula for determining obesity based on a person's weight relative to height. To estimate BMI, multiply weight in pounds by 705 and then divide by your height in inches squared:

$$\text{BMI} = \text{wt(lb)} \times 705/\text{ht(inches)}^2$$

Overweight is defined by a BMI between 25 and 30 and carries some health risk. Obesity is a BMI greater than 30 and has a markedly increased health risk.

A body fat content of 18–20% of body weight (males and females respectively) is deemed normal for adults.

However it's defined, obesity is perplexing and poorly understood, and the economic toll of obesity-related disease is staggering. Chronic low-grade systemic inflammation accompanies obesity and contributes to insulin resistance and type 2 diabetes mellitus. People who are obese also have a higher incidence of atherosclerosis, hypertension, heart disease, and osteoarthritis.

The U.S. is big and getting bigger, at least around its middle. Two out of three adults are overweight, one out of three is obese, and one in ten has diabetes. U.S. kids are getting fatter too: 40 years ago, 5% were obese; today over 17% are. **A Closer Look** on pp. 958–959 discusses the obesity epidemic.

Regulation of Food Intake

Control of food intake poses difficult questions for researchers. For example, what type of receptor could sense the body's total calorie content and alert us to start eating or put down that fork? Despite heroic research efforts, no such single receptor type has been found.

Current theories of how feeding behavior and hunger are regulated focus mainly on (1) neural signals from the digestive tract, (2) hormones, and (3) blood levels of nutrients. To a smaller degree, body temperature and psychological factors also play a role. All these factors appear to operate through feedback signals to the feeding centers of the brain.

It has been known for some time that the hypothalamus, particularly its *arcuate nucleus* (*ARC*) and two other areas—the *lateral hypothalamic area* (*LHA*) and the *ventromedial nucleus* (*VMN*)—release several peptides that influence feeding behavior (◀ p. 449). Most importantly, this influence ultimately reflects the activity of two opposing sets of neurons:

- **Hunger-promoting neurons.** The NPY/AgRP neurons of ARC release neuropeptide Y (NPY) and agouti-related peptide (AgRP), which enhance appetite by stimulating the neurons of the LHA that release orexins (**Figure 24.25**, right side).
- **Satiety-promoting neurons.** The other neuron group in ARC consists of the POMC/CART neurons, which suppress appetite by releasing the peptides α-melanocyte stimulating hormone [α-MSH, derived from pro-opiomelanocortin (POMC)] and cocaine- and amphetamine-regulated transcript (CART). α-MSH and CART act on the ventromedial nucleus, causing its neurons to release CRH (corticotropin-releasing hormone), an important appetite suppressor.

The hypothalamic nuclei play an essential role in regulating hunger and satiety, but brain stem areas are also involved. Sensors in peripheral locations have also been suggested, with the liver and gut itself the prime candidates. Controls of food intake come in two varieties—short term and long term.

Short-Term Regulation of Food Intake

Short-term regulation of appetite and feeding behavior involves neural signals from the GI tract, blood levels of nutrients, and GI tract hormones. For the most part, the short-term signals target hypothalamic centers via the solitary tract (and nucleus) of the brain stem (Figure 24.25).

Neural Signals from the Digestive Tract One way the brain evaluates the contents of the gut depends on vagal nerve fibers that carry on a two-way conversation between gut and brain. For example, clinical tests show that ingesting protein produces a 30–40% larger and longer response in vagal afferents than ingesting the same amount of glucose. Furthermore, activating stretch receptors ultimately inhibits appetite, because GI tract distension sends signals along vagus nerve afferents that suppress the appetite-enhancing or hunger center. Using these signals, together with others it receives, the brain can decode what is eaten and how much.

Nutrient Signals Related to Energy Stores Blood levels of glucose, amino acids, and fatty acids provide information to the brain that may help adjust energy intake to energy output. Nutrient signals that indicate fullness or satiety include:

- *Rising blood glucose levels.* When we eat, rising blood glucose levels ultimately depress eating (Figure 24.25). During fasting and hypoglycemia, this signal is absent, resulting in hunger and "turning on" food-seeking behavior.

  The brain shows other responses to glucose and high-caloric food as well. When we ingest sugar, the brain's reward (pleasure) system "gives off fireworks" in the form of rising dopamine levels to a greater or lesser degree. Perhaps this response is the genesis of overeating (hedonistic) behavior.
- *Elevated blood levels of amino acids* depress eating, but the precise mechanism is unknown.
- *Blood concentrations of fatty acids* influence hunger. The more fatty acids in the blood, the more eating behavior is inhibited.

Hormones Gut hormones, including insulin and cholecystokinin (CCK) released during food absorption, act as satiety signals to depress hunger. Cholecystokinin (◀ p. 891), which blocks the appetite-inducing effect of NPY, is most important.

In contrast, glucagon and epinephrine levels rise during fasting and stimulate hunger. Ghrelin (Ghr), produced by the stomach, is a powerful appetite stimulant. In fact, ghrelin appears to be the "dinner bell" or trigger for initiating a meal. Its level peaks just before mealtime, signaling the brain that it is time to eat, and then the level drops after the meal.

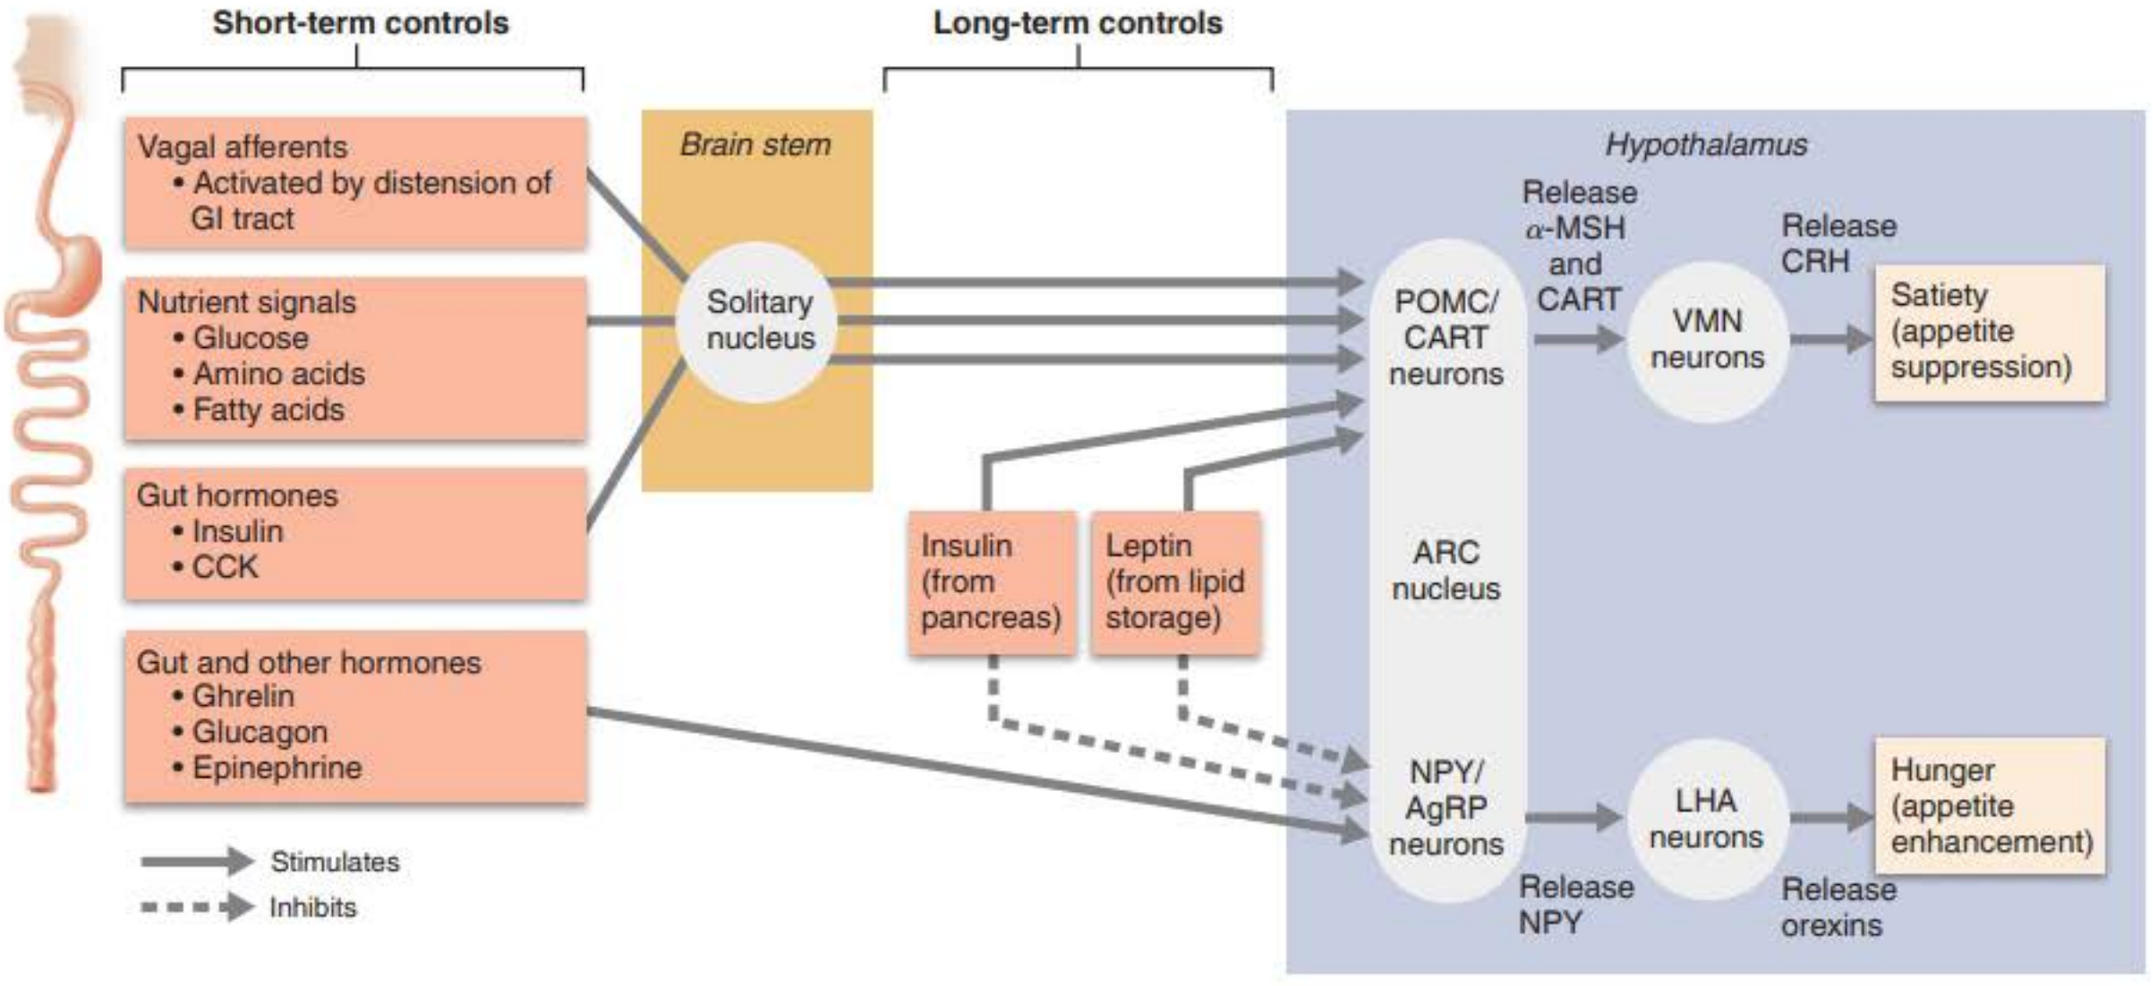

Figure 24.25 Model for hypothalamic command of appetite and food intake. The arcuate nucleus (ARC) of the hypothalamus contains two sets of neurons with opposing effects. Activating the NPY and orexin neurons enhances appetite, whereas activating POMC/CART neurons has the opposite effect. These centers connect with other brain centers, and signals are transmitted through the brain stem to the body. Many appetite-regulating hormones act through the ARC, though they may also exert direct effects on other brain centers. (AgRP = agouti-related peptide, CART = cocaine- and amphetamine-regulated transcript, CCK = cholecystokinin, CRH = corticotropin-releasing hormone, LHA = lateral hypothalamic area, α-MSH = α-melanocyte-stimulating hormone, NPY = neuropeptide Y, POMC = pro-opiomelanocortin, VMN = ventromedial nucleus)

Long-Term Regulation of Food Intake

A key component of the long-term controls of feeding behavior is the hormone **leptin** ("thin"). Secreted exclusively by adipose cells in response to an increase in body fat mass, leptin indicates the body's total energy stores in fat tissue. (Thus adipose tissue acts as a "Fat-o-Stat" that sends chemical messages to the brain in the form of leptin.)

When levels of leptin rise in the blood, leptin binds to receptors in ARC that specifically (1) suppress the release of NPY and (2) stimulate the expression of CART. NPY is the most potent appetite stimulant known. By blocking its release, leptin prevents the release of the appetite-enhancing orexins from the LHA. This decreases appetite and food intake, eventually promoting weight loss.

When fat stores shrink, leptin blood levels drop, an event that exerts opposite effects on the two sets of ARC neurons. Consequently, appetite and food intake increase, and (eventually) weight gain occurs.

Initially it seemed that leptin was the magic bullet that obesity researchers were looking for, but their hopes were soon dashed. Rising leptin levels do promote weight loss, but only to a certain point. Furthermore, individuals who are obese have higher-than-normal leptin blood levels, but for some unknown reason, they are resistant to its action. Now the consensus is that leptin's main role is to protect against weight loss in times of nutritional deprivation.

Although leptin has received the most attention as a long-term appetite and metabolism regulator, there are several other players. Insulin, like leptin, inhibits NPY release in non-insulin-resistant individuals, but its effect is less potent.

Additional Regulatory Factors

There is no easy answer to explain how body weight is regulated, but theories abound. Rising ambient temperature discourages food seeking, whereas cold temperature activates the hunger center. Depending on the individual, stress may increase or decrease food-seeking behavior, but chronic stress in combination with a junk food (high in sugar and fat) diet sharply increases release of NPY.

Psychological factors are thought to be important in people who are obese, but even when psychological factors contribute to obesity, individuals do not continue to gain weight endlessly. Controls still operate but at a higher set-point weight. The composition of gut bacteria, sleep deprivation, and even certain adenovirus infections are additional factors that may affect a person's fat mass and weight regulation.

Whew! How does all this information fit together? So far we only have bits and pieces of the story, but Figure 24.25 shows the best current model.

Check Your Understanding

27. What three groups of stimuli influence short-term regulation of feeding behavior?

28. What is the most important long-term regulator of feeding behavior and appetite?

29. PREDICT Suppose your patient has had a stroke that damaged the ventromedial nucleus (VMN). Would you expect this patient's weight to increase, decrease, or stay the same? Why? (Hint: See Figure 24.25 on p. 961.)

24.10 Thyroxine is the major hormone that controls basal metabolic rate

Learning Outcome

- **Define basal metabolic rate and total metabolic rate. Name factors that influence each.**

The body's rate of energy output, the **metabolic rate**, is the total heat produced by all the chemical reactions and mechanical work of the body. We can measure metabolic rate directly or indirectly. In the *direct method*, a person enters a chamber called a **calorimeter** and water circulating around the chamber absorbs heat liberated by the body. The rise in water temperature is directly related to the heat produced by the person's body. The *indirect method* uses a **respirometer** to measure oxygen consumption, which is directly proportional to heat production. For each liter of oxygen used, the body produces about 4.8 kcal of heat.

Basal Metabolic Rate (BMR)

Because many factors influence metabolic rate, it is usually measured under standardized conditions. The person is in a postabsorptive state (has not eaten for at least 12 hours), is reclining, and is mentally and physically relaxed. The temperature of the room is a comfortable 20–25°C. The measurement obtained under these circumstances, the **basal metabolic rate (BMR)**, reflects the energy the body needs to perform only its most essential activities, such as breathing and maintaining resting levels of organ function. Although named the *basal* metabolic rate, this measurement is *not* the lowest metabolic state of the body. That situation occurs during sleep, when skeletal muscles are completely relaxed.

The BMR, often referred to as the "energy cost of living," is reported in kilocalories per square meter of body surface per hour (kcal/m^2/h). Why do we take surface area into account in this formula? It is because the rate at which energy is used depends on the body surface area. As the ratio of body surface area to body volume increases, heat loss to the environment increases and the metabolic rate must be higher to replace the lost heat. For this reason, if two people weigh the same, the taller or thinner person will use more energy.

A 70-kg adult male of average height has a BMR of approximately 66 kcal/h. You can approximate your BMR by multiplying weight in kilograms (2.2 lb = 1 kg) by 1 if you are male and by 0.9 if you are female.

Several factors influence BMR, including age, gender, body temperature, stress, and the hormone thyroxine.

Age and Gender

In general, the younger the person, the higher the BMR. Children and adolescents require large amounts of energy for

growth. In old age, BMR declines dramatically as skeletal muscles begin to atrophy.

Gender also plays a role. Metabolic rate is higher in males than in females, mainly because males typically have more muscle, which is very active metabolically even during rest. Fatty tissue, present in greater relative amounts in females, is metabolically more sluggish than muscle.

Body Temperature

Body temperature and BMR tend to rise and fall together. Fever markedly increases metabolic rate above basal levels.

Stress

Whether physical or emotional, stress increases BMR by mobilizing the sympathetic nervous system. As epinephrine and norepinephrine flood into the blood from the adrenal medulla, they raise BMR primarily by stimulating fat catabolism.

Thyroxine

The amount of **thyroxine** produced by the thyroid gland (◀ p. 618) is probably the most important hormonal factor in determining BMR. For this reason, thyroxine has been dubbed the "metabolic hormone." Its direct effect on most body cells (except brain cells) is to increase O_2 consumption and heat production, in part by accelerating the use of ATP to operate the sodium-potassium pump. As ATP reserves decline, cellular respiration accelerates. Thus, the more thyroxine produced, the higher the BMR.

HOMEOSTATIC IMBALANCE 24.5 CLINICAL

Hyperthyroidism causes a host of problems resulting from the excessive BMR it produces. The body catabolizes stored fats and tissue proteins and, despite increased hunger and food intake, the person often loses weight. Bones weaken and muscles, including the heart, begin to atrophy.

In contrast, *hypothyroidism* results in slowed metabolism, obesity, and diminished thought processes (◀ Table 16.4, p. 618).

Total Metabolic Rate (TMR)

The **total metabolic rate (TMR)** is the rate of kilocalorie consumption needed to fuel *all* ongoing activities—involuntary and voluntary. BMR accounts for a surprisingly large part of TMR. For example, a woman whose total energy needs per day are about 2000 kcal may spend 1400 kcal or so supporting vital body activities.

Skeletal muscles make up nearly half of body mass, so skeletal muscle activity causes the most dramatic short-term changes in TMR. Even slight increases in muscular work can cause remarkable leaps in TMR and heat production. When a well-trained athlete exercises vigorously for several minutes, TMR may increase 20-fold and remain elevated for several hours after exercise stops.

Food ingestion also induces a rapid increase in TMR. This effect, called **food-induced thermogenesis**, is greatest when proteins and alcohol are ingested. The heightened metabolic activity of the liver during such periods probably accounts for the bulk of additional energy use. In contrast, fasting or very low caloric intake depresses TMR and results in a slower breakdown of body reserves.

Check Your Understanding

30. Which of the following contributes to a person's BMR? Kidney function, breathing, jogging, eating, fever.

31. MAKE CONNECTIONS Samantha tells her doctor that she has been feeling jittery and has had trouble falling asleep. She complains that her roommates always set the thermostat too high. Blood tests reveal antibodies that suggest an autoimmune disease. Explain Samantha's symptoms. What organ are the antibodies binding to and how does this cause her symptoms? (Hint: See Chapter 16.)

For answers, see Answers Appendix.

24.11 The hypothalamus acts as the body's thermostat

Learning Outcomes

- **Distinguish between core and shell body temperature.**
- **Describe how body temperature is regulated, and indicate the common mechanisms regulating heat production/retention and heat loss from the body.**

As shown in **Figure 24.26**, body temperature represents the balance between heat production and heat loss. All body tissues produce heat, but those most active metabolically produce the

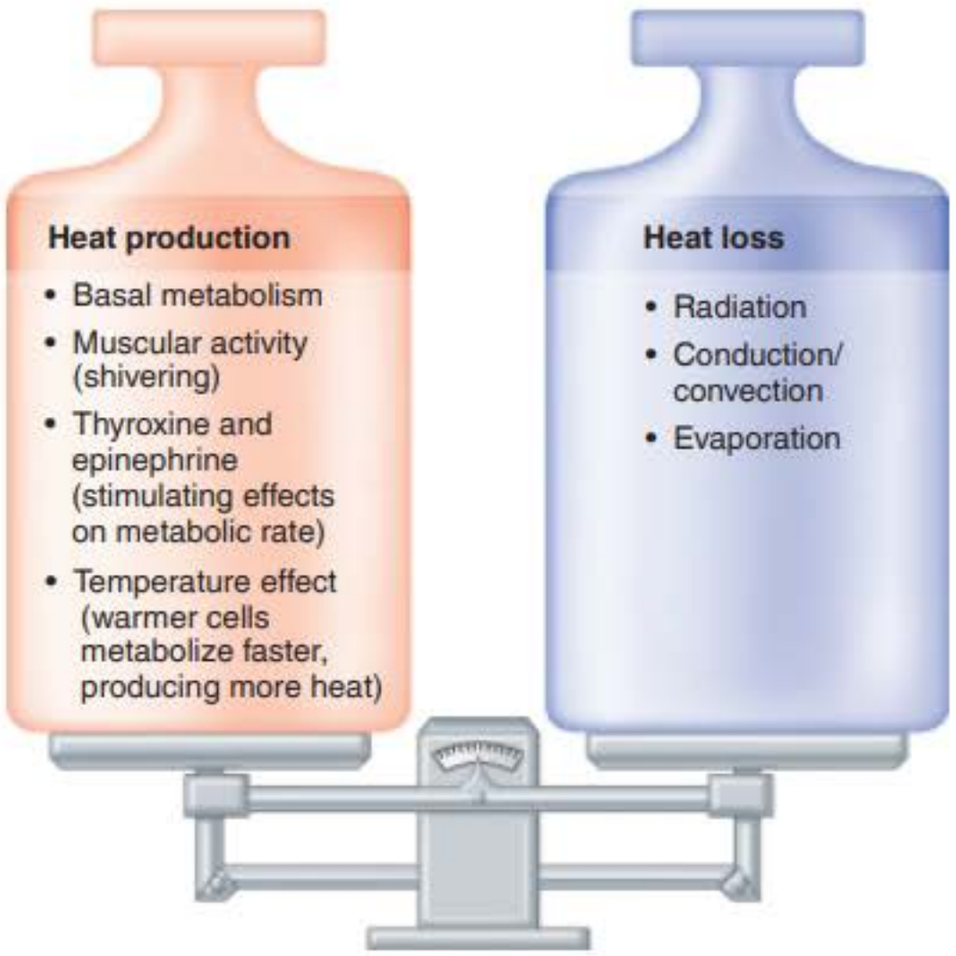

Figure 24.26 Body temperature remains constant as long as heat production and heat loss are balanced.

greatest amounts. When the body is at rest, most heat is generated by the liver, heart, brain, kidneys, and endocrine organs, with the inactive skeletal muscles accounting for only 20–30%.

This situation changes dramatically with even slight changes in muscle tone. When we are cold, shivering helps warm us up, and during vigorous exercise, skeletal muscles can produce 30 to 40 times more heat than the rest of the body. A change in muscle activity is one of the most important means of modifying body temperature.

Body temperature averages 37°C ± 0.5°C (98.6°F) and is usually maintained within the range 35.8–38.2°C (96–101°F), despite considerable change in external (air) temperature. A healthy individual's body temperature fluctuates approximately 1°C (1.8°F) in 24 hours, lowest in early morning and highest in late afternoon or early evening.

The adaptive value of temperature homeostasis becomes apparent when we consider how temperature affects enzymatic activity. At normal body temperature, conditions are optimal for enzymatic activity. Rising body temperature accelerates enzymatic catalysis: With each rise of 1°C, the rate of chemical reactions increases about 10%. If temperature rises above the homeostatic range, neurons are depressed and proteins begin to denature. Children below the age of 5 may go into convulsions when body temperature reaches 41°C (106°F), and 43°C (about 109°F) appears to be the absolute limit for life.

In contrast, most body tissues can withstand marked reductions in temperature if other conditions are carefully controlled. This fact underlies the use of body cooling during open heart surgery when the heart must be stopped. Low body temperature reduces metabolic rate (and consequently oxygen and nutrient requirements of body tissues and the heart), allowing more time for surgery without incurring tissue damage.

Core and Shell Temperatures

Different body regions have different resting temperatures. The body's **core** (organs within the skull and the thoracic and abdominal cavities) has the highest temperature and its **shell** (essentially the skin) has the lowest temperature in most circumstances. Of the two body sites used most often to obtain body temperature clinically, the rectum typically has a temperature about 0.4°C (0.7°F) higher than the mouth and is a better indicator of core temperature.

It is core temperature that is precisely regulated. Blood serves as the major *agent of heat exchange* between the core and shell. Whenever the shell is warmer than the external environment, the body loses heat as warm blood is allowed to flush into skin capillaries. On the other hand, when heat must be conserved, blood largely bypasses the skin. This reduces heat loss and allows the shell temperature to fall toward that of the environment.

For this reason, core temperature stays relatively constant, but the temperature of the shell may fluctuate substantially. For example, it can vary between 20°C (68°F) and 40°C (104°F), as it adapts to changes in body activity and external temperature. (You really *can* have cold hands and a warm heart.)

Mechanisms of Heat Exchange

Heat exchange between our skin and the external environment works in the same way as heat exchange between inanimate objects. It helps to think of an object's temperature—whether that object is a radiator or your skin—as a guide to its heat content (think "heat concentration"). Then just remember that heat always flows down its concentration gradient from a warmer region to a cooler region. The body uses four mechanisms of heat transfer—radiation, conduction, convection, and evaporation (**Figure 24.27**).

Radiation

Radiation is the loss of heat in the form of infrared waves (thermal energy). Any object that is warmer than objects in its environment—for example, a radiator and (usually) the

Figure 24.27 Mechanisms of heat exchange. A woman enjoying a hot tub illustrates several mechanisms of heat exchange between the body and the environment—conduction, radiation, convection, and (possibly) evaporation.

body—will transfer heat to those objects. Under normal conditions, close to half of your body heat loss occurs by radiation.

Because radiant energy flows from warmer to cooler, radiation explains why a cold room warms up shortly after it fills with people. Your body also gains heat by radiation, as demonstrated by the way your skin warms when you sunbathe.

Conduction

Conduction transfers heat from a warmer object to a cooler one when the two are in direct contact with each other. For example, when you step into a hot tub, some of the heat of the water transfers to your skin, and warm buttocks transfer heat to the seat of a chair by conduction.

Convection

Convection is the transfer of heat that occurs because warm air expands and rises and cool air, being denser, falls. Consequently, the warmed air enveloping the body is continually replaced by cooler air molecules. Convection substantially enhances heat transfer from the body surface to the air because the cooler air absorbs heat by conduction more rapidly than the already-warmed air.

Together, conduction and convection account for 15–20% of heat loss to the environment. These processes are enhanced by anything that moves air more rapidly across the body surface, such as wind or a fan, in other words, by *forced convection*.

Evaporation

The fourth mechanism by which the body loses heat is **evaporation**. Water evaporates because its molecules absorb heat from the environment and become energetic enough—in other words, vibrate fast enough—to escape as a gas, which we know as water vapor. The heat absorbed by water during evaporation is called **heat of vaporization** (◀ p. 38). The evaporation of water from body surfaces removes large amounts of body heat. Every gram of water that evaporates removes about 0.58 kcal of heat from the body.

There is a basal level of body heat loss due to the continuous evaporation of water from the lungs and oral mucosa, and through the skin. The unnoticeable water loss occurring via these routes is called **insensible water loss**, and the accompanying heat loss is **insensible heat loss**. Insensible heat loss dissipates about 10% of the basal heat production of the body and is a constant not subject to body temperature controls.

Evaporative heat loss becomes an active or *sensible* process when body temperature rises and sweating produces increased amounts of water for vaporization. Extreme emotional states activate the sympathetic nervous system, causing body temperature to rise by one degree or so, and vigorous exercise can raise body temperature as much as 2–3°C (3.6–5.4°F). Vigorous muscular activity can produce and evaporate 1–2 L/h of sweat, removing 600–1200 kcal of heat from the body each hour. This is more than 30 times the amount of heat lost via insensible heat loss!

Role of the Hypothalamus

Although other brain regions contribute, the hypothalamus (◀ p. 449), particularly its anterior region, is the main integrating center for thermoregulation. Together the **heat-loss center** (located more anteriorly) and the **heat-promoting center** make up the brain's **thermoregulatory centers**.

The hypothalamus receives afferent input from (1) **peripheral thermoreceptors** located in the shell (the skin), and (2) **central thermoreceptors** sensitive to blood temperature and located in the body core including the anterior portion of the hypothalamus. Much like a thermostat, the hypothalamus responds to this input by reflexively initiating appropriate heat-promoting or heat-loss activities.

The central thermoreceptors have more influence than the peripheral ones, but varying inputs from the shell probably alert the hypothalamus to the need to prevent temperature changes in the core. In other words, they allow the hypothalamus to anticipate changes to be made.

Heat-Promoting Mechanisms

When the external temperature is low or blood temperature falls for any reason, the heat-promoting center is activated. It triggers one or more of the following mechanisms to maintain or increase core body temperature (**Figure 24.28**, bottom).

- **Constriction of cutaneous blood vessels.** Activation of the sympathetic vasoconstrictor fibers serving the blood vessels of the skin causes strong vasoconstriction. This restricts blood to deep body areas and largely bypasses the skin. Because a layer of insulating subcutaneous (fatty) tissue separates the skin from deeper organs, heat loss from the core through the shell is dramatically lowered. As a result, the shell temperature is closer to that of the external environment.

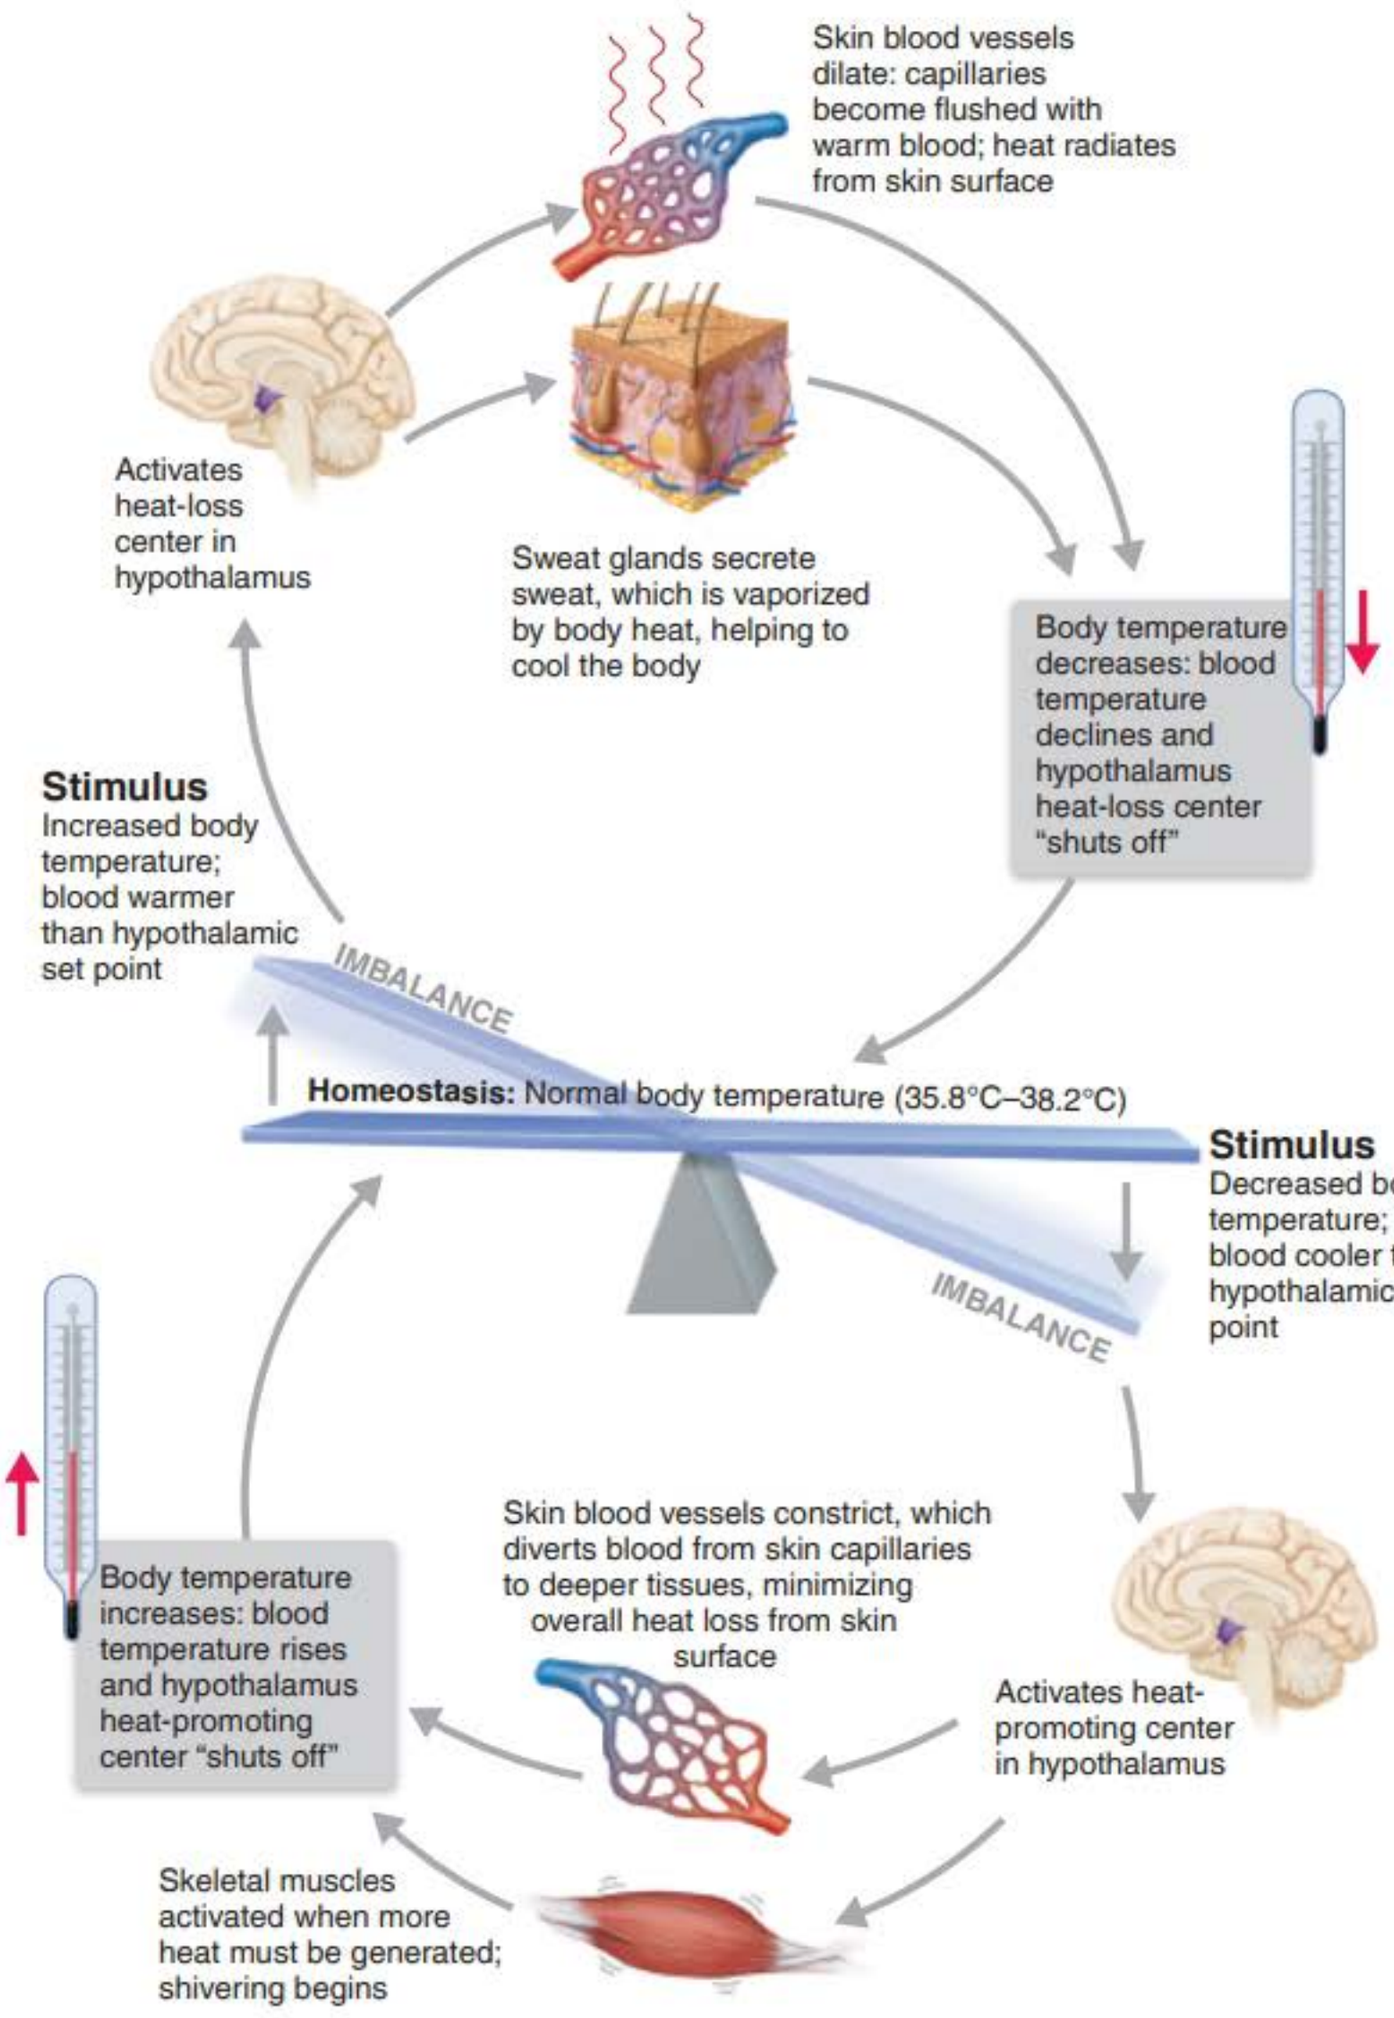

Figure 24.28 Mechanisms of body temperature regulation.

HOMEOSTATIC IMBALANCE 24.6 CLINICAL

Restricting blood flow to the skin is not a problem for a brief period. If it is prolonged (as during exposure to very cold weather), the lack of heat transfer can lead to the formation of ice crystals in and around cells, causing them to die. This extremely serious condition is *frostbite*.

- **Shivering.** Shivering—involuntary shuddering contractions—is triggered when the hypothalamus activates brain centers that cause an increase in muscle tone. When muscle tone reaches sufficient levels, stretch receptors are alternately stimulated in antagonistic muscles. Shivering raises body temperature because skeletal muscle activity produces large amounts of heat.
- **Increase in metabolic rate.** Cold increases sympathetic stimulation of the adrenal medulla, releasing epinephrine and norepinephrine (◀ p. 627). These hormones elevate the metabolic rate and enhance heat production. This mechanism, called **chemical (nonshivering) thermogenesis**, occurs primarily in infants. Small deposits of *brown adipose tissue*, a special kind of adipose tissue that dissipates energy and produces heat by this mechanism, are also found in adults.
- **Enhanced release of thyroxine.** When environmental temperature decreases gradually, as in the transition from summer to winter, the hypothalamus of infants releases *thyrotropin-releasing hormone* (◀ p. 616). This hormone activates the anterior pituitary to release *thyroid-stimulating hormone*, which induces the thyroid to liberate more thyroid hormone to the blood. Because thyroid hormone raises metabolic rate, body heat production rises. Adults do not show a similar TSH response to cold exposure.

Besides these involuntary adjustments, we humans make a number of *behavioral modifications* to prevent overcooling of our body core:

- Putting on more or warmer clothing to restrict heat loss (hat, gloves, and insulated outer garments)
- Drinking hot fluids
- Changing posture to reduce exposed body surface area (hunching over or clasping the arms across the chest)
- Increasing physical activity to generate more heat (jumping up and down, clapping the hands)

Heat-Loss Mechanisms

How do heat-loss mechanisms protect the body from excessively high temperatures? Whenever core body temperature rises above normal, it inhibits the hypothalamic heat-promoting center. At the same time, it activates the heat-loss center and triggers one or both of the following (Figure 24.28, top):

- **Dilation of cutaneous blood vessels.** Inhibiting the vasomotor fibers serving blood vessels of the skin allows the vessels to dilate. As the blood vessels swell with warm blood, the shell loses heat by radiation, conduction, and convection.
- **Enhanced sweating.** If the body is extremely overheated or if the environment is so hot—over 33°C (about 92°F)—that heat cannot be lost by other means, evaporation becomes necessary. Sympathetic fibers activate the sweat glands to spew out large amounts of sweat.

Evaporation of sweat is an efficient means of ridding the body of surplus heat as long as the air is dry. However, when the relative humidity is high, evaporation occurs much more slowly. In such cases, the heat-liberating mechanisms cannot work well, and we feel miserable and irritable. Behavioral or voluntary measures commonly taken to reduce body heat in such circumstances include:

- Reducing activity ("laying low")
- Seeking a cooler environment (a shady spot) or using a device to increase convection (a fan) or cooling (an air conditioner)
- Wearing light-colored, loose clothing that reflects radiant energy. (This is actually cooler than being nude because bare skin absorbs most of the radiant energy striking it.)

HOMEOSTATIC IMBALANCE 24.7 CLINICAL

Overexposure to a hot and humid environment makes normal heat-loss processes ineffective. The resulting **hyperthermia** (elevated body temperature) depresses the hypothalamus. At a core temperature of around 41°C (105°F), heat-control mechanisms are suspended, creating a vicious *positive feedback cycle*. Increasing temperatures increase the metabolic rate, which increases heat production. The skin becomes hot and dry and, as the temperature continues to spiral upward, multiple organ damage becomes a distinct possibility, including brain damage. This condition, called **heat stroke**, can be fatal unless corrective measures are initiated immediately (immersing the body in cool water and administering fluids).

The terms *heat exhaustion* and *exertion-induced heat exhaustion* are often used to describe the heat-associated extreme sweating and collapse of an individual during or following vigorous physical activity. This condition, evidenced by elevated body temperature and mental confusion and/or fainting, is due to dehydration and consequent low blood pressure. As heat-loss mechanisms struggling to function in heat exhaustion further give way, heat exhaustion merges into heat stroke. Death results if the body is not cooled and rehydrated promptly.

Hypothermia (hi″po-ther′me-ah) is low body temperature resulting from prolonged uncontrolled exposure to cold. Vital signs (respiratory rate, blood pressure, and heart rate) decrease as cellular enzymes become sluggish. Drowsiness sets in and, oddly, the person becomes comfortable even though previously he or she felt extremely cold. Shivering stops at a core temperature of 30–32°C (87–90°F) when the body has exhausted its heat-generating capabilities. Uncorrected, hypothermia progresses to coma and finally death (by cardiac arrest), when body temperatures approach 21°C (70°F).

Fever

Fever is *controlled hyperthermia*. Most often, it results from infection somewhere in the body, but it may be caused by cancer, allergic reactions, or CNS injuries.

Whatever the cause, macrophages and other cells release cytokines that act as *pyrogens* (literally, "fire starters"). These chemicals act on the hypothalamus, causing release of prostaglandins which reset the hypothalamic thermostat to a higher-than-normal temperature, so that heat-promoting mechanisms kick in. As a result of vasoconstriction, heat loss from the body surface declines, the skin cools, and shivering begins to generate heat. These "chills" are a sure sign body temperature is rising.

The temperature rises until it reaches the new setting, and then is maintained at that setting until natural body defenses or medications reverse the disease process. Then, heat-loss mechanisms swing into action. Sweating begins and the skin becomes flushed and warm. Physicians have long recognized these signs as signals that body temperature is falling (the fever has broken). As we explained in Chapter 21, fever speeds healing by increasing the metabolic rate, and it also appears to inhibit bacterial growth.

Developmental Aspects of Nutrition and Metabolism

Good nutrition is essential *in utero*, as well as throughout life. If the mother is ill nourished, the development of her infant is affected. Most serious is the lack of adequate calories, proteins, and vitamins needed for fetal tissue growth, especially brain growth. Additionally, inadequate nutrients during the first three years after birth will lead to mental deficits or learning disorders because brain growth continues during this time. Proteins are needed for muscle and bone growth, and calcium is required for strong bones. Although anabolic processes are less critical after growth is completed, sufficient nutrients are still essential to maintain normal tissue replacement and metabolism.

HOMEOSTATIC IMBALANCE 24.8 — CLINICAL

There are many inborn errors of metabolism (or genetic disorders), but one of the most common is *phenylketonuria* (*PKU*) (fen″il-ke″to-nu′re-ah).

In PKU, tissue cells are unable to use the amino acid phenylalanine (fen″il-al′ah-nēn), which is present in all protein foods. The enzyme that converts phenylalanine to tyrosine is defective. Phenylalanine cannot be metabolized, so it and its deaminated products accumulate in the blood and act as neurotoxins that cause brain damage. These consequences are uncommon today because most states require a urine or blood test to identify affected newborns, and these children are put on a diet low in phenylalanine. People with PKU must restrict their intake of phenylalanine throughout life, especially during pregnancy.

There are a number of other enzyme defects, classified according to the impaired process as carbohydrate, lipid, or mineral metabolic disorders. The carbohydrate deficit *galactosemia* results from an abnormality in or lack of the liver enzymes needed to transform galactose to glucose. Galactose accumulates in the blood and leads to mental deficits.

In *glycogen storage disease*, glycogen synthesis is normal, but one of the enzymes needed to convert it back to glucose is missing. As excessive amounts of glycogen are stored, its storage organs (liver and skeletal muscles) become glutted with glycogen and enlarge tremendously.

With the exception of *type 1 diabetes mellitus*, children free of genetic disorders rarely exhibit metabolic problems. However, by middle age and particularly old age, *type 2 diabetes mellitus* becomes a major problem, particularly in people who are obese.

HOMEOSTATIC IMBALANCE 24.9 — CLINICAL

Metabolic syndrome is defined as a cluster of five risk factors (**Figure 24.29**). Together, they double the chance of getting heart disease and stroke, and increase the chance of developing type 2 diabetes by five times. About 32% of the U.S. population has the dubious distinction of qualifying for this syndrome by having three of the five risk factors.

Metabolic syndrome reflects abnormal adipose tissue function, and visceral fat in the abdominal cavity is particularly susceptible. Increased visceral fat (as in the "apple" body shape) is associated with increased inflammatory cytokines and insulin resistance, which contribute to elevated blood glucose and

Metabolic syndrome:

- ↑ Waist circumference
- ↑ Blood pressure
- ↑ Blood glucose
- ↑ Blood triglycerides
- ↓ Blood HDL cholesterol

Figure 24.29 Metabolic syndrome. Increased abdominal fat deposition (the "apple" body shape) is associated with metabolic syndrome.

triglycerides, and the development of atherosclerosis. On the other hand, subcutaneous fat (as in the "pear" body shape where fat is deposited in the hips) is less susceptible to dysfunction.

What can those of us with metabolic syndrome do? The key is to reduce abdominal fat. As always, changes to diet and increased exercise are the first steps. In addition, drugs are usually used to manage the individual components of metabolic syndrome (hypertension, insulin resistance, and abnormal blood lipid profile).

Metabolic rate declines throughout the life span. In old age, muscle and bone wasting and declining efficiency of the endocrine system take their toll. Because many elderly are also less active, their metabolic rate is sometimes so low that it becomes nearly impossible to obtain adequate nutrition without gaining weight. The elderly also use more medications than any other group, at a time of life when the liver has become less efficient in its detoxifying duties.

Many drugs and popular remedies influence nutrition. For example:

- Some diuretics prescribed for congestive heart failure or hypertension (to flush fluids out of the body) can cause severe hypokalemia by promoting excessive loss of potassium.
- Some antibiotics—for example, sulfa drugs, tetracycline, and penicillin—interfere with food digestion and absorption. They may also cause diarrhea, further decreasing absorption.
- Although physicians discourage its use because it interferes with absorption of fat-soluble vitamins, mineral oil is still a popular laxative with the elderly.
- About half the elderly in the U.S. consume alcohol. When it is substituted for food, nutrient stores can be depleted. Excessive alcohol intake leads to absorption problems, certain vitamin and mineral deficiencies, deranged metabolism, and damage to the liver and pancreas.

Although malnutrition and a waning metabolic rate present problems to some elderly, certain nutrients—notably glucose—appear to contribute to the aging process in all of us. Nonenzymatic reactions (the so-called *browning reactions*) between glucose and proteins, long known to discolor and toughen foods, may have the same effects on body proteins. When enzymes attach sugars to proteins, they do so at specific sites and the glycoproteins produced play well-defined roles in the body. In contrast, nonenzymatic binding of glucose to proteins (a process that increases with age) is haphazard and eventually causes cross-links between proteins. This type of binding probably contributes to lens clouding, and the general tissue stiffening and loss of elasticity so common in the aged.

RELATED CLINICAL TERMS

Appetite A desire for food. A psychological phenomenon dependent on memory and associations, as opposed to hunger, which is a physiological need to eat.

Familial hypercholesterolemia (hi″per-ko-les″ter-ol-e′me-ah) An inherited condition in which the LDL receptors are absent or abnormal, the uptake of cholesterol by tissue cells is blocked, and the total concentration of cholesterol (and LDLs) in the blood is enormously elevated. Atherosclerosis develops at an early age, heart attacks begin in the third or fourth decade, and most die by age 60 from coronary artery disease. Treatment entails dietary modifications, exercise, and cholesterol-reducing drugs.

Pica (pi′kah) Craving and eating nonfood substances such as clay or dirt.

Protein energy malnutrition Severe deficiency of calories or calories and protein. **Marasmus** (mah-raz′mus), caused by inadequate overall calorie intake, results in weight loss and depletion of fat and muscle. **Kwashiorkor** (kwash″e-or′kor) is caused by proportionately lower protein intake than calories in children. It is characterized by a bloated abdomen (edema) because the amount of plasma proteins is inadequate to keep fluid in the bloodstream (◀ p. 734). Skin lesions and infections are likely. In children, both conditions result in failure to grow.

Skin-fold test Clinical test of body fatness. A skin fold in the back of the arm or below the scapula is measured with a caliper. A fold over 1 inch in thickness indicates excess fat.

CHAPTER SUMMARY

PART 1
NUTRIENTS

1. Nutrients include carbohydrates, lipids, proteins, vitamins, and minerals. The bulk of the organic nutrients is used as fuel to produce cellular energy (ATP). The energy value of foods is measured in kilocalories (kcal).
2. Essential nutrients are those that are inadequately synthesized by body cells and must be ingested in the diet.

24.1 Carbohydrates, lipids, and proteins supply energy and are used as building blocks (pp. 927–931)

Carbohydrates (pp. 927–928)

1. Carbohydrates are obtained primarily from plant products. Absorbed monosaccharides other than glucose are converted to glucose by the liver.

9. When blood glucose levels begin to fall, glycogenolysis occurs, in which glycogen stores are converted to glucose. The liver can also perform gluconeogenesis, the formation of glucose from noncarbohydrate (fat or protein) molecules.

24.5 Lipid metabolism is key for long-term energy storage and release (pp. 946–948)

1. End products of lipid digestion (and cholesterol) are transported in blood in the form of chylomicrons.
2. Glycerol is converted to glyceraldehyde 3-phosphate and enters the citric acid cycle or is converted to glucose.
3. Fatty acids are oxidized by beta oxidation into acetic acid fragments. These are bound to coenzyme A and enter the citric acid cycle as acetyl CoA. Dietary fats not needed for energy or structural materials are stored in adipose tissue.
4. There is a continual turnover of fats in fat depots. Breakdown of fats to fatty acids and glycerol is called lipolysis.
5. When excessive amounts of fats are used, the liver converts acetyl CoA to ketone bodies and releases them to the blood. Excessive levels of ketone bodies (ketosis) lead to metabolic acidosis.
6. All cells use phospholipids and cholesterol to build their plasma membranes. The liver forms many functional molecules from lipids.

24.6 Amino acids are used to build proteins or for energy (pp. 948–949)

1. To be oxidized for energy, amino acids are converted to keto acids that can enter the citric acid cycle. This involves transamination, oxidative deamination, and keto acid modification.
2. Amine groups removed during deamination (as ammonia) are combined with carbon dioxide by the liver to form urea. Urea is excreted in urine.
3. Deaminated amino acids may also be converted to fatty acids and glucose.
4. Amino acids are the body's most important building blocks. Nonessential amino acids are made in the liver by transamination.
5. In adults, most protein synthesis serves to replace tissue proteins and to maintain nitrogen balance.
6. Protein synthesis requires the presence of all essential amino acids. If any are lacking, amino acids are used as energy fuels.

24.7 Energy is stored in the absorptive state and released in the postabsorptive state (pp. 949–955)

Catabolic-Anabolic Balance of the Body (pp. 949–950)

1. The amino acid pool provides amino acids for synthesis of proteins and amino acid derivatives, ATP synthesis, and energy storage.
2. The carbohydrate-fat pool primarily provides fuels for ATP synthesis and other molecules that can be stored as energy reserves.
3. The nutrient pools are connected by the bloodstream; fats, carbohydrates, and proteins may be interconverted via common intermediates.

Absorptive State (pp. 950–952)

4. During the absorptive state (during and shortly after a meal), glucose is the major energy source; needed structural and functional molecules are made; excess carbohydrates, fats, and amino acids are stored as glycogen and fat.
5. Events of the absorptive state are controlled by insulin, which enhances the entry of glucose (and amino acids) into cells and accelerates its use for ATP synthesis or storage as glycogen or fat.

Postabsorptive State (pp. 952–955)

6. The postabsorptive state is the period when bloodborne fuels are provided by breakdown of energy reserves. Glucose is made available to the blood by glycogenolysis, lipolysis, and gluconeogenesis. Glucose sparing begins. During prolonged fasting, the brain also begins to metabolize ketone bodies.
7. Events of the postabsorptive state are controlled largely by glucagon and the sympathetic nervous system, which mobilize glycogen and fat reserves and trigger gluconeogenesis.

24.8 The liver metabolizes, stores, and detoxifies (pp. 955–960)

1. The liver is the body's main metabolic organ and it plays a crucial role in processing (or storing) virtually every nutrient group. It helps maintain blood energy sources, metabolizes hormones, and detoxifies drugs and other substances.
2. The liver synthesizes cholesterol, catabolizes cholesterol and secretes it in the form of bile salts, and makes lipoproteins. The liver makes a basal amount of cholesterol (85%) even when dietary cholesterol intake is excessive.
3. LDLs transport cholesterol from the liver to the tissues, whereas HDLs transport cholesterol from the tissues to the liver (for catabolism and elimination).
4. Excessively high LDL levels are implicated in atherosclerosis, cardiovascular disease, and stroke.

PART 3 ENERGY BALANCE

1. Body energy intake (derived from food oxidation) is precisely balanced by energy output (heat, work, and energy storage). Eventually, all of the energy intake is converted to heat.

24.9 Neural and hormonal factors regulate food intake (pp. 960–962)

1. When energy balance is maintained, weight remains stable. When excess amounts of energy are stored, the result is obesity (condition of excessive fat storage resulting in a BMI above 30).
2. The hypothalamus (particularly its arcuate nucleus) and other brain centers are involved in regulating eating behavior.
3. Factors thought to be involved in regulating food intake include (a) neural signals from the gut to the brain; (b) nutrient signals related to total energy storage; (c) plasma concentrations of hormones that control events of the absorptive and postabsorptive states, and hormones that provide feedback signals to brain feeding centers (leptin appears to exert the main long-term controls of appetite and energy metabolism); (d) body temperature, psychological factors, and others.

24.10 Thyroxine is the major hormone that controls basal metabolic rate (pp. 962–963)

1. Energy used by the body per hour is the metabolic rate.
2. Basal metabolic rate (BMR), reported in kcal/m^2/h, is the measurement obtained when the person is at comfortable room temperature, supine, relaxed, and in the postabsorptive state. BMR indicates energy needed to drive only the resting body processes.

3. Factors influencing metabolic rate include body surface area, age and gender, body temperature, stress, and thyroxine; also the specific dynamic action of foods, and muscular activity.

24.11 The hypothalamus acts as the body's thermostat (pp. 963–968)

1. Body temperature reflects the balance between heat production and heat loss and is normally 37°C (± 0.5°C), which is optimal for physiological activities.
2. At rest, most body heat is produced by the liver, heart, brain, kidneys, and endocrine organs. Activation of skeletal muscles causes dramatic increases in body heat production.
3. The body core (organs within the skull and the ventral body cavity) generally has the highest temperature. The shell (the skin) is the heat-exchange surface, and is usually coolest.
4. Blood serves as the major heat-exchange agent between the core and the shell. When skin capillaries are flushed with blood and the skin is warmer than the environment, the body loses heat. When blood is withdrawn to deep organs, heat loss from the shell is inhibited.
5. Heat-exchange mechanisms include radiation, conduction, convection, and evaporation. Evaporation, the conversion of water to water vapor, requires the absorption of heat. For each gram of water vaporized, about 0.6 kcal of heat is absorbed.
6. The hypothalamus acts as the body's thermostat. Its heat-promotion and heat-loss centers receive inputs from peripheral and central thermoreceptors, integrate these inputs, and initiate responses leading to heat loss or heat promotion.
7. Heat-promoting mechanisms include constriction of skin vasculature, and shivering.
8. When heat must be removed from the body, dermal blood vessels dilate, allowing heat loss through radiation, conduction, and convection. When greater heat loss is mandated (or the environmental temperature is so high that radiation and conduction are ineffective), sweating is initiated. Evaporation of sweat is an efficient means of heat loss as long as the humidity is low.
9. When the body cannot rid itself of surplus heat, body temperature rises to the point where all thermoregulatory mechanisms become ineffective—a potentially lethal condition called heat stroke. Physical activity in hot temperatures can lead to heat exhaustion, indicated by a rise in temperature, a drop in blood pressure, and collapse.
10. Fever is controlled hyperthermia, which follows thermostat resetting to higher levels by prostaglandins and initiation of heat-promotion mechanisms, evidenced by the chills. When the disease process is reversed, heat-loss mechanisms are initiated.

Developmental Aspects of Nutrition and Metabolism (pp. 968–969)

1. Good nutrition is essential for normal fetal development and normal growth during childhood.
2. Inborn errors of metabolism include PKU, glycogen storage disease, galactosemia, and many others. Hormonal disorders, such as lack of insulin or thyroid hormone, may also lead to metabolic abnormalities. Diabetes mellitus and metabolic syndrome are the most significant metabolic disorders in middle-aged and older adults.
3. In old age, metabolic rate declines as enzyme and endocrine systems become less efficient and skeletal muscles atrophy. Reduced caloric needs make it difficult to obtain adequate nutrition without becoming overweight.
4. Elderly individuals ingest more medications than any other age group, and many of these drugs negatively affect their nutrition.

REVIEW QUESTIONS

To access additional practice questions using your smartphone, tablet, or computer: MasteringA&P® > Study Area > Practice Tests & Quizzes

Level 1 Remember/Understand

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Which of the following reactions would liberate the most energy? **(a)** complete oxidation of a molecule of sucrose to CO_2 and water, **(b)** conversion of a molecule of ADP to ATP, **(c)** respiration of a molecule of glucose to lactic acid, **(d)** conversion of a molecule of glucose to carbon dioxide and water.
2. The formation of glucose from glycogen is **(a)** gluconeogenesis, **(b)** glycogenesis, **(c)** glycogenolysis, **(d)** glycolysis.
3. The net gain of ATP from the complete metabolism (aerobic) of glucose is closest to **(a)** 2, **(b)** 30, **(c)** 3, **(d)** 4.
4. Which of the following best defines cellular respiration? **(a)** intake of carbon dioxide and output of oxygen by cells, **(b)** excretion of waste products, **(c)** inhalation of oxygen and exhalation of carbon dioxide, **(d)** oxidation of substances by which energy is released in usable form to the cells.
5. What is formed during aerobic respiration when electrons are passed down the electron transport chain? **(a)** oxygen, **(b)** water, **(c)** glucose, **(d)** $NADH + H^+$.
6. Metabolic rate is relatively low in **(a)** youth, **(b)** physical exercise, **(c)** old age, **(d)** fever.
7. In a temperate climate under ordinary conditions, the greatest loss of body heat occurs through **(a)** radiation, **(b)** conduction, **(c)** evaporation, **(d)** none of the above.
8. Which of the following is not a function of the liver? **(a)** glycogenolysis and gluconeogenesis, **(b)** synthesis of cholesterol, **(c)** detoxification of alcohol and drugs, **(d)** synthesis of glucagon, **(e)** deamination of amino acids.
9. Amino acids are essential (and important) to the body for all the following except **(a)** production of some hormones, **(b)** production of antibodies, **(c)** formation of most structural materials, **(d)** as a source of quick energy.
10. Transamination is a chemical process by which **(a)** protein is synthesized, **(b)** an amine group is transferred from an amino acid to a keto acid, **(c)** an amine group is split from the amino acid, **(d)** amino acids are broken down for energy.
11. Body temperature regulation is **(a)** influenced by temperature receptors in the skin, **(b)** influenced by the temperature of the blood perfusing the heat regulation centers of the brain, **(c)** subject to both neural and hormonal control, **(d)** all of the above.
12. Which of the following yields the greatest caloric value per gram? **(a)** fats, **(b)** proteins, **(c)** carbohydrates, **(d)** all are equal in caloric value.

Level 2 Apply/Analyze

13. A person has been on a hunger strike for seven days. Compared to normal, he has **(a)** increased release of fatty acids from adipose tissue, and ketosis, **(b)** elevated glucose concentration in the blood, **(c)** increased plasma insulin concentration, **(d)** increased glycogen synthase (enzyme) activity in the liver.

14. What is cellular respiration? What is the common role of FAD and NAD^+ in cellular respiration?

15. Describe the site, major events, and outcomes of glycolysis.

16. Define glycogenesis, glycogenolysis, gluconeogenesis, and lipogenesis. Which is (are) likely to be occurring **(a)** shortly after a carbohydrate-rich meal, **(b)** just before waking up in the morning?

17. What is the harmful result when excessive amounts of fats are burned for energy? Name two conditions that might lead to this result.

18. Distinguish between the role of HDLs and that of LDLs.

19. List some factors that influence plasma cholesterol levels. Also list the sources and fates of cholesterol in the body.

20. What is meant by "body energy balance," and what happens if the balance is not precise?

21. Calculate the number of ATP molecules that can be harvested during the complete oxidation of an 18-carbon fatty acid. (Take a deep breath and think about it—you can do it.)

Level 3 Evaluate/Synthesize

22. Make a flowchart that indicates the pivotal intermediates through which glucose can be converted to fat.

23. Explain the effect of the following on metabolic rate: thyroxine levels, eating, body surface area, muscular exercise, emotional stress, starvation.

24. Compare and contrast mechanisms of heat loss with mechanisms of heat promotion, and explain how these mechanisms determine body temperature.

25. Every year dozens of elderly people are found dead in their unheated apartments and listed as victims of hypothermia. What is hypothermia, and how does it kill? Why are the elderly more susceptible to hypothermia than the young?

26. While attempting to sail solo from Los Angeles to Tahiti, Seth encountered a storm that marooned him on an uninhabited island. He was able, using his ingenuity and a pocket knife, to obtain plenty of fish to eat, and roots were plentiful. However, the island was barren of fruits and soon his gums began to bleed and he started to develop several infections. Analyze his problem.

27. Gregor, a large, beefy man, came home from the doctor's office and complained to his wife that his blood tests "were bad." He told her that the doctor said he would have to give up some of his steaks and butter. He went on to mourn the fact that he would have to start eating more cottage cheese and olive oil instead. What kind of problem was revealed by his "bad" blood tests? What do you think of his choice of food substitutes and why? What would you suggest?

CLINICAL CASE STUDY

32-Year-Old Male with Altered Mental Status

First responders retrieve Kyle Boulard, 32, from a local mall. Bystanders reported that he was behaving erratically, appeared disoriented, and staggered as he walked. When he arrives in your emergency department, you note that his breath has a fruity acetone odor. Tests are ordered and the following results obtained:

GENERAL	BLOOD	URINE
BP: 95/58	pH: 7.1	pH: 4.3
HR: 110	Glucose: 345 mg/dl	Glucose: strongly positive
	Ketone bodies: 22 mg/dl	Ketone bodies: strongly positive; odor "fruity acetone"

1. Urine glucose and ketone bodies are usually negative. Using the information in Appendix F, look up normal values for blood pH, blood glucose, blood ketone bodies, and urine pH, and identify whether each test result is normal or abnormal.

2. A "fruity acetone" smell was detected in Kyle's breath, and in his urine. Which substance is producing the "fruity acetone" smell?

3. ✚ NCLEX-STYLE Given the lab results above, what is the most likely explanation for Kyle's condition?
- **a.** The presence of ketone bodies in Kyle's blood suggests that Kyle is starving.
- **b.** The presence of glucose in Kyle's urine suggests that he has uncontrolled diabetes insipidus.
- **c.** The presence of glucose in Kyle's urine suggests that he has uncontrolled diabetes mellitus.
- **d.** The low pH in Kyle's blood and urine suggest that Kyle has ingested a poison.

4. ✚ NCLEX-STYLE Kyle's blood contains ketone bodies. What is the most likely explanation for this?
- **a.** The major source for ketones is dietary, so he must have been eating or drinking them.
- **b.** Kyle's blood contains ketone bodies because his kidney is not excreting them at the normal rate.
- **c.** He was eating excess carbohydrates, and his liver turned these into ketones for storage.
- **d.** His body cells are not able to use carbohydrates for fuel, so the liver is converting fats into ketone bodies.

5. Explain how the pH of Kyle's blood and urine is related to the ketone bodies measured in each of these fluids.

25 The Urinary System

In this chapter, you will learn that

The kidneys maintain the composition of the body's extracellular fluids

- starting with

- and then asking
  - **25.9 How does the body transport, store, and eliminate urine?**

and finally, exploring

- **Developmental Aspects of the Urinary System**

Every day the kidneys filter nearly 200 liters of fluid from our bloodstream, allowing toxins, metabolic wastes, and excess ions to leave the body in urine while returning needed substances to the blood. Much like a water purification plant that keeps a city's water drinkable and disposes of its wastes, the kidneys are usually unappreciated until they malfunction and body fluids become contaminated.

The kidneys perform a chemical balancing act that would be tricky even for the best chemical engineer. They maintain the body's internal environment by:

- Regulating the total volume of water in the body and the total concentration of solutes in that water (osmolality).
- Regulating the concentrations of the various ions in the extracellular fluids. (Even relatively small changes in some ion concentrations such as K^+ can be fatal.)
- Ensuring long-term acid-base balance.
- Excreting metabolic wastes and foreign substances such as drugs or toxins.

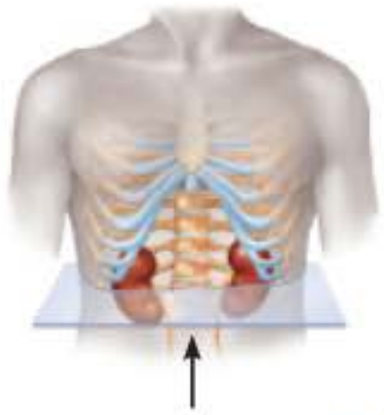

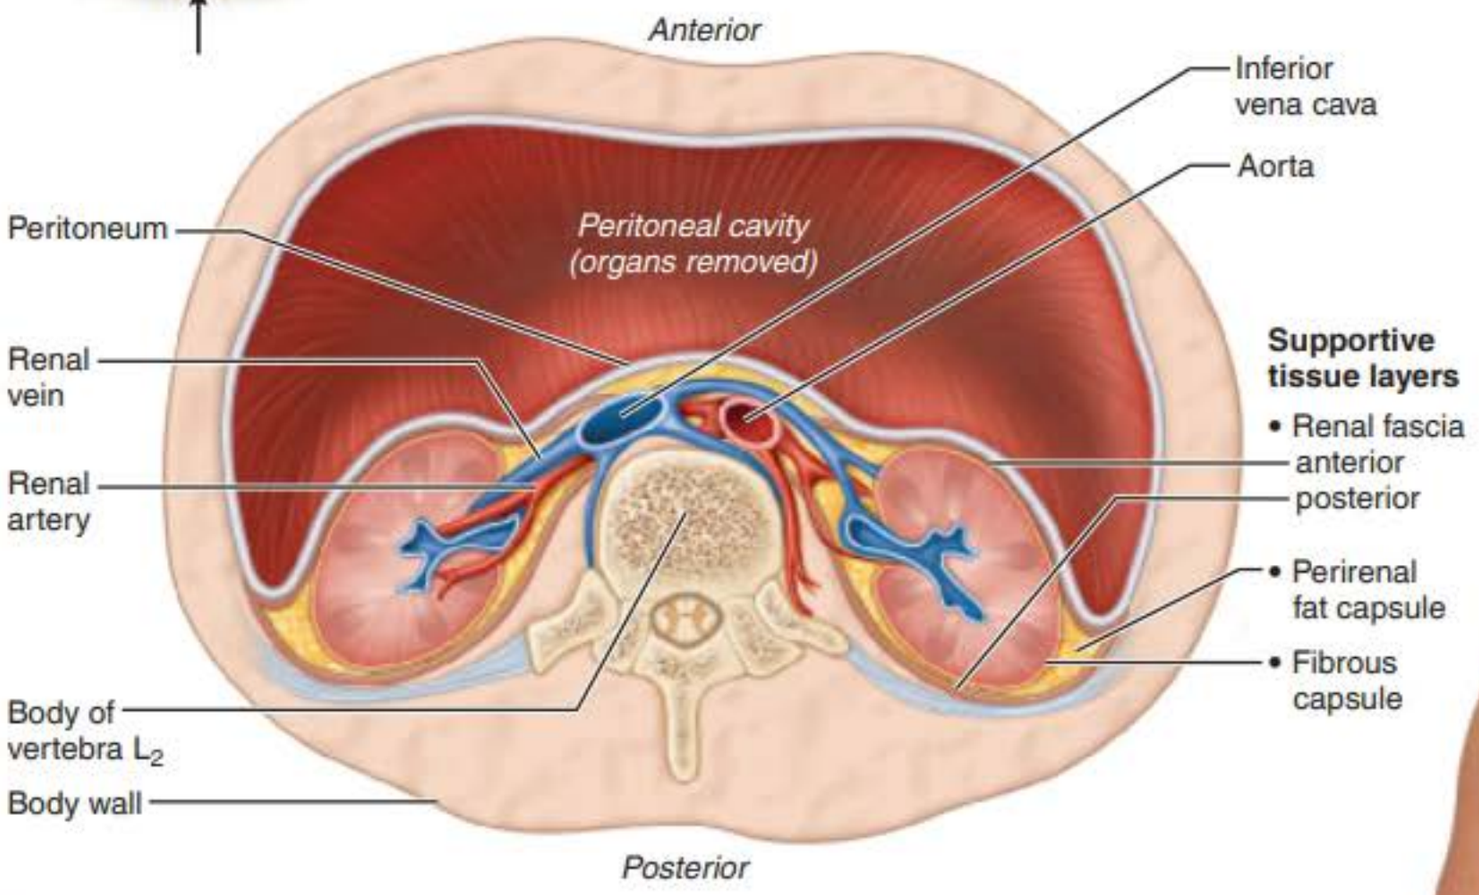

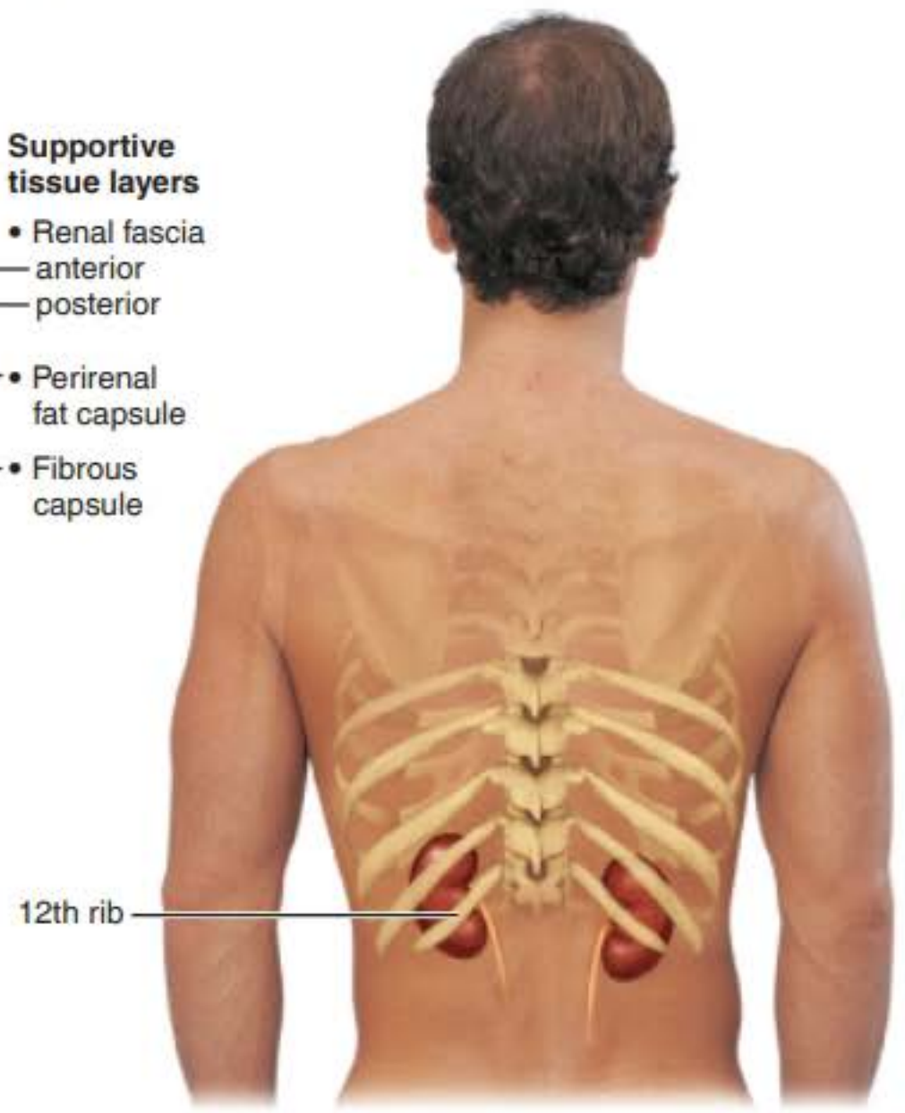

Figure 25.3 Position of the kidneys against the posterior body wall. (a) Cross section viewed from inferior direction. Note the retroperitoneal position and the supportive tissue layers of the kidney. **(b)** Posterior *in situ* view showing relationship of the kidneys to the 12th ribs.

the *superior* lumbar region (**Figure 25.3**). Extending approximately from T_{12} to L_3, the kidneys receive some protection from the lower part of the rib cage (Figure 25.3b). The right kidney is crowded by the liver and lies slightly lower than the left.

An adult's kidney has a mass of about 150 g (5 ounces) and its average dimensions are 11 cm long, 6 cm wide, and 3 cm thick—about the size of a large bar of soap. The lateral surface is convex. The medial surface is concave and has a vertical cleft called the **renal hilum** (see Figures 25.1, 25.2, and 25.4) that leads into an internal space called the *renal sinus*. The ureter, renal blood vessels, lymphatics, and nerves all join each kidney at the hilum and occupy the sinus. Atop each kidney is an *adrenal* (or *suprarenal*) *gland*, an endocrine gland that is functionally unrelated to the kidney.

Three layers of supportive tissue surround each kidney (Figure 25.3a). From superficial to deep, these are:

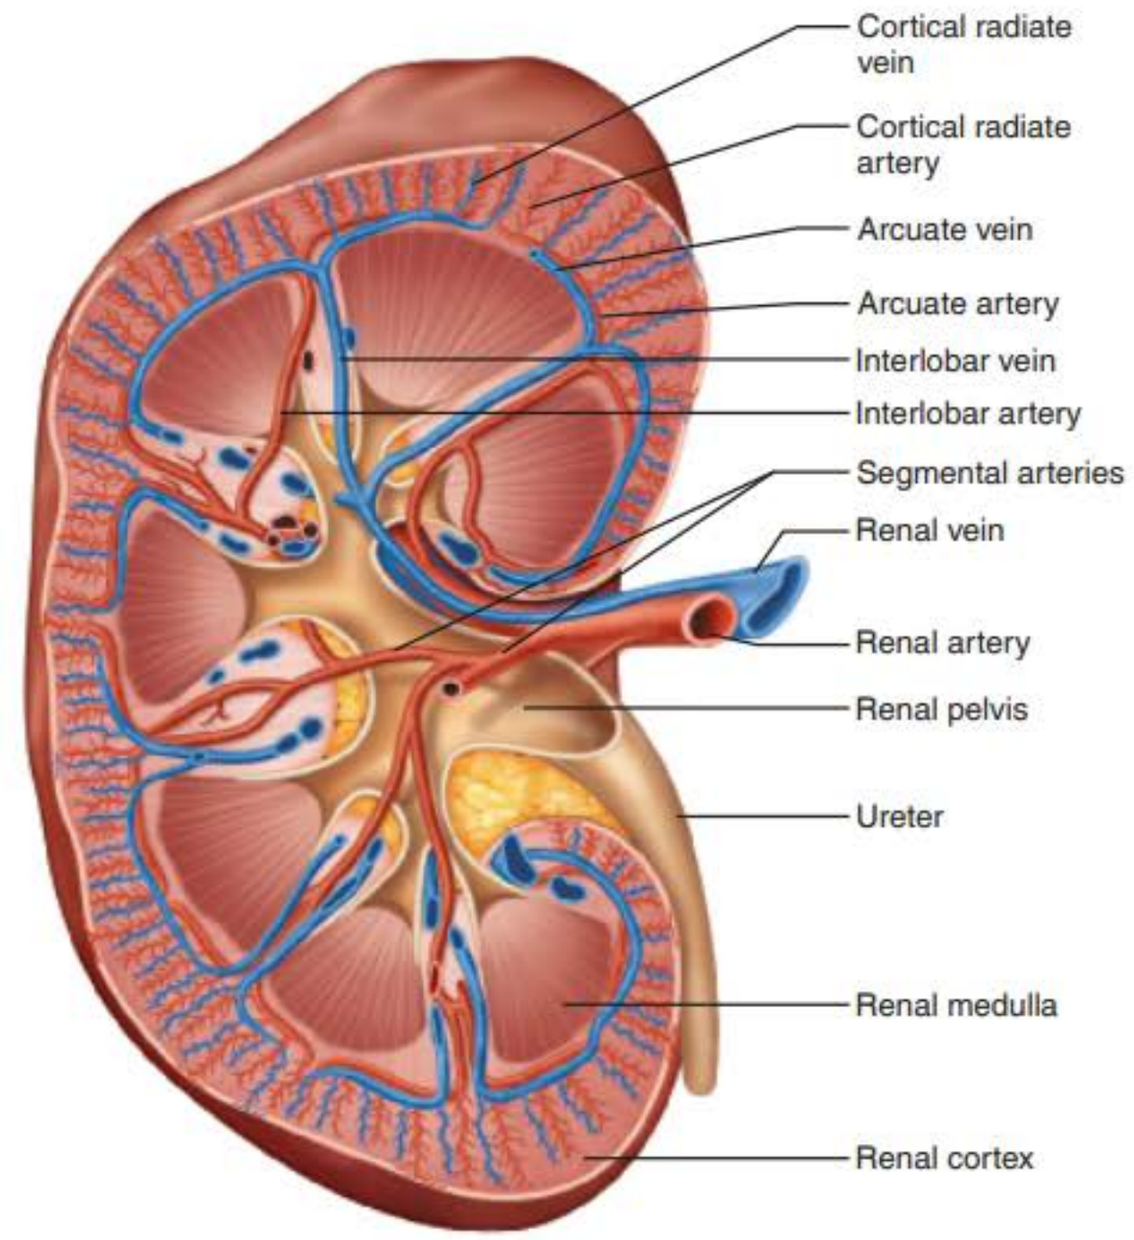
- The **renal fascia**, an outer layer of dense fibrous connective tissue that anchors the kidney and the adrenal gland to surrounding structures
- The **perirenal fat capsule**, a fatty mass that surrounds the kidney and cushions it against blows
- The **fibrous capsule**, a transparent capsule that prevents infections in surrounding regions from spreading to the kidney

HOMEOSTATIC IMBALANCE 25.1 CLINICAL

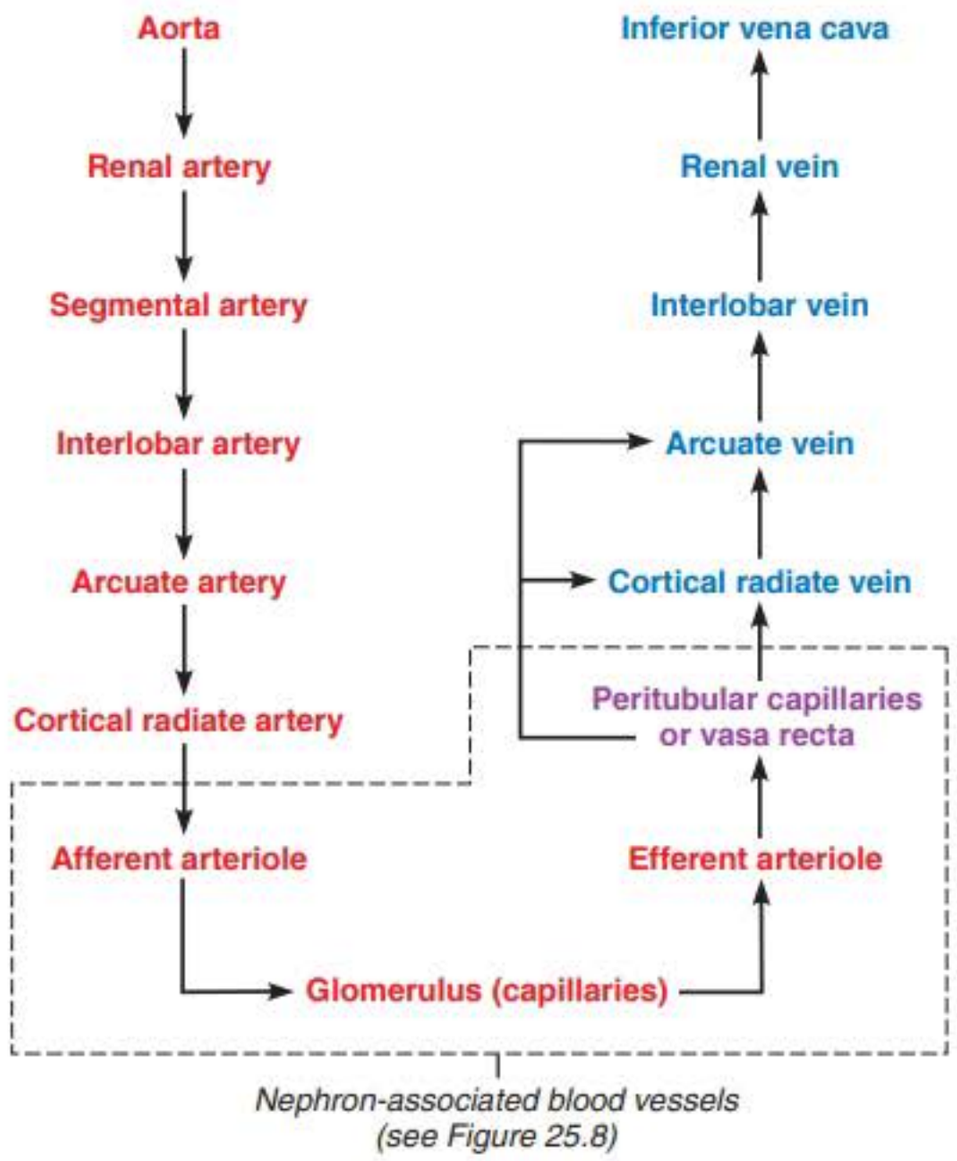
The upper parts of both kidneys are protected by the thoracic cage, and the perirenal fat provides cushioning. However, the lower parts of the kidneys, especially the right kidney, are susceptible to blunt trauma such as from falls, motor vehicle accidents, or contact sports injuries. The renal artery is especially vulnerable to injury from rapid deceleration during car crashes, and may be lacerated (torn) or develop a thrombosis (blood clot). The presence of *hematuria* (blood in the urine) is an important sign of such renal trauma. Occasionally, surgical treatment is required.

Internal Gross Anatomy

A frontal section through a kidney reveals three distinct regions: *cortex*, *medulla*, and *pelvis* (**Figure 25.4**). The most superficial region, the **renal cortex**, is light-colored and has a granular appearance. Deep to the cortex is the darker, reddish-brown



(a) Frontal section illustrating major blood vessels



(b) Path of blood flow through renal blood vessels

Figure 25.5 Blood vessels of the kidney.

The renal arteries exit at right angles from the abdominal aorta, and the right renal artery is longer than the left because the aorta lies to the left of the midline. As each renal artery approaches a kidney, it divides into five **segmental arteries** (**Figure 25.5**). Within the renal sinus, each segmental artery branches further to form several **interlobar arteries**.

At the cortex-medulla junction, the interlobar arteries branch into the **arcuate arteries** (ar′ku-āt) that arch over the bases of the medullary pyramids. Small **cortical radiate arteries** (also called *interlobular arteries*) radiate outward from the arcuate arteries to supply the cortical tissue. More than 90% of the blood entering the kidney perfuses the renal cortex.

Afferent arterioles branching from the cortical radiate arteries begin a complex arrangement of microscopic blood vessels. These vessels are key elements of kidney function, and we will examine them in the next module when we describe the nephron.

Veins mostly trace the pathway of the arterial supply in reverse (Figure 25.5). Blood leaving the renal cortex drains sequentially into the **cortical radiate**, **arcuate**, **interlobar**, and finally **renal veins**. (There are no segmental veins.) The renal veins exit from the kidneys and empty into the inferior vena cava. Because the inferior vena cava lies to the right of the vertebral column, the left renal vein is about twice as long as the right.

The **renal plexus**, a variable network of autonomic nerve fibers and ganglia, provides the nerve supply of the kidney and its ureter. An offshoot of the celiac plexus, the renal plexus is largely supplied by sympathetic fibers from the most inferior thoracic and first lumbar splanchnic nerves, which course along with the renal artery to reach the kidney. These sympathetic vasomotor fibers regulate renal blood flow by adjusting the diameter of renal arterioles and also influence the formation of urine by the nephron.

Check Your Understanding

1. Zach is hit in the lower back by an errant baseball. What protects his kidneys from this mechanical trauma?
2. From inside to outside, list the three layers of supportive tissue that surround each kidney. Where is the parietal peritoneum in relation to these layers?
3. The lumen of the ureter is continuous with a space inside the kidney. This space has branching extensions. What are the names of this space and its extensions?

For answers, see Answers Appendix.

25.2 Nephrons are the functional units of the kidney

Learning Outcome

- **Describe the anatomy of a nephron.**

Nephrons (nef′ronz) are the structural and functional units of the kidneys. (A functional unit is the smallest physical structure capable of carrying out the function of an organ.) If you understand how a single nephron works, then you will understand

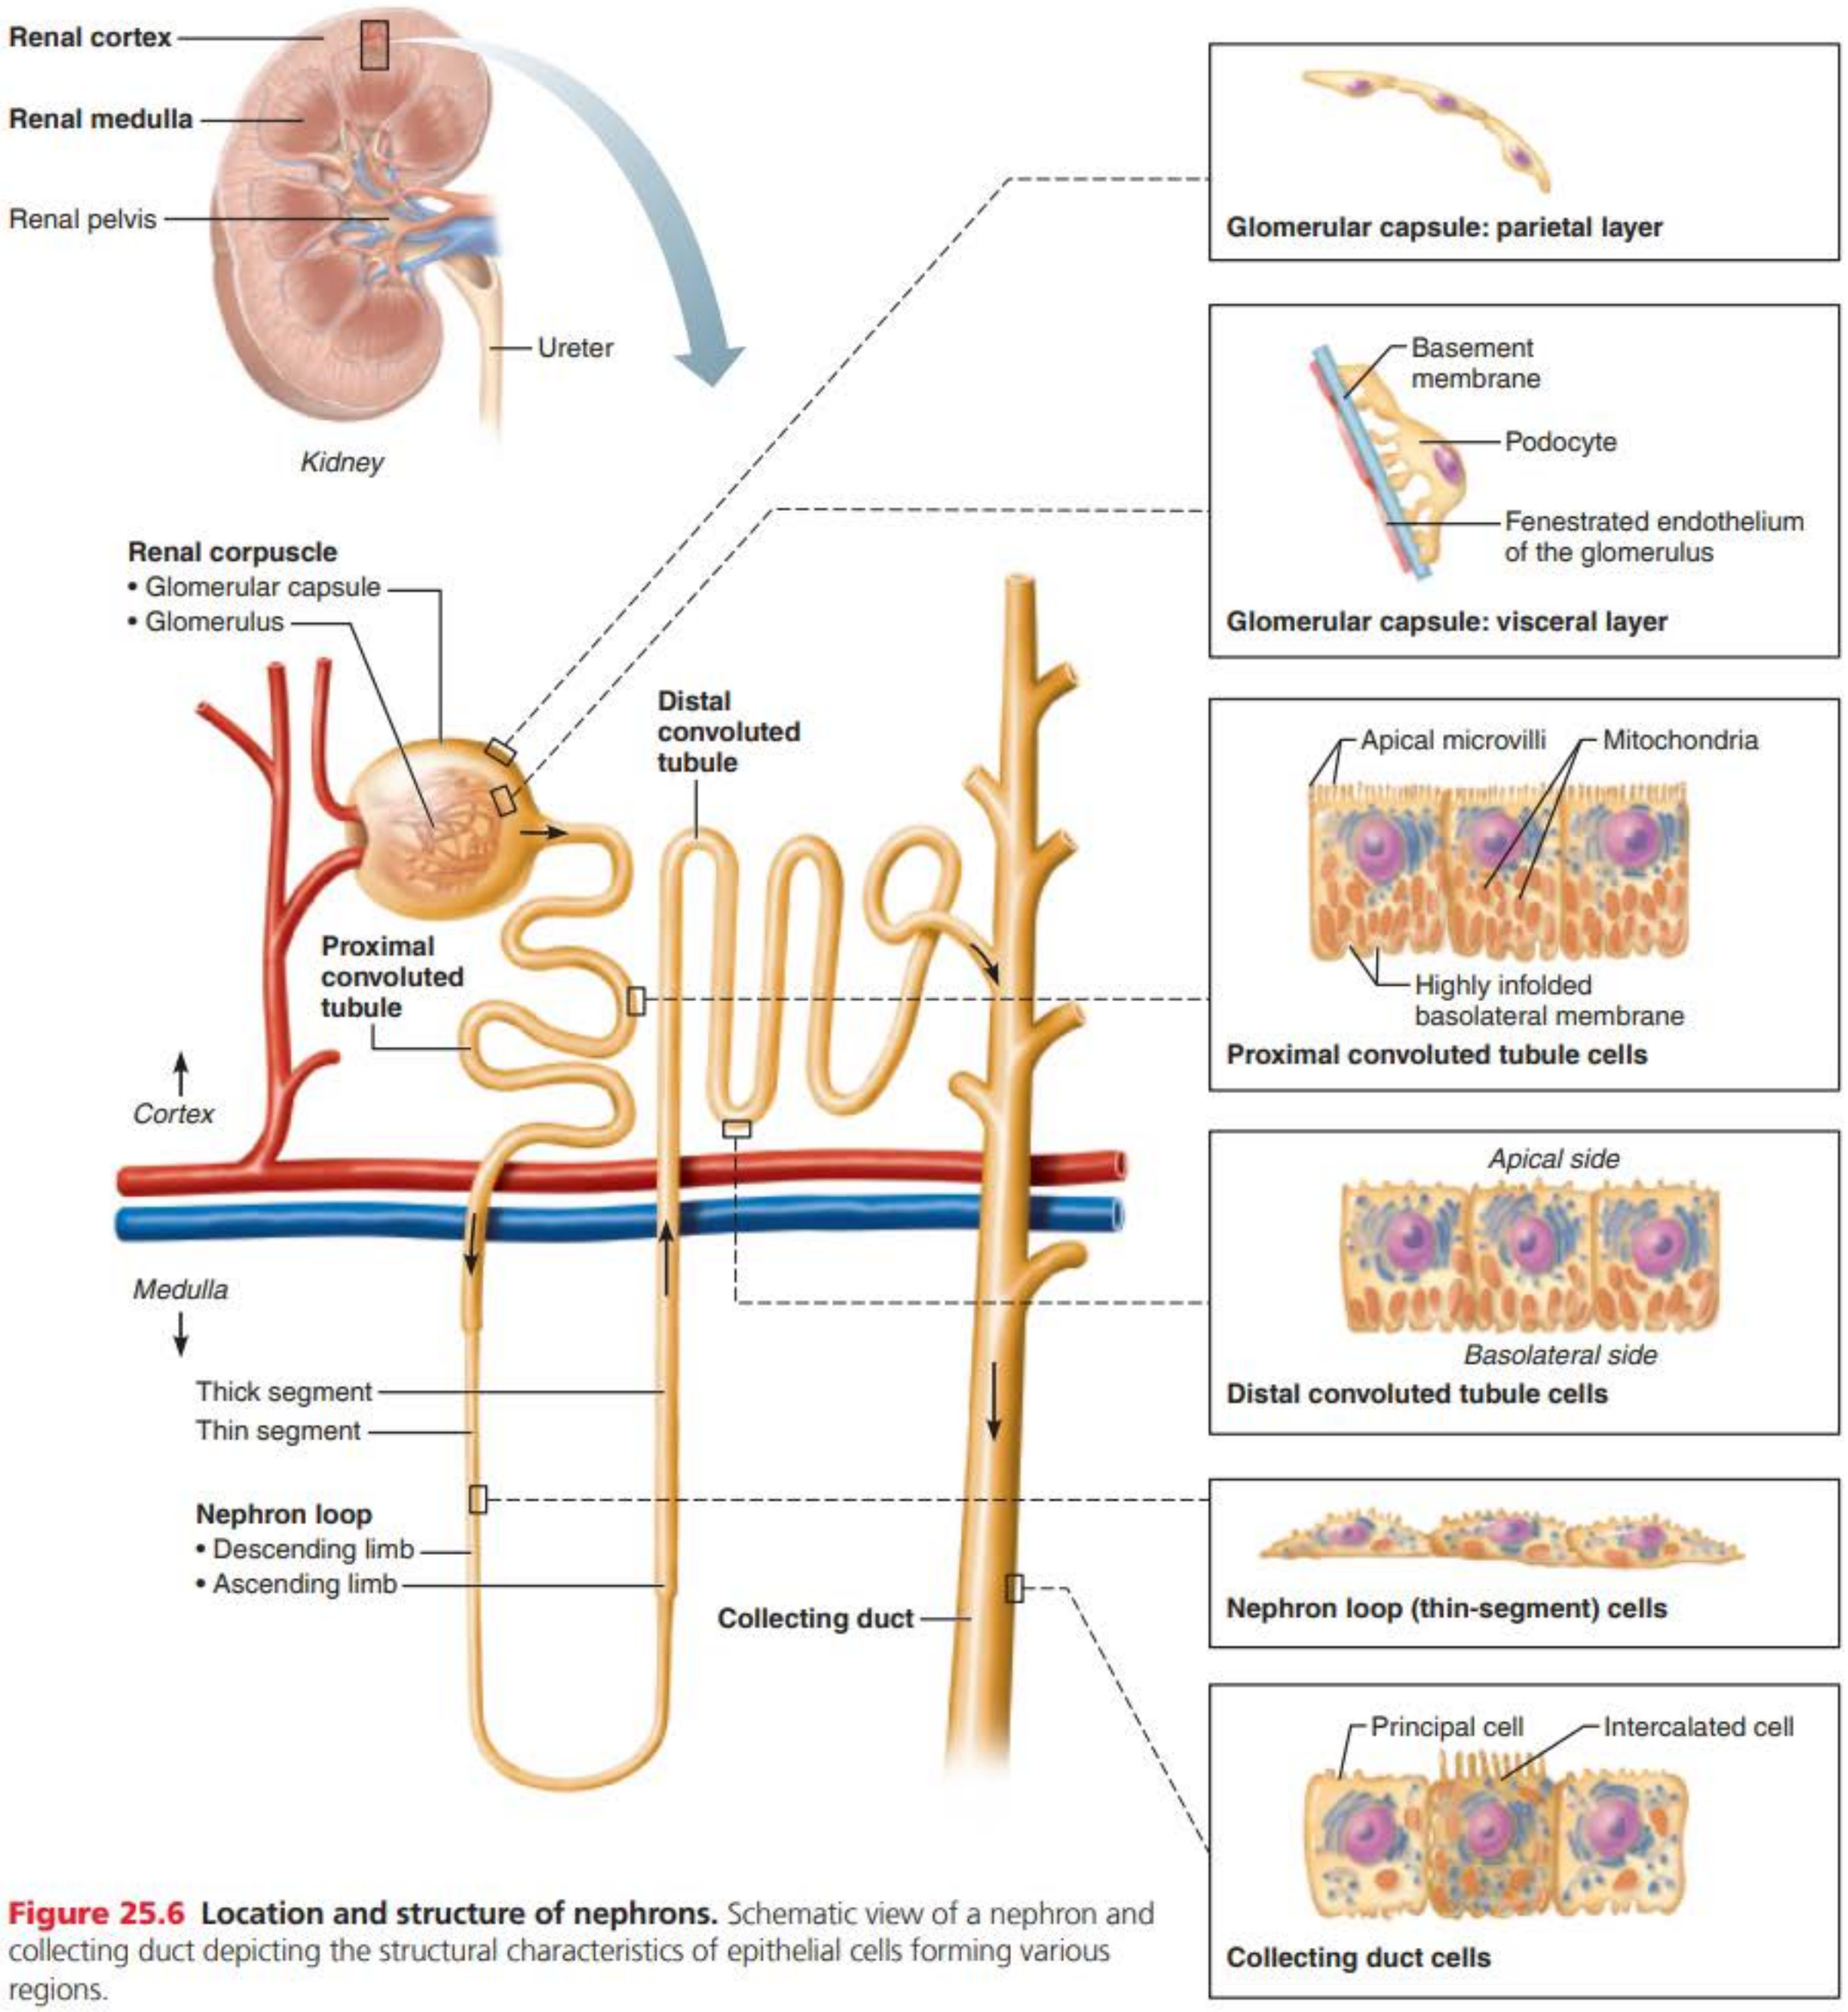


Figure 25.6 Location and structure of nephrons. Schematic view of a nephron and collecting duct depicting the structural characteristics of epithelial cells forming various regions.

how the kidneys work. Each kidney contains about 1 million nephrons acting in parallel to make urine (**Figure 25.6**). Each nephron creates a cell- and protein-free filtrate from blood. From that filtrate, it recovers chemicals the body needs while also secreting into that filtrate selected chemicals that the body needs to get rid of. Nearby nephrons empty their processed filtrate into one of the thousands of *collecting ducts*, which convey this fluid, now called urine, into the renal pelvis.

Each nephron consists of a *renal corpuscle* and a *renal tubule*. All of the renal corpuscles are located in the renal

cortex, while the renal tubules begin in the cortex and then pass into the medulla before returning to the cortex.

Renal Corpuscle

Each **renal corpuscle** consists of a tuft of capillaries called a **glomerulus** (glo-mer′u-lus; *glom* = ball of yarn) and a cup-shaped hollow structure called the **glomerular capsule** (or **Bowman's capsule**) (Figures 25.6 and 25.8). The glomerular capsule is continuous with its renal tubule and completely surrounds the glomerulus, much as a well-worn baseball glove encloses a ball.

Glomerulus

The endothelium of the glomerular capillaries is *fenestrated* (penetrated by many pores; ◀ p. 711), which makes these capillaries exceptionally porous. This property allows large amounts of solute-rich but virtually protein-free fluid to pass from the blood into the glomerular capsule. This plasma-derived fluid or **filtrate** is the raw material that the renal tubules process to form urine.

Glomerular Capsule

The glomerular capsule has an external parietal layer and a visceral layer that clings to the glomerular capillaries.

- The *parietal layer* is simple squamous epithelium (Figures 25.6, 25.7, 25.10, and 25.12a). This layer contributes to the capsule structure but plays no part in forming filtrate.
- The *visceral layer*, which clings to the glomerular capillaries, consists of highly modified, branching epithelial cells called **podocytes** (pod′o-sīts; "foot cells") (see Figure 25.12a–c). The octopus-like podocytes have **foot processes** that cling to the basement membrane of the glomerulus. The clefts or openings between the foot processes are called **filtration slits**. Through these slits, filtrate enters the **capsular space** inside the glomerular capsule.

We describe the *filtration membrane*, the filter that lies between the blood in the glomerulus and the filtrate in the capsular space, on pp. 984–986.

Renal Tubule and Collecting Duct

The **renal tubule** is about 3 cm (1.2 inches) long and has three major parts. It leaves the glomerular capsule as the elaborately coiled *proximal convoluted tubule*, drops into a hairpin loop called the *nephron loop*, and then winds and twists again as the *distal convoluted tubule* before emptying into a collecting duct. The terms *proximal* and *distal* indicate the relationship of the convoluted tubules to the renal corpuscle—filtrate from the renal corpuscle passes through the proximal convoluted tubule first and then the distal convoluted tubule, which is thus "further away" from the renal corpuscle. The meandering nature of the renal tubule increases its length and enhances its filtrate processing capabilities.

Throughout their length, the renal tubule and collecting duct consist of a single layer of epithelial cells on a basement membrane. However, each region has a unique histology that reflects its role in processing filtrate.

Proximal Convoluted Tubule (PCT)

The walls of the **proximal convoluted tubule** (**PCT**) are formed by cuboidal epithelial cells with large mitochondria. Their apical (luminal) surfaces bear dense microvilli (Figure 25.6 and **Figure 25.7**). Just as in the intestine, this *brush border* dramatically increases the surface area and capacity for reabsorbing water and solutes from the filtrate and secreting substances into it.

Nephron Loop

The U-shaped **nephron loop** (formerly called the *loop of Henle*) has **descending** and **ascending limbs**. The proximal part of the descending limb is continuous with the proximal tubule and its cells are similar. The rest of the descending limb, called the *descending thin limb*, consists of a simple squamous epithelium. The epithelium becomes cuboidal or even low columnar in the ascending part of the nephron loop, which is therefore called the *thick ascending limb*. In most nephrons, the entire ascending limb is thick, but in some nephrons, the thin segment extends around the bend as the *ascending thin limb*. The thick and thin parts of the nephron loop are also referred to as thick and thin segments.

Distal Convoluted Tubule (DCT)

The epithelial cells of the **distal convoluted tubule** (**DCT**), like those of the PCT, are cuboidal and confined to the cortex,

Practice Histology questions:
MasteringA&P® > Study Area > Lab Tools > PAL

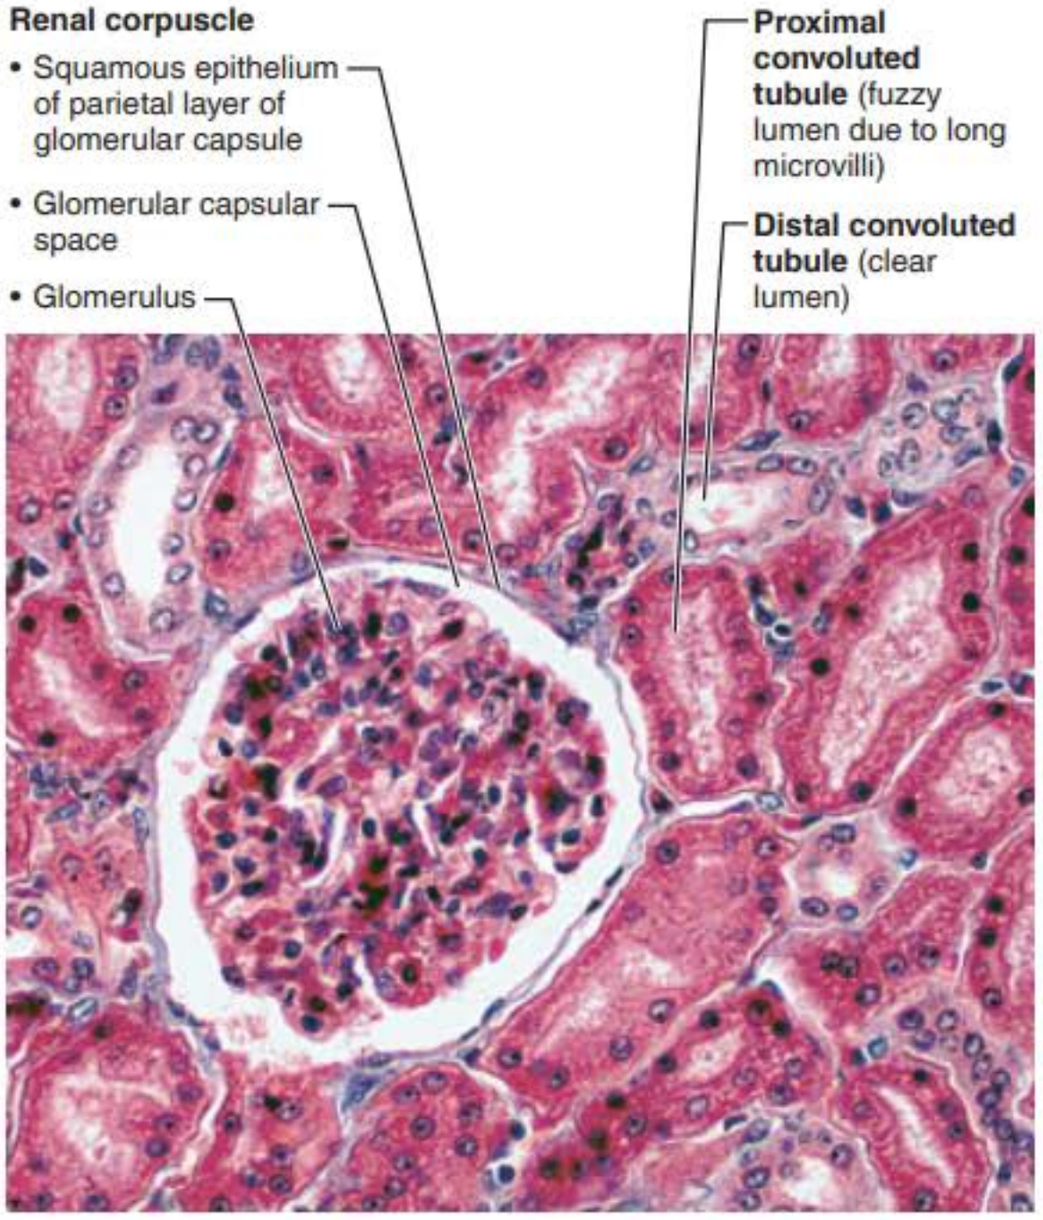

Figure 25.7 Renal cortical tissue. Photomicrograph (415×).

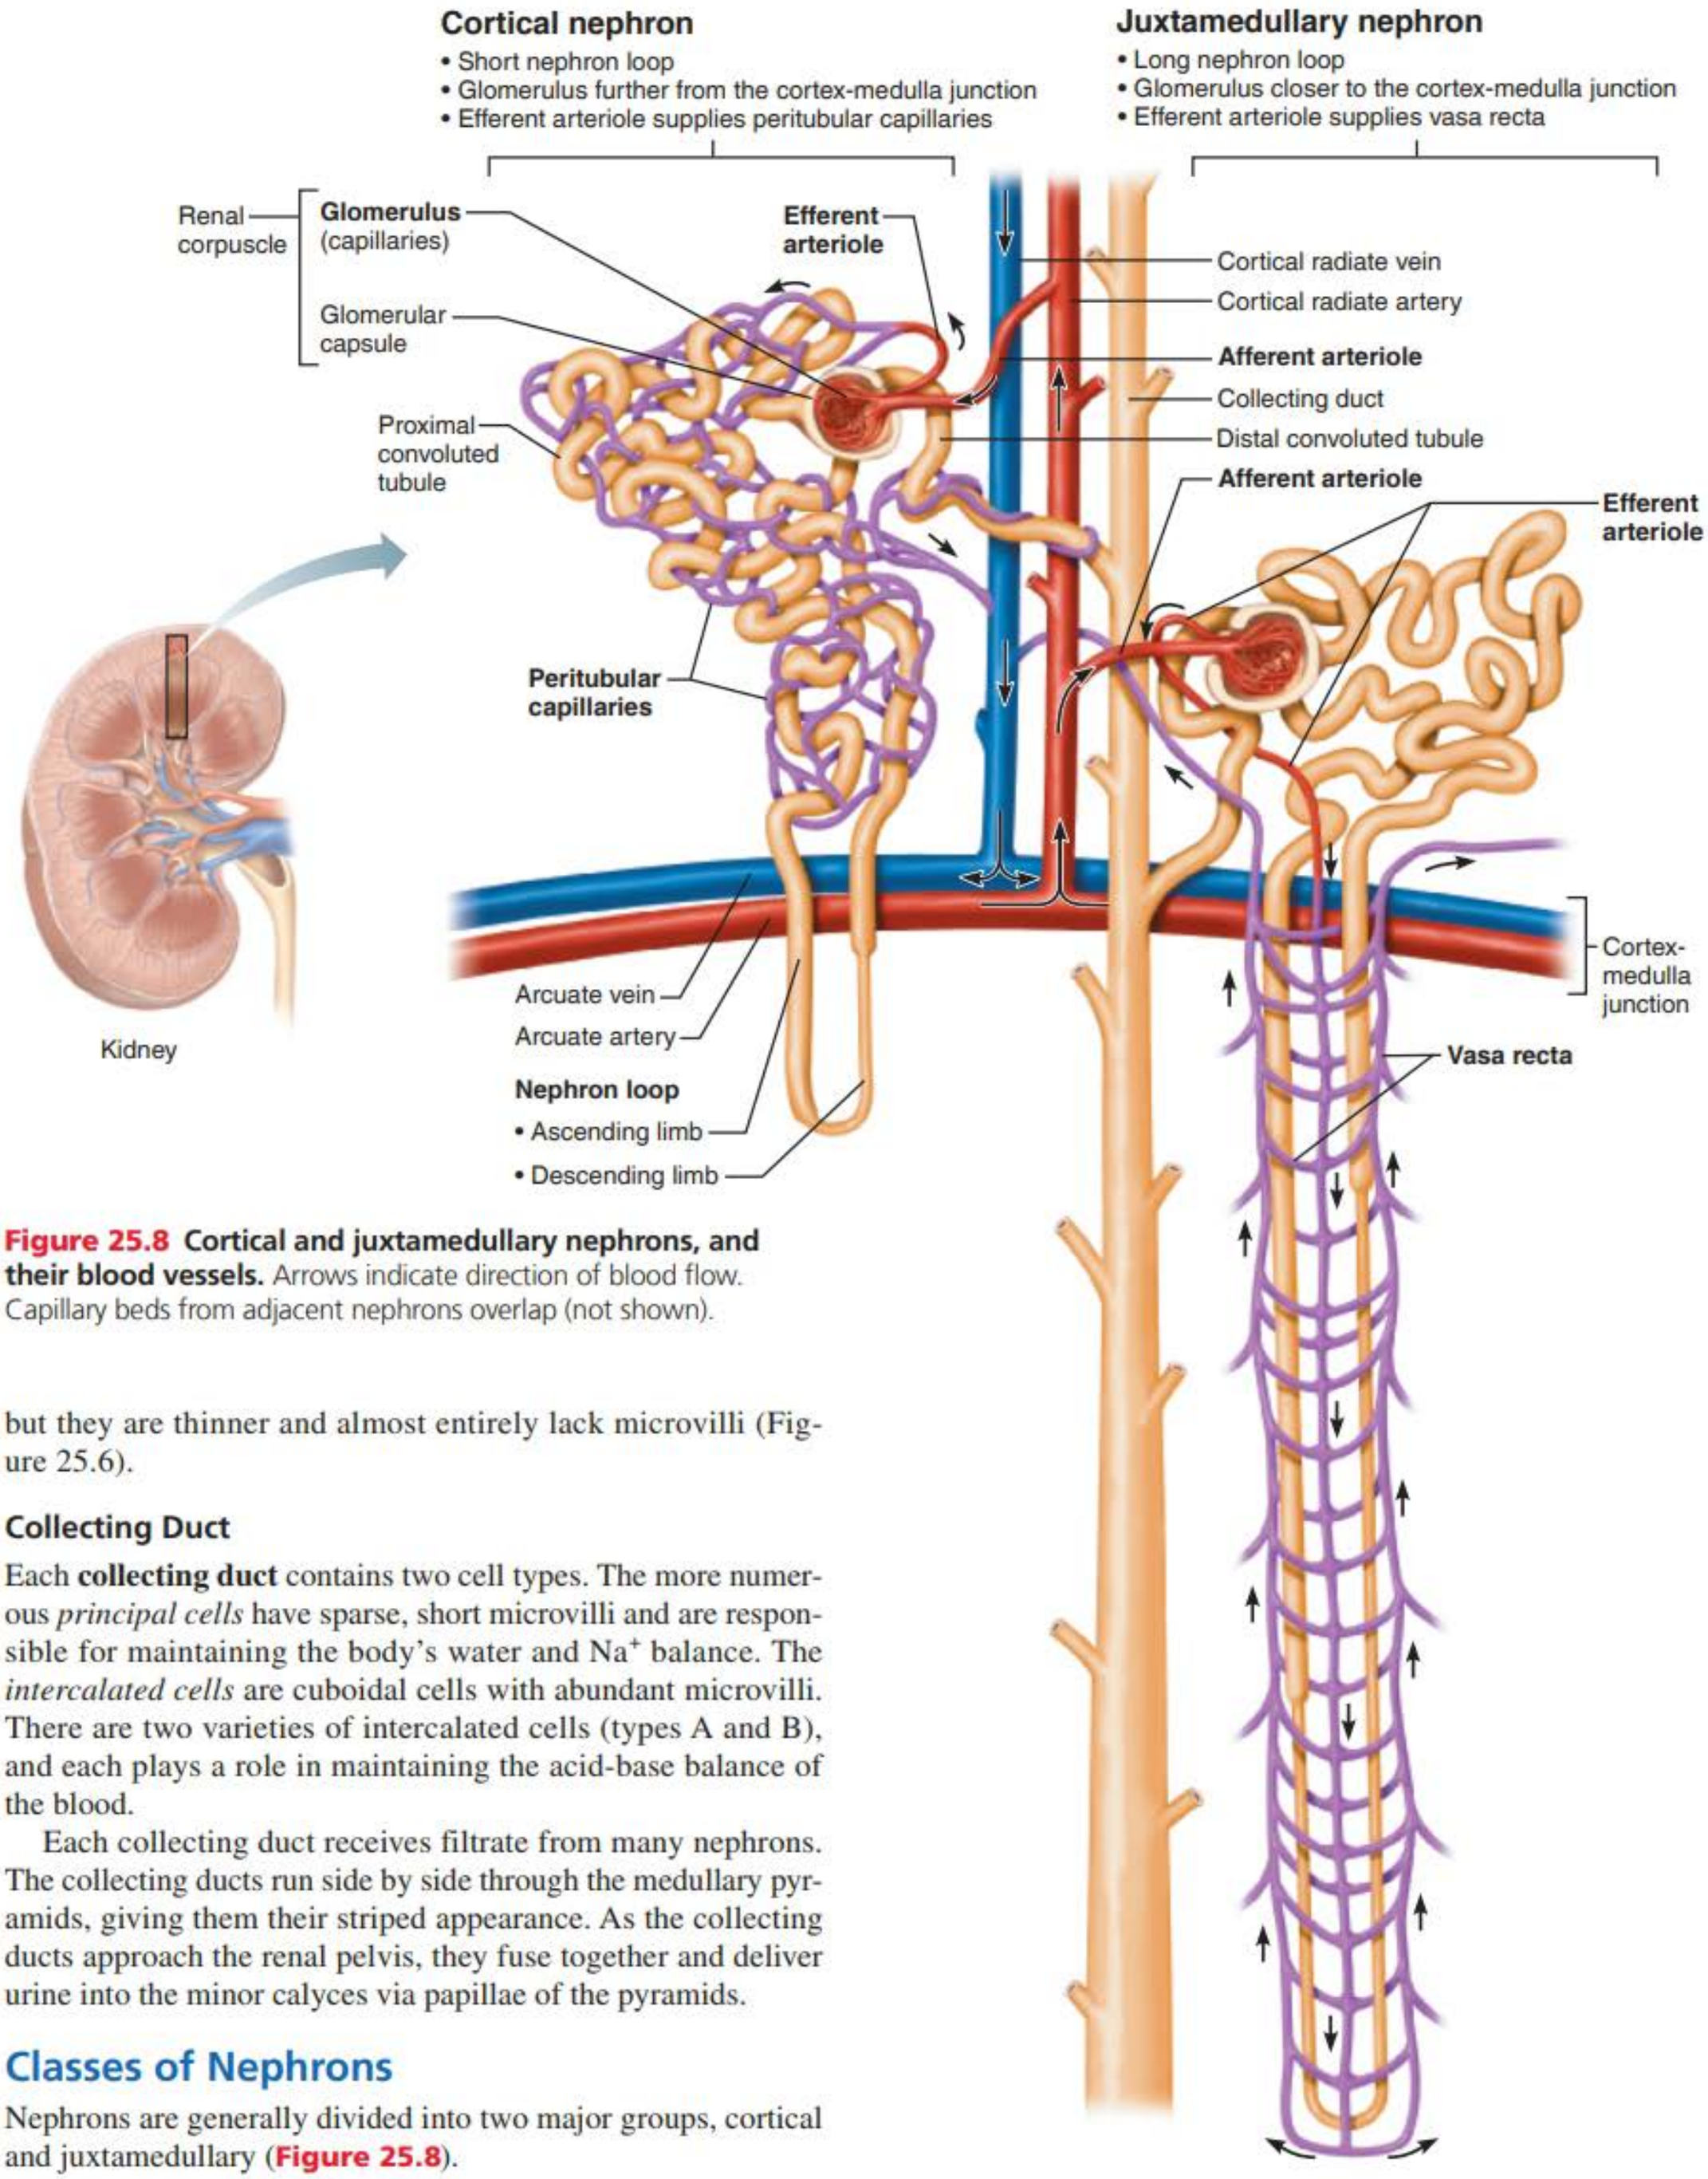

Figure 25.8 Cortical and juxtamedullary nephrons, and their blood vessels. Arrows indicate direction of blood flow. Capillary beds from adjacent nephrons overlap (not shown).

but they are thinner and almost entirely lack microvilli (Figure 25.6).

Collecting Duct

Each **collecting duct** contains two cell types. The more numerous *principal cells* have sparse, short microvilli and are responsible for maintaining the body's water and Na^+ balance. The *intercalated cells* are cuboidal cells with abundant microvilli. There are two varieties of intercalated cells (types A and B), and each plays a role in maintaining the acid-base balance of the blood.

Each collecting duct receives filtrate from many nephrons. The collecting ducts run side by side through the medullary pyramids, giving them their striped appearance. As the collecting ducts approach the renal pelvis, they fuse together and deliver urine into the minor calyces via papillae of the pyramids.

Classes of Nephrons

Nephrons are generally divided into two major groups, cortical and juxtamedullary (**Figure 25.8**).

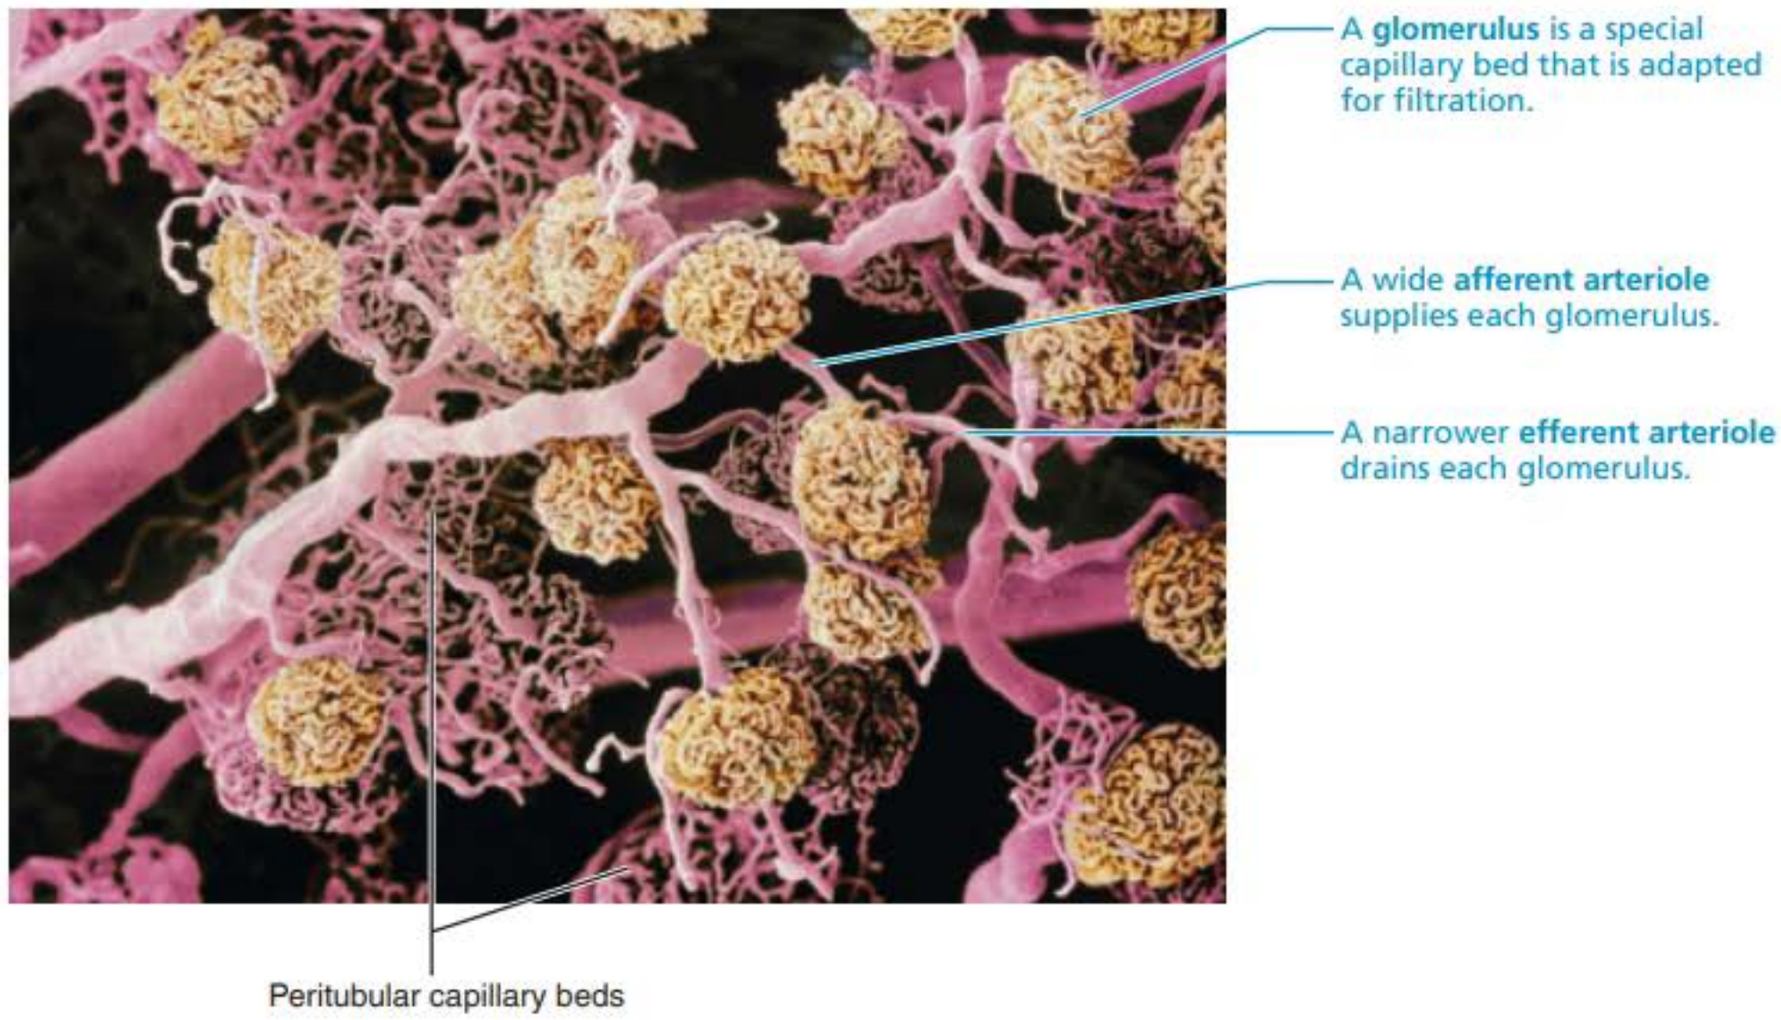

Figure 25.9 Blood vessels of the renal cortex. Scanning electron micrograph of a cast of blood vessels associated with nephrons (125×). View looking down onto the cortex.

- **Cortical nephrons** account for 85% of the nephrons in the kidneys. Except for small parts of their nephron loops that dip into the outer medulla, they are located entirely in the cortex.
- **Juxtamedullary nephrons** (juks″tah-mĕ′dul-ah-re) originate close to (*juxta* = near to) the cortex-medulla junction, and they play an important role in the kidneys' ability to produce urine that is concentrated (which conserves water). They have long nephron loops that deeply invade the medulla, and their ascending limbs have both thin and thick segments.

25

Nephron Capillary Beds

The renal tubule of every nephron is closely associated with two capillary beds. The first capillary bed (the *glomerulus*) produces the filtrate. The second (a combination of *peritubular capillaries* and *vasa recta*) reclaims most of that filtrate.

Glomerulus

The glomerulus, in which the capillaries run in parallel, is specialized for filtration. It differs from all other capillary beds in the body in that it is both fed and drained by arterioles—the **afferent arteriole** and **efferent arteriole**, respectively (Figure 25.8 and **Figure 25.9**). This arrangement maintains the high pressure in the glomerulus that is needed for filtration, a process we discuss in Module 25.4. Filtration produces a large amount of fluid, most (99%) of which is reabsorbed by the renal tubule cells and returned to the blood in the peritubular capillary beds.

The afferent arterioles arise from the *cortical radiate arteries* that run through the renal cortex. The efferent arterioles feed into either the peritubular capillaries or the vasa recta.

Peritubular Capillaries

The **peritubular capillaries** cling closely to adjacent renal tubules and empty into nearby venules. Because they arise from the efferent arterioles (which have high resistance), they only experience low pressure. As a result, these low-pressure, porous capillaries readily absorb solutes and water from the tubule cells as these substances are reclaimed from the filtrate. Renal tubules are closely packed together, so the peritubular capillaries of each nephron absorb substances from several adjacent nephrons.

Vasa Recta

Notice in Figure 25.8 that the efferent arterioles serving the juxtamedullary nephrons tend *not* to break up into meandering peritubular capillaries. Instead they form bundles of long straight vessels called **vasa recta** (va′sah rek′tah; "straight vessels") that extend deep into the medulla paralleling the longest nephron loops. Like all blood vessels, the vasa recta supply oxygen and nutrients to the tissue through which they pass (the renal medulla). However, the thin-walled vasa recta also play an important role in forming concentrated urine, as we will describe shortly.

Juxtaglomerular Complex (JGC)

Each nephron has a **juxtaglomerular complex (JGC)** (juks″-tah-glo-mer′u-lar), a region where the most distal portion of the ascending limb of the nephron loop lies against the afferent arteriole feeding the glomerulus (and sometimes the efferent arteriole) (**Figure 25.10**). Both the ascending limb and the afferent arteriole are modified at the point of contact.

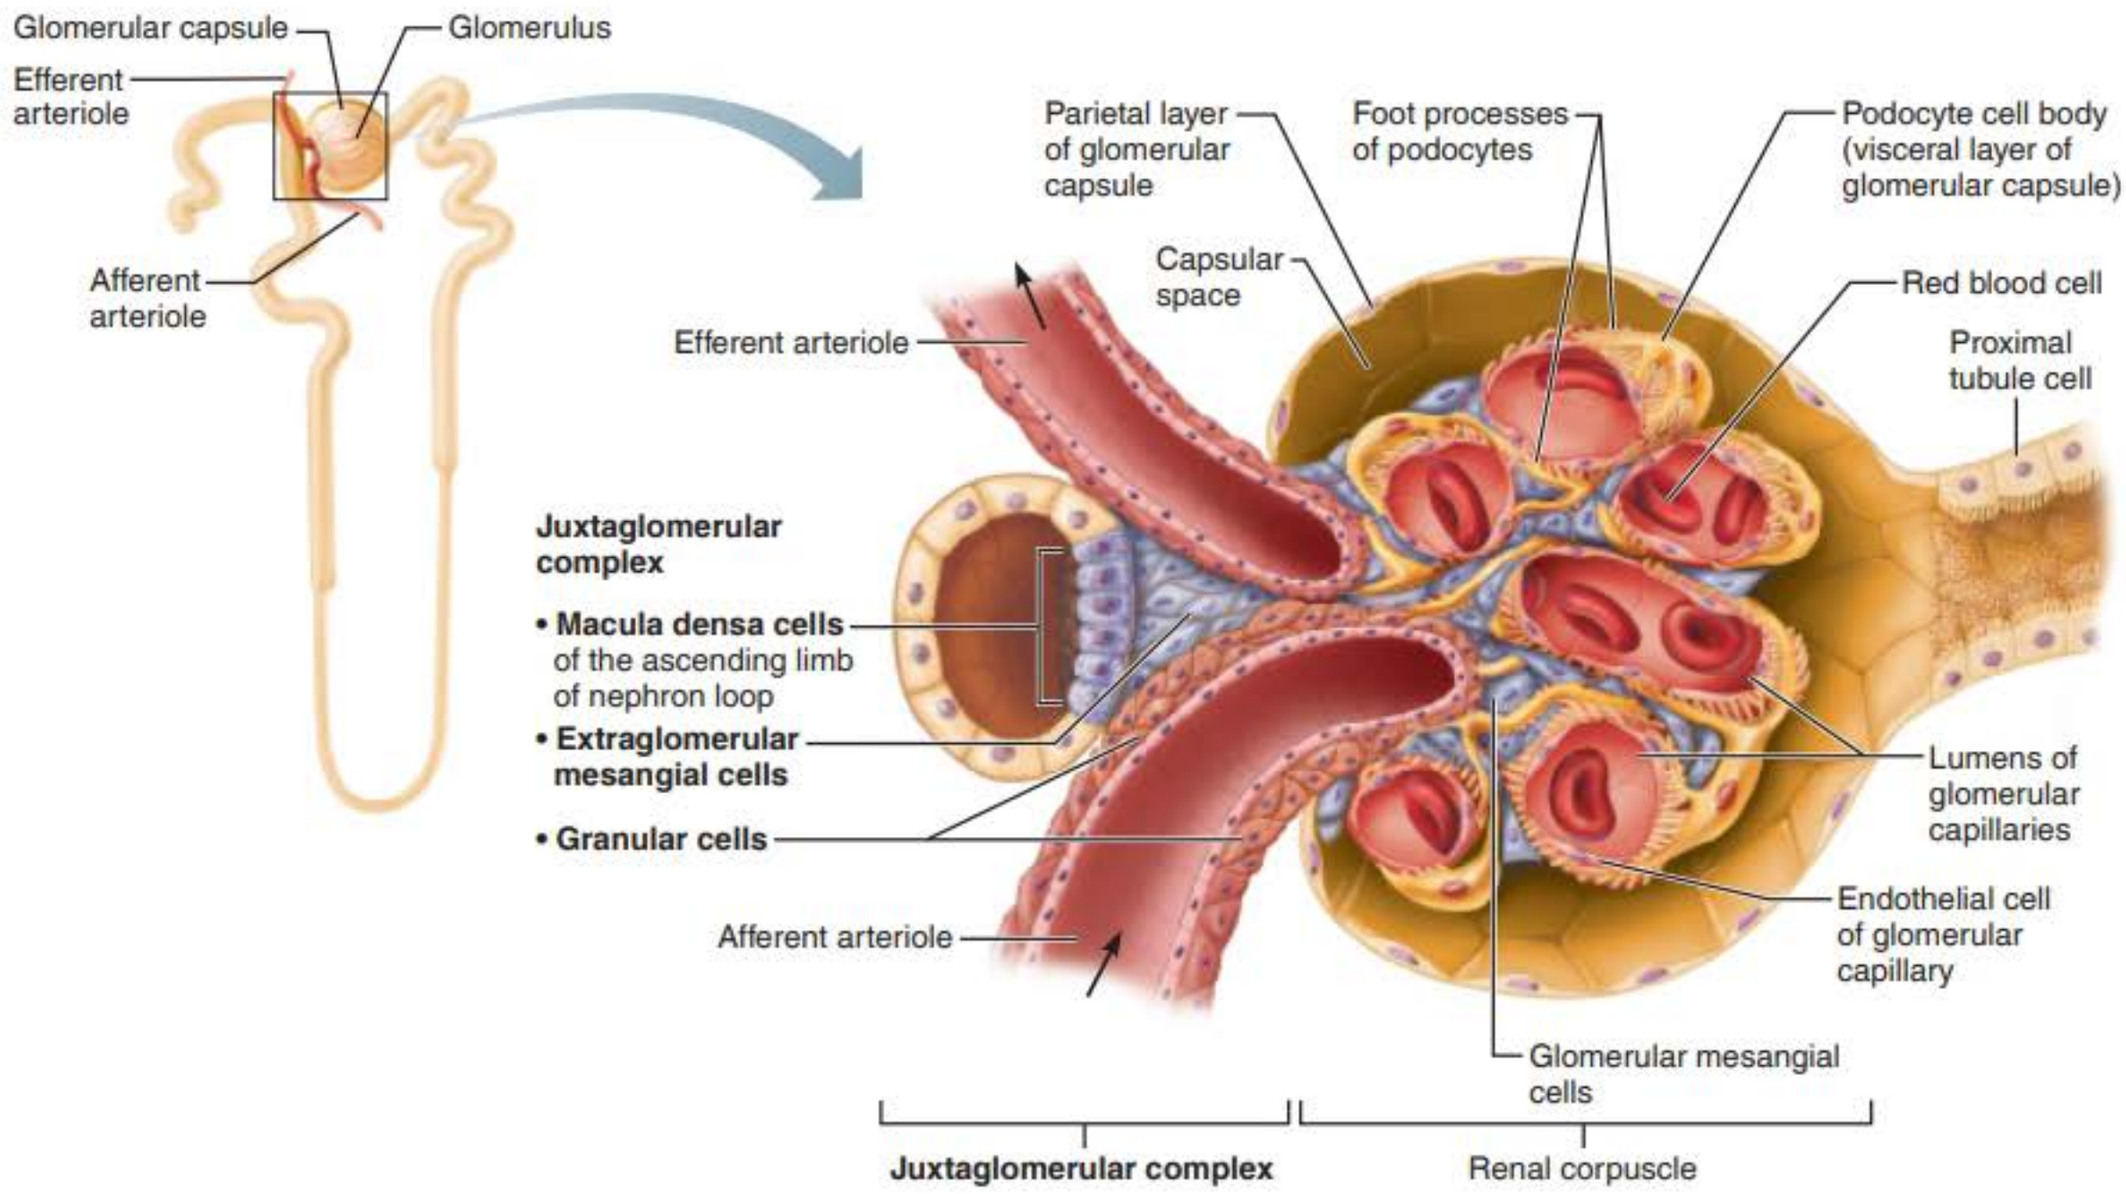

Figure 25.10 Juxtaglomerular complex (JGC) of a nephron. Mesangial cells that surround the glomerular capillaries (glomerular mesangial cells) are not part of the JGC.

The JGC includes three populations of cells that help regulate the rate of filtrate formation and systemic blood pressure.

- The **macula densa** (mak′u-lah den′sah; "dense spot") is a group of tall, closely packed cells in the ascending limb of the nephron loop that lies adjacent to the granular cells (Figure 25.10). The macula densa cells are chemoreceptors that monitor the NaCl content of the filtrate entering the distal convoluted tubule.
- **Granular cells** [also called *juxtaglomerular (JG) cells*] are in the arteriolar walls. They are enlarged smooth muscle cells with prominent secretory granules containing the enzyme *renin* (see p. 989). Granular cells act as mechanoreceptors that sense the blood pressure in the afferent arteriole.
- *Extraglomerular mesangial cells* lie between the arteriole and tubule cells, and are interconnected by gap junctions. These cells may pass regulatory signals between macula densa and granular cells.

We discuss the physiological role of the JGC on pp. 988–989.

Check Your Understanding

4. Name the tubular components of a nephron in the order that filtrate passes through them.
5. What are the structural differences between juxtamedullary and cortical nephrons, and between their capillary beds?
6. What type of capillaries are the glomerular capillaries? What is their function?
7. For the juxtamedullary nephron and collecting duct illustrated below, name each of the structures labeled a–f.

For answers, see Answers Appendix.

25.3 Overview: Filtration, absorption, and secretion are the key processes of urine formation

Learning Outcome

▶ **List and define the three major renal processes.**

If you had to design a system to chemically balance and cleanse the blood, how would you do it? Conceptually, it's really very

simple. The body solves this problem in the following way. First, it "dumps" cell- and protein-free filtered blood into a separate "waste container." From this container, it reclaims everything the body needs to keep (which is almost everything in the container). Finally, the kidney selectively adds specific things to the container, fine-tuning the body's chemical balance. Anything left in the container becomes urine. This is basically how nephrons work.

Urine formation and the adjustment of blood composition involve three processes (**Figure 25.11**):

1. **Glomerular filtration.** *Glomerular filtration* ("dumping filtrate into the waste container") takes place in the renal corpuscle and produces a cell- and protein-free filtrate.
2. **Tubular reabsorption.** *Tubular reabsorption* ("reclaiming what the body needs to keep") is the process of selectively moving substances from the filtrate back into the blood. It takes place in the renal tubules and collecting ducts. Tubular reabsorption reclaims almost everything filtered—all of the glucose and amino acids, and some 99% of the water, salt, and other components. Anything that is *not* reabsorbed becomes urine.
3. **Tubular secretion.** *Tubular secretion* ("selectively adding to the waste container") is the process of selectively moving substances from the blood into the filtrate. Like tubular reabsorption, it occurs along the length of the tubule and collecting duct.

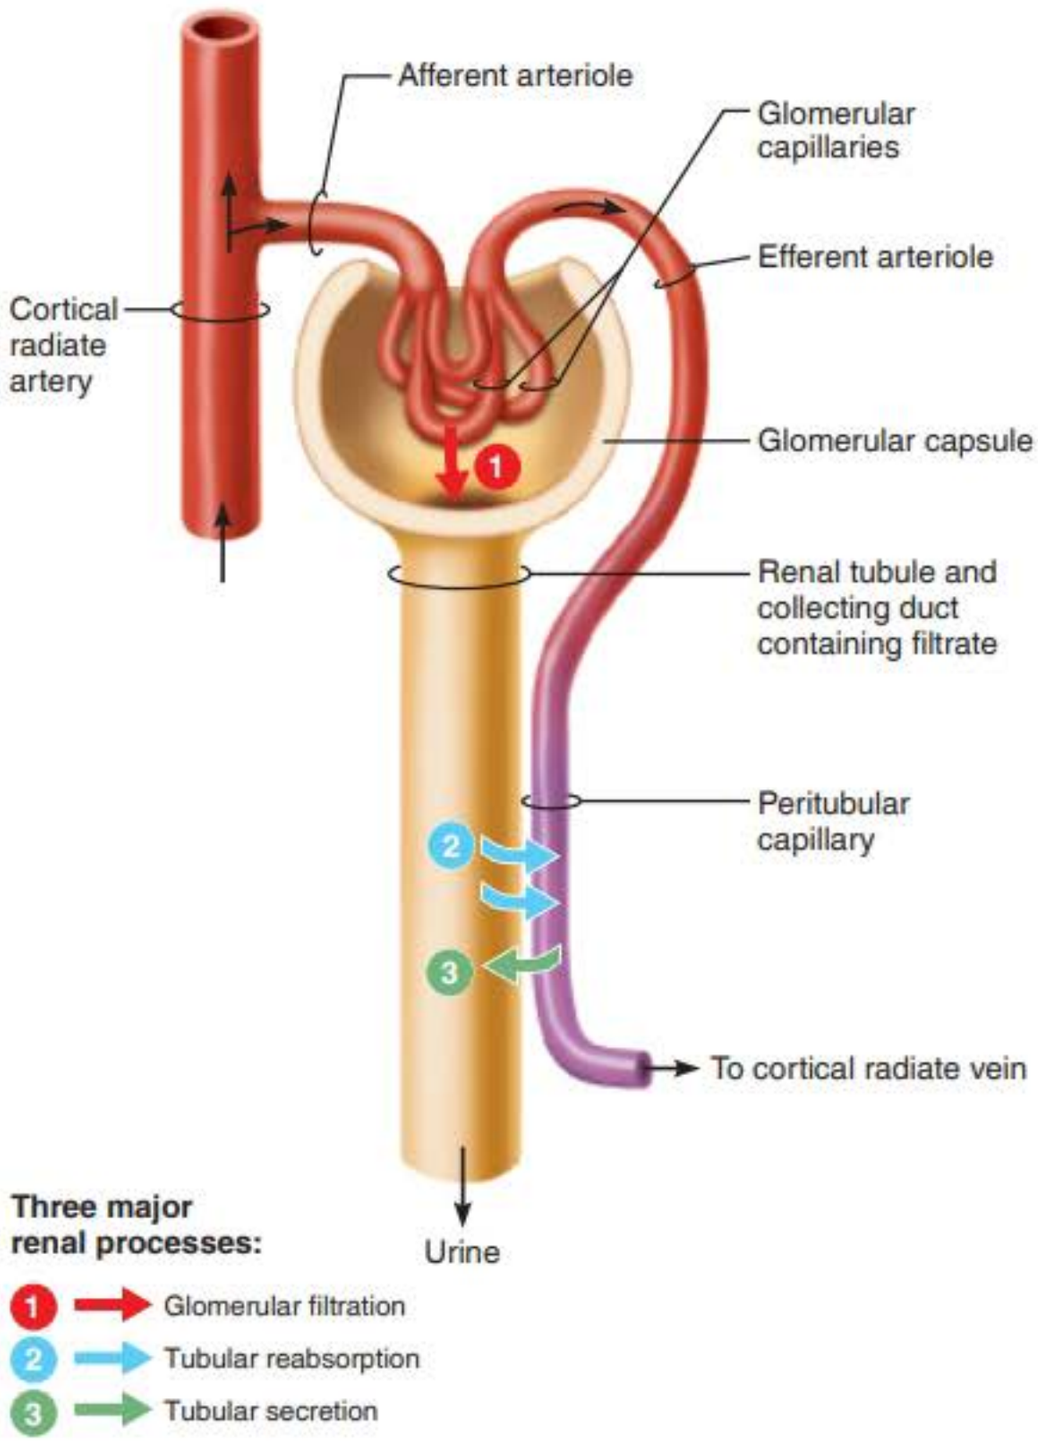

Figure 25.11 The three major renal processes. A single nephron is shown schematically, as if uncoiled. Each kidney actually has more than a million nephrons acting in parallel.

The kidneys process an enormous volume of blood each day. Of the approximately 1200 ml of blood that passes through the glomeruli each minute, some 650 ml is plasma, and about one-fifth of this (120–125 ml) is forced into the glomerular capsules as filtrate. This is equivalent to filtering your entire plasma volume more than 60 times each day! Considering the magnitude of their task, it is not surprising that the kidneys (which account for only 1% of body weight) consume 20–25% of all oxygen used by the body at rest.

Filtrate and urine are quite different. Filtrate contains everything found in blood plasma except proteins. **Urine** contains unneeded substances such as excess salts and metabolic wastes. The kidneys process about 180 L (47 gallons!) of blood-derived fluid daily. Of this amount, less than 1% (1.5 L) typically leaves the body as urine; the rest returns to the circulation.

Check Your Understanding

8. MAKE CONNECTIONS In the kidneys, tubular secretion of a substance usually results in its excretion as well. Explain the difference between excretion (defined in Chapter 1) and tubular secretion.

For answers, see Answers Appendix.

25.4 Urine formation, step 1: The glomeruli make filtrate

Learning Outcomes

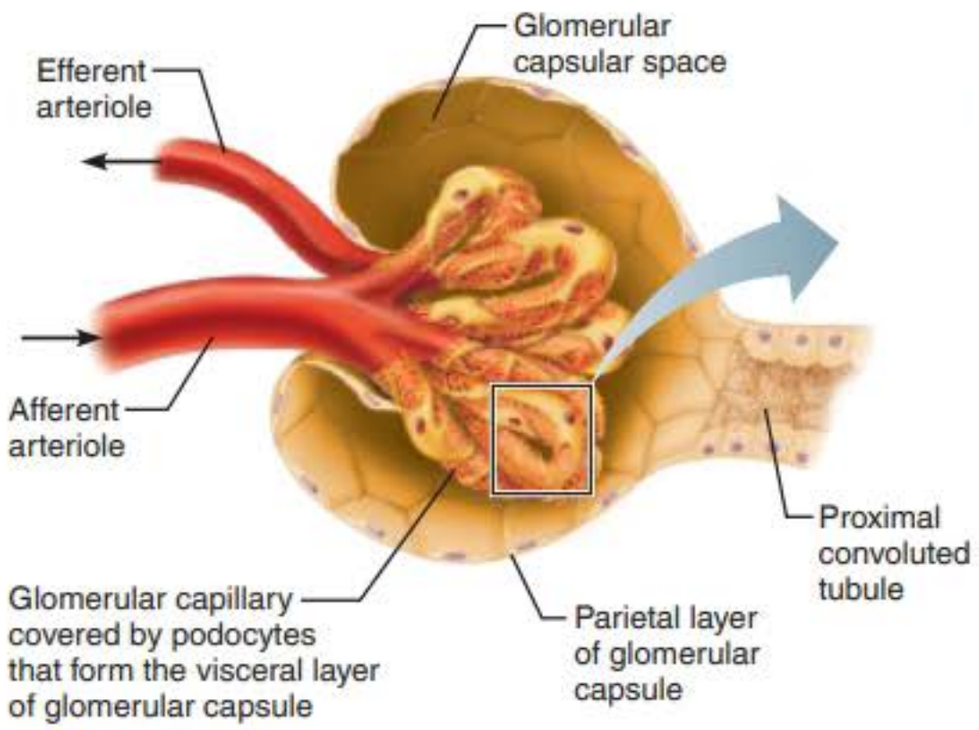
- **Describe the forces (pressures) that promote or counteract glomerular filtration.**
- **Compare the intrinsic and extrinsic controls of the glomerular filtration rate.**

Glomerular filtration is a passive process in which hydrostatic pressure forces fluids and solutes through a membrane. The glomeruli can be viewed as simple mechanical filters because filtrate formation does not directly consume metabolic energy. Let's first look at the structure of the filtration membrane and then see how it works.

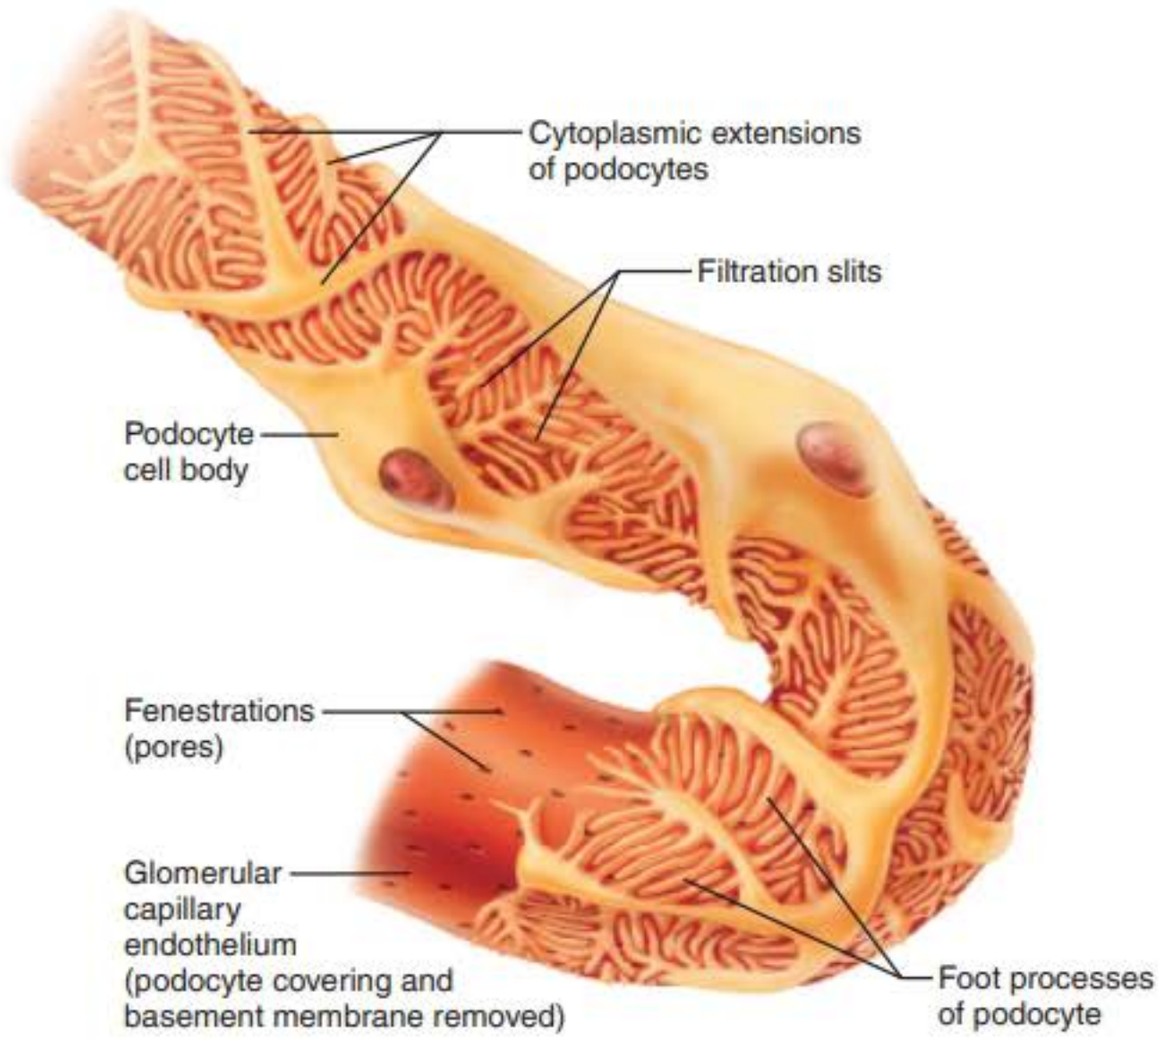
The Filtration Membrane

The **filtration membrane** lies between the blood and the interior of the glomerular capsule. It is a porous membrane that allows free passage of water and solutes smaller than plasma proteins. As **Figure 25.12d** shows, its three layers are:

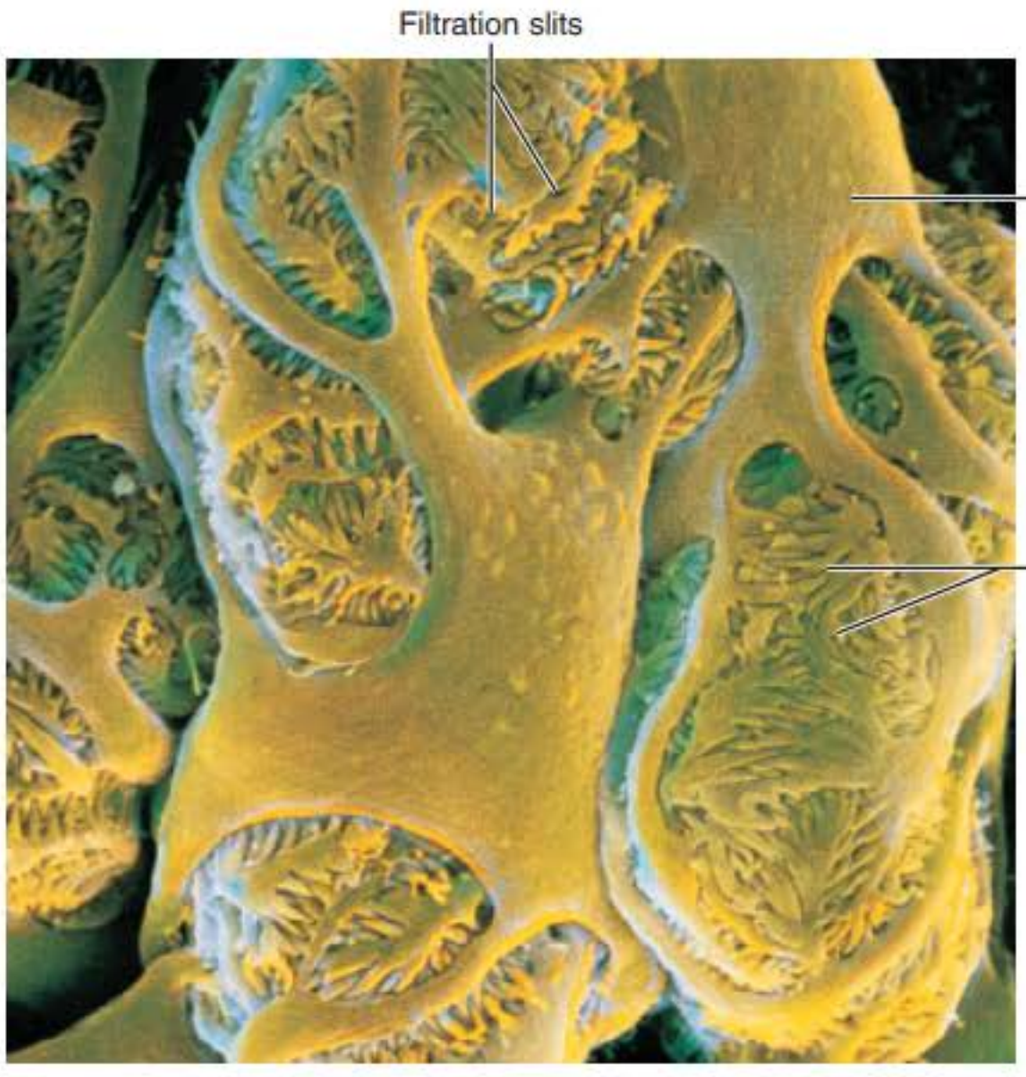
- **Fenestrated endothelium of the glomerular capillaries.** The fenestrations (capillary pores) allow all blood components except blood cells to pass through.
- **Basement membrane.** The basement membrane lies between the other two layers and is composed of their fused basal laminae (◀ p. 118). It forms a physical barrier that blocks all



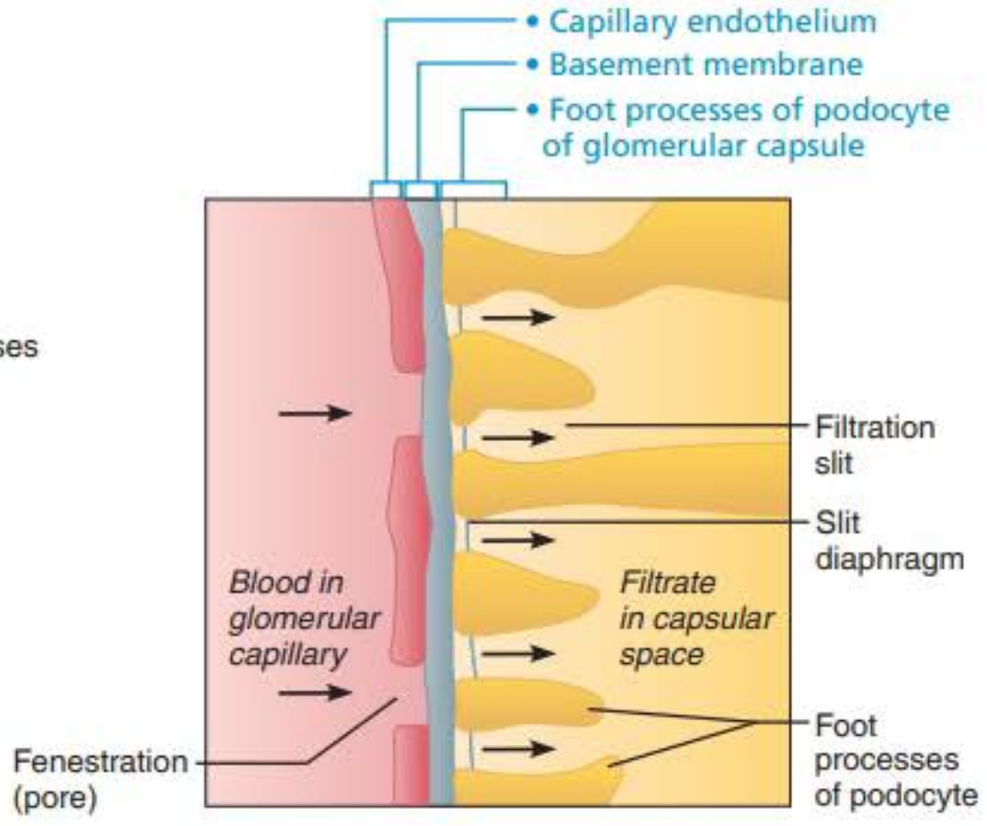
(a) Renal corpuscle



(b) Glomerular capillary surrounded by podocytes



(c) Filtration slits between the podocyte foot processes



(d) Filtration membrane

Figure 25.12 The filtration membrane. (a) The renal corpuscle consists of a glomerulus surrounded by a glomerular capsule. **(b)** Enlargement of a glomerular capillary covered by the visceral (inner) layer of the glomerular capsule consisting of podocytes. Some podocytes and the basement membrane have been removed to show the fenestrations (pores) in the underlying capillary wall. **(c)** Scanning electron micrograph of the visceral layer (6000×). **(d)** Diagram of a section through the filtration membrane showing its three layers.

but the smallest proteins while still permitting most other solutes to pass. The glycoproteins of the gel-like basement membrane give it a negative charge. As a result, the basement membrane electrically repels many negatively charged macromolecular anions such as plasma proteins, reinforcing the blockade based on molecular size.

- **Foot processes of podocytes of the glomerular capsule.** The visceral layer of the glomerular capsule is made of podocytes that have filtration slits between their foot processes. If any macromolecules manage to make it through the basement membrane, *slit diaphragms*—thin membranes that extend across the filtration slits—prevent almost all of them from traveling farther.

Macromolecules that get "hung up" in the filtration membrane are engulfed by specialized pericytes (◀ p. 710) called *glomerular mesangial cells* (Figure 25.10).

Molecules smaller than 3 nm in diameter—such as water, glucose, amino acids, and nitrogenous wastes—pass freely from the blood into the glomerular capsule. As a result, these substances usually have similar concentrations in the blood and the glomerular filtrate. Larger molecules pass with greater difficulty, and those larger than 5 nm are generally barred from entering the tubule. Keeping the plasma proteins *in* the capillaries maintains the colloid osmotic (oncotic) pressure (◀ p. 731) of the glomerular blood, preventing the loss of all its water to the capsular space. The presence of proteins or blood cells in the urine usually indicates a problem with the filtration membrane.

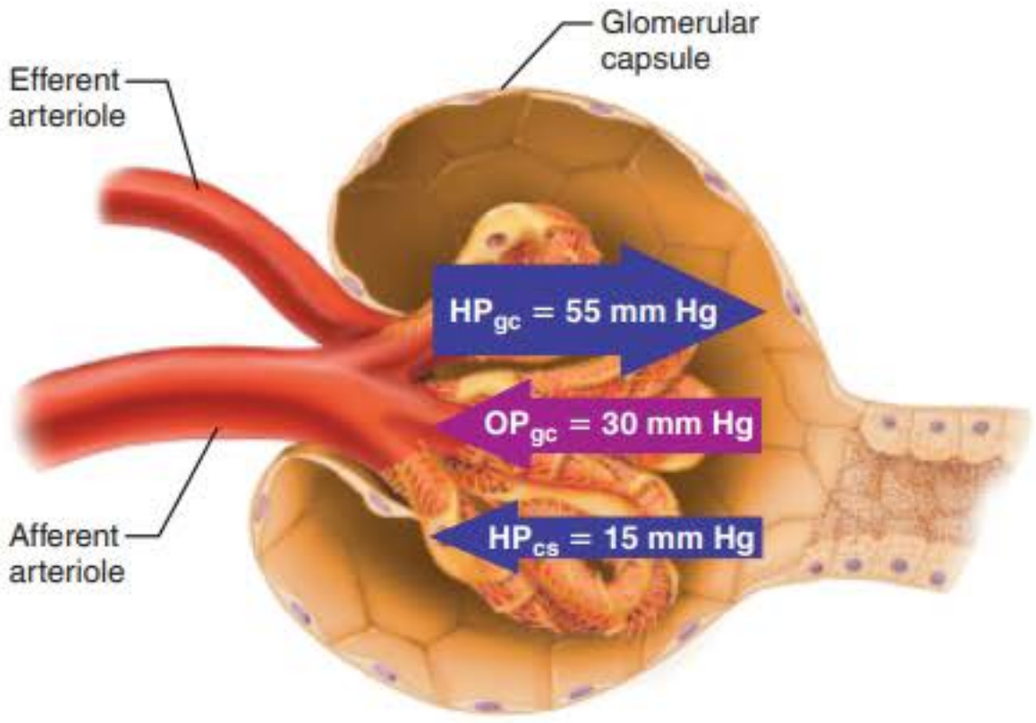
Pressures That Affect Filtration

The principles that govern filtration from the glomerulus are the same as those that govern filtration from any capillary bed. *Focus on Bulk Flow across Capillary Walls* (◀ Focus Figure 19.1, pp. 732–733) shows filtration in normal capillary beds. **Figure 25.13** applies these principles to the glomerular capillaries of the nephron.

Outward Pressures

Outward pressures promote filtrate formation.

- The **hydrostatic pressure in glomerular capillaries (HP_{gc})** is essentially glomerular blood pressure. It is the chief force pushing water and solutes out of the blood and across the filtration membrane. The blood pressure in the glomerulus is extraordinarily high (approximately 55 mm Hg compared to an average of 26 mm Hg or so in other capillary beds) and it remains high across the entire capillary bed. This is because the glomerular capillaries are drained by a high-resistance efferent arteriole whose diameter is smaller than the afferent arteriole that feeds them. As a result, filtration occurs along the entire length of each glomerular capillary and reabsorption does not occur as it would in other capillary beds.
- Theoretically, the *colloid osmotic pressure in the capsular space* of the glomerular capsule would "pull" filtrate into the tubule. However, this pressure is essentially zero because virtually no proteins enter the capsule, so we will not consider it further.



NFP = Net filtration pressure
= outward pressures − inward pressures
= $(HP_{gc}) - (HP_{cs} + OP_{gc})$
= (55) − (15 + 30)
= 10 mm Hg

Figure 25.13 Forces determining net filtration pressure (NFP). The pressure values cited in the diagram are approximate. (HP_{gc} = hydrostatic pressure in glomerular capillaries, OP_{gc} = osmotic pressure in glomerular capillaries, HP_{cs} = hydrostatic pressure in capsular space)

Inward Pressures

Two inward forces inhibit filtrate formation by opposing HP_{gc}.

- The **hydrostatic pressure in the capsular space (HP_{cs})** is the pressure exerted by filtrate in the glomerular capsule. HP_{cs} is much higher than hydrostatic pressure surrounding most capillaries because filtrate is confined in a small space with a narrow outlet.
- The **colloid osmotic pressure in glomerular capillaries (OP_{gc})** is the pressure exerted by the proteins in the blood that "sucks" water into the capillary.

As shown in Figure 25.13, the above pressures determine the **net filtration pressure (NFP)**. NFP largely determines the glomerular filtration rate, which we consider next.

Glomerular Filtration Rate (GFR)

The **glomerular filtration rate** is the volume of filtrate formed each minute by the combined activity of all 2 million glomeruli of the kidneys. GFR is directly proportional to each of the following factors:

- **Net filtration pressure.** NFP is the main controllable factor. Of the pressures determining NFP, the most important is hydrostatic pressure in the glomerulus. This pressure can be controlled by changing the diameter of the afferent (and sometimes the efferent) arterioles, as we will see shortly.
- **Total surface area available for filtration.** Glomerular capillaries have a huge surface area (collectively equal to the

surface area of the skin). Glomerular mesangial cells surrounding these capillaries can fine-tune GFR by contracting to adjust the total surface area available for filtration.

- **Filtration membrane permeability.** Glomerular capillaries are thousands of times more permeable than other capillaries because of their fenestrations.

The huge surface area and high permeability of the filtration membrane explain how the relatively modest 10 mm Hg NFP can produce huge amounts of filtrate. Furthermore, the NFP in the glomerulus favors filtration over the entire length of the capillary, unlike other capillary beds where filtration occurs only at the arteriolar end and reabsorption occurs at the venous end. As a result, the adult kidneys produce about 180 L of filtrate daily, in contrast to the 2 to 4 L formed daily by all other capillary beds combined. This 180 L of filtrate per day translates to the normal GFR of 120–125 ml/min.

Complete an interactive tutorial: MasteringA&P® > Study Area > Interactive Physiology

Regulation of Glomerular Filtration

GFR is tightly regulated to serve two crucial and sometimes opposing needs. The kidneys need a relatively constant GFR to make filtrate and do their job of maintaining extracellular homeostasis. On the other hand, the body as a whole needs a constant blood pressure, and this is closely tied to GFR in the following way: Assuming nothing else changes, an increase in GFR increases urine output, which reduces blood volume and blood pressure. The opposite holds true for a decrease in GFR.

Two types of controls serve these two different needs. *Intrinsic controls* (*renal autoregulation*) act locally within the kidney to maintain GFR, while *extrinsic controls* by the nervous and endocrine systems maintain blood pressure. In extreme changes of blood pressure (mean arterial pressure less than 80 or greater than 180 mm Hg), extrinsic controls take precedence over intrinsic controls in an effort to prevent damage to the brain and other crucial organs. These controls are summarized in **Table 25.1** and explained in detail on the next two pages.

GFR can be controlled by changing a single variable—glomerular hydrostatic pressure. All major control mechanisms act primarily to change this one variable. If the glomerular hydrostatic pressure rises, NFP rises and so does GFR. If the glomerular hydrostatic pressure falls by as little as 18%, GFR drops to zero. Clearly hydrostatic pressure in the glomerulus must be tightly controlled. Let's see how the intrinsic and extrinsic mechanisms accomplish this feat.

Intrinsic Controls: Renal Autoregulation

By adjusting its own resistance to blood flow, a process called **renal autoregulation**, the kidney can maintain a nearly constant GFR despite fluctuations in systemic arterial blood pressure. Renal autoregulation uses two different mechanisms: (1) a *myogenic*

Table 25.1 Summary of Regulation of GFR

	INTRINSIC CONTROL (RENAL AUTOREGULATION)	EXTRINSIC CONTROL
Purpose	Maintain GFR in spite of changes in blood pressure (so kidneys can "do their job")	Maintain systemic blood pressure
Mechanisms	• Myogenic • Tubuloglomerular feedback	• Hormonal (renin-angiotensin-aldosterone) • Neural (baroreceptor reflex via sympathetic nervous system)
Operating conditions	Mean arterial pressure between 80 and 180 mm Hg	Mean arterial pressure far outside of the normal range (<80 or >180 mm Hg)

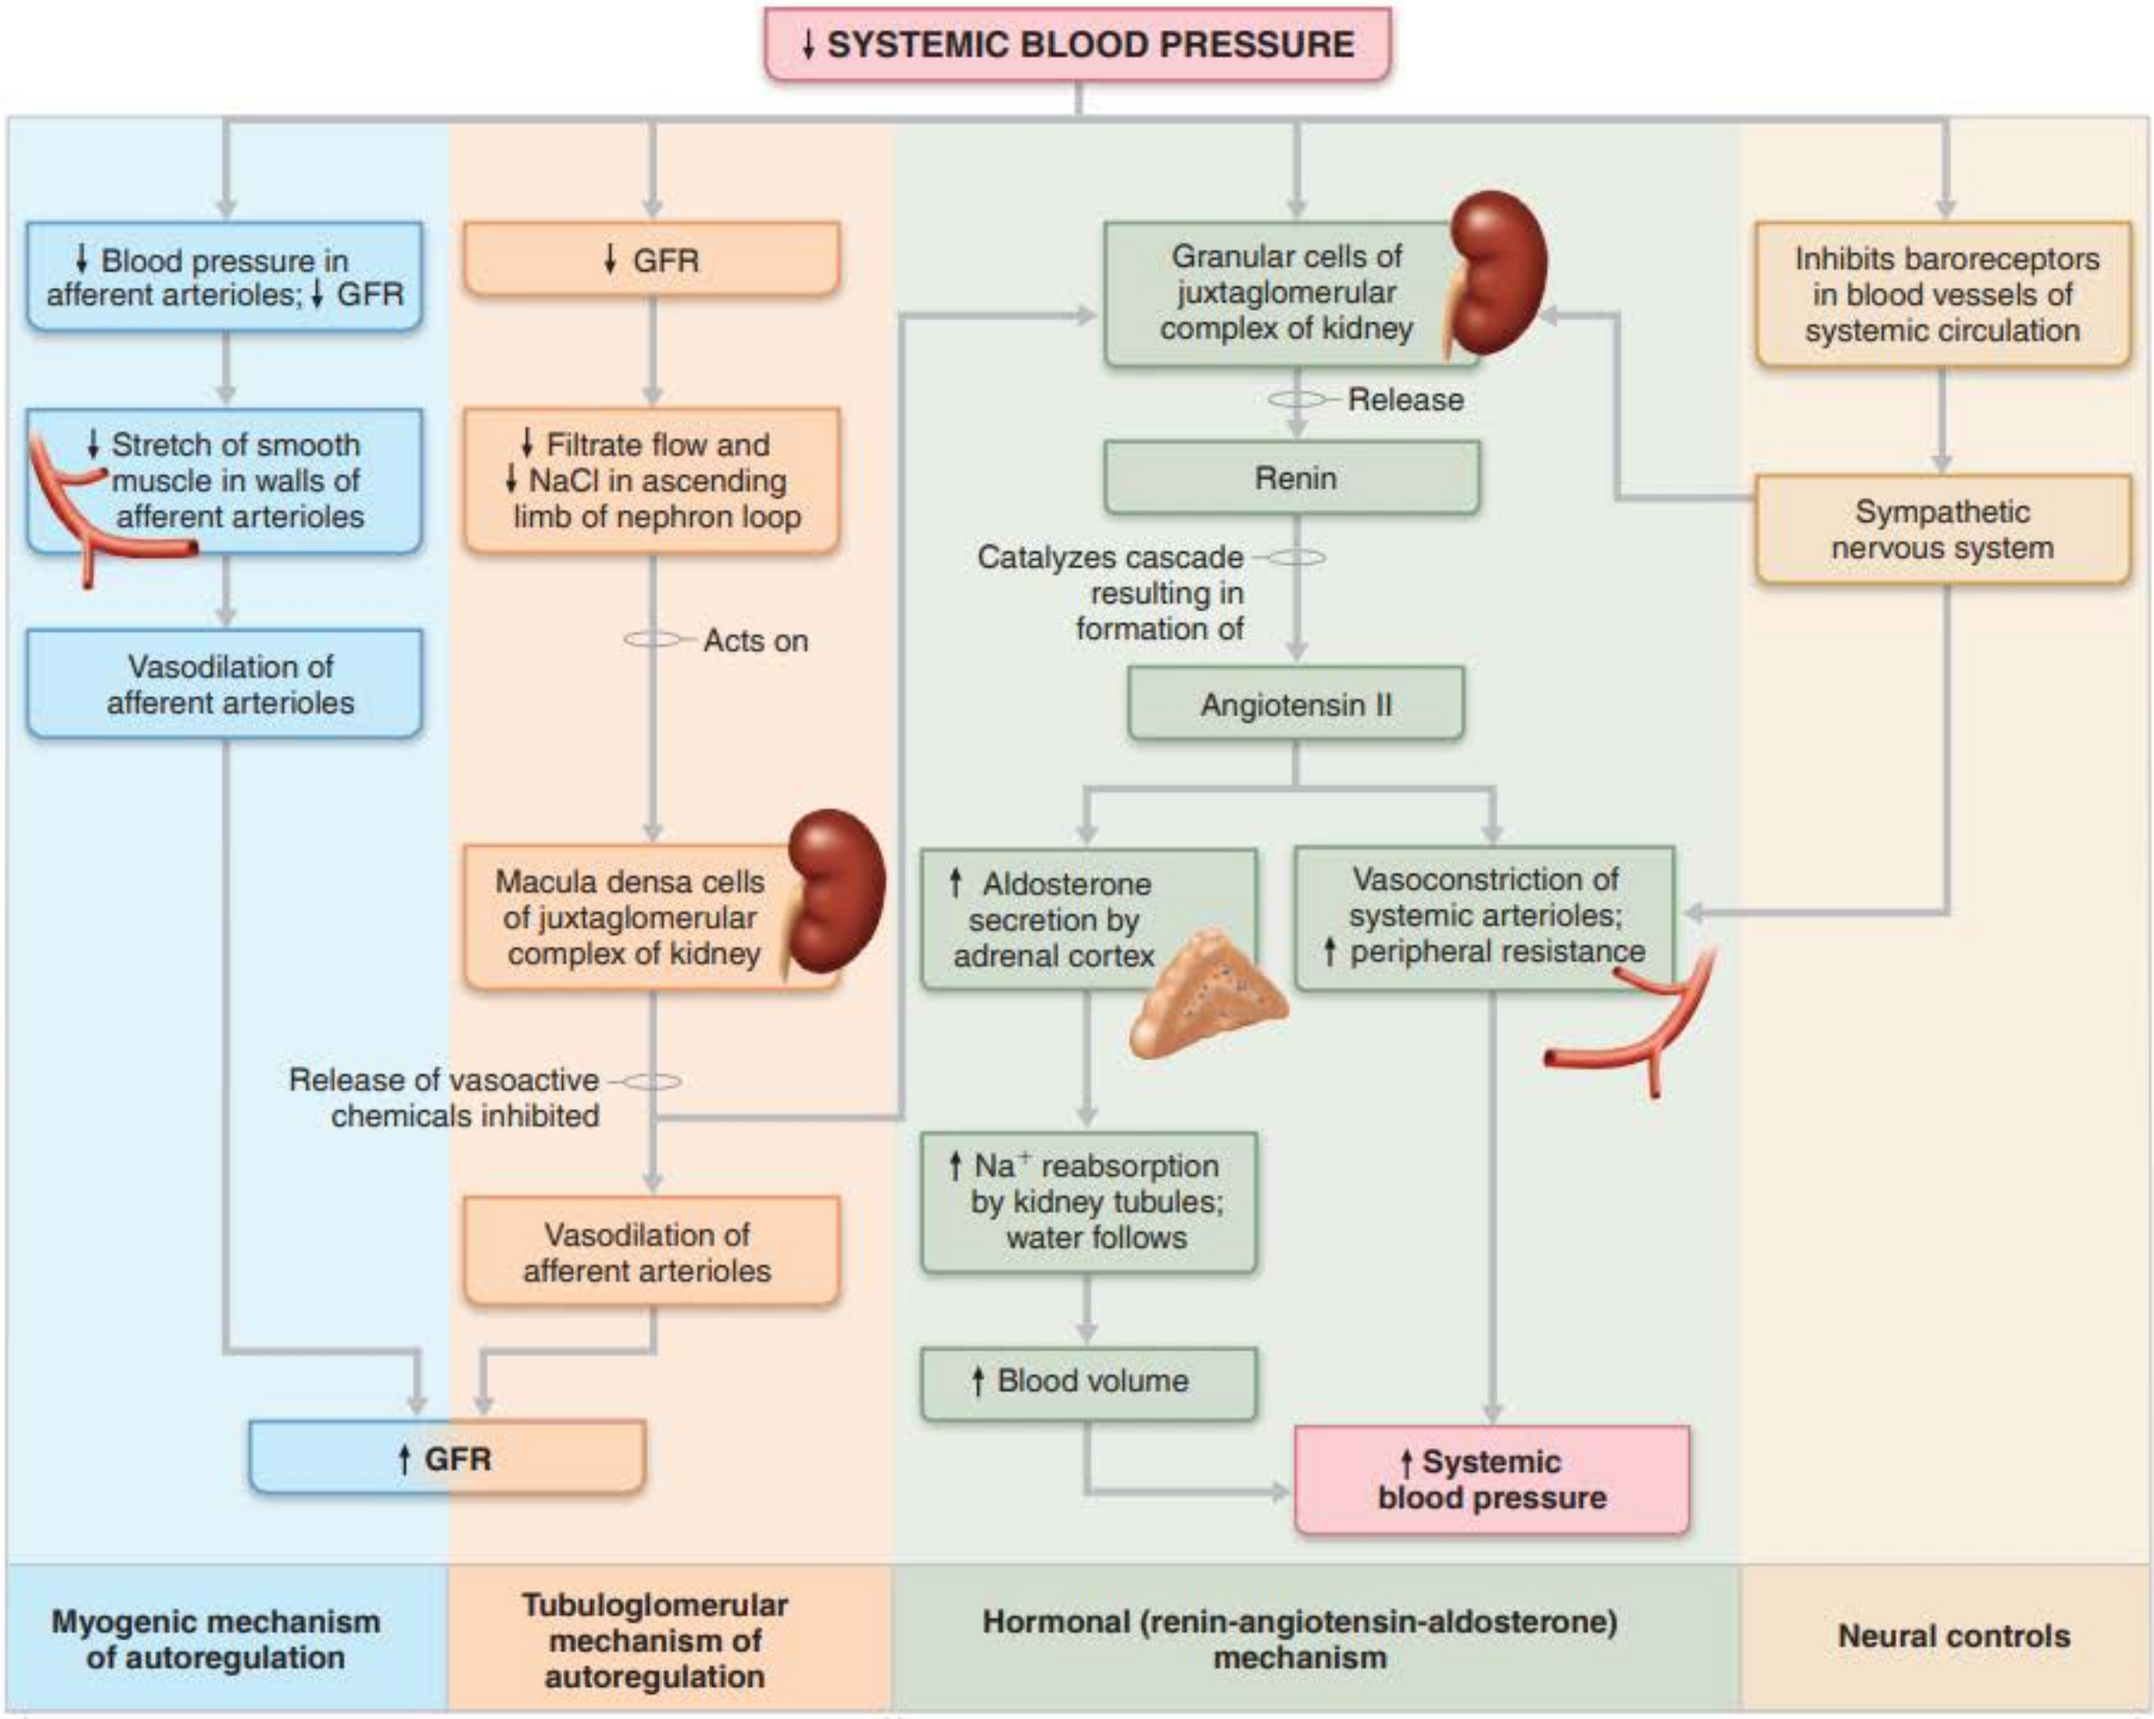


Figure 25.14 Regulation of glomerular filtration rate (GFR) in the kidneys. (Note that while the extrinsic controls are aimed at maintaining blood pressure, they also maintain GFR since bringing blood pressure back up allows the kidneys to maintain GFR.)

mechanism and (2) a *tubuloglomerular feedback mechanism* (**Figure 25.14**, left side).

Myogenic Mechanism The **myogenic mechanism** (mi″o-jen′ik) reflects a property of vascular smooth muscle—it contracts when stretched and relaxes when not stretched (◀ p. 727). Rising systemic blood pressure stretches vascular smooth muscle in the arteriolar walls, causing the afferent arterioles to constrict. This constriction restricts blood flow into the glomerulus and keeps the GFR at a level ideal for kidney function. Declining systemic blood pressure causes dilation of afferent arterioles and raises glomerular hydrostatic pressure. Both responses help maintain normal NFP and GFR.

Tubuloglomerular Feedback Mechanism Autoregulation by the flow-dependent **tubuloglomerular feedback mechanism** is "directed" by the *macula densa cells* of the *juxtaglomerular complex* (see Figure 25.10). These cells, located in the walls of the ascending limb of the nephron loop, respond to filtrate NaCl concentration (which varies directly with filtrate flow rate). When GFR increases, there is not enough time for reabsorption and the concentration of NaCl in the filtrate remains high. The macula densa cells respond to high levels of NaCl in filtrate by releasing vasoconstrictor chemicals (ATP and others) that cause intense constriction of the afferent arteriole, reducing blood flow into the glomerulus. This drop in blood flow decreases the

NFP and GFR, slowing the flow of filtrate and allowing more time for filtrate processing (NaCl reabsorption).

In contrast, the low NaCl concentration of slowly flowing filtrate inhibits ATP release from macula densa cells, causing vasodilation of the afferent arterioles (Figure 25.14). This allows more blood to flow into the glomerulus, thus increasing NFP and GFR.

Autoregulatory mechanisms maintain a relatively constant GFR over an arterial pressure range from about 80 to 180 mm Hg. Consequently, normal day-to-day changes in our blood pressure (such as during exercise, sleep, or changes in posture) do not cause large changes in water and solute excretion. However, the intrinsic controls cannot handle extremely low systemic blood pressure, such as might result from serious hemorrhage (*hypovolemic shock*). Once the mean arterial pressure drops below 80 mm Hg, autoregulation ceases and extrinsic controls take over.

Extrinsic Controls: Neural and Hormonal Mechanisms

The purpose of the extrinsic controls regulating the GFR is to maintain systemic blood pressure (Figure 25.14, right side).

Sympathetic Nervous System Controls Neural renal controls serve the needs of the body as a whole—sometimes to the detriment of the kidneys. When the volume of the extracellular fluid is normal and the sympathetic nervous system is at rest, the renal blood vessels are dilated and renal autoregulation mechanisms prevail. However, when the extracellular fluid volume is extremely low (as in hypovolemic shock during severe hemorrhage), it is necessary to shunt blood to vital organs, and neural controls may override autoregulatory mechanisms. This could reduce renal blood flow to the point of damaging the kidneys.

When blood pressure falls, norepinephrine released by sympathetic nerve fibers (and epinephrine released by the adrenal medulla) causes vascular smooth muscle to constrict, increasing peripheral resistance and bringing blood pressure back up toward normal. [This is the *baroreceptor reflex* that we discussed previously (◀ p. 719).] As part of this reflex, the afferent arterioles also constrict. Constriction of the afferent arterioles decreases GFR and so helps restore blood volume and blood pressure to normal.

Renin-Angiotensin-Aldosterone Mechanism As we discussed in Chapter 19 (◀ pp. 722–723), the **renin-angiotensin-aldosterone mechanism** is the body's main mechanism for increasing blood pressure. Without adequate blood pressure (as might be due to hemorrhage, dehydration, etc.), glomerular filtration is not possible, so this mechanism regulates GFR indirectly.

Low blood pressure causes the granular cells of the juxtaglomerular complex to release **renin**. There are three pathways that stimulate granular cells:

- *Sympathetic nervous system.* As part of the baroreceptor reflex, renal sympathetic nerves activate β_1-adrenergic receptors that cause the granular cells to release renin.
- *Activated macula densa cells.* Low blood pressure or vasoconstriction of the afferent arterioles by the sympathetic nervous system reduces GFR, slowing down the flow of filtrate through the renal tubules. When macula densa cells sense the low NaCl concentration of this sluggishly flowing filtrate, they signal the granular cells to release renin. They may signal by releasing less ATP (also thought to be the tubuloglomerular feedback messenger), by releasing *more* prostaglandin PGE_2, or both.
- *Reduced stretch.* Granular cells act as mechanoreceptors. A drop in mean arterial blood pressure reduces the tension in the granular cells' plasma membranes and stimulates them to release more renin.

Other Factors Affecting GFR

Renal cells produce a battery of chemicals, many of which act as paracrines (local signaling molecules) affecting renal arterioles. These include *adenosine* and *prostaglandin* E_2 (PGE_2). In addition, the kidney makes its own locally acting *angiotensin II* that reinforces the effects of hormonal angiotensin II described in Chapter 19 (◀ pp. 721–723).

HOMEOSTATIC IMBALANCE 25.3 CLINICAL

Abnormally low urinary output (less than 50 ml/day), called *anuria* (ah-nu′re-ah), may indicate that glomerular blood pressure is too low to cause filtration. Renal failure and anuria can also result from situations in which the nephrons stop functioning, including acute nephritis, transfusion reactions, and crush injuries.

Check Your Understanding

9. Extrinsic and intrinsic controls of GFR serve two different purposes. What are they?
10. Which of the pressures that determine NFP is regulated by both intrinsic and extrinsic controls of GFR?
11. APPLY Calculate net filtration pressure given the following values: glomerular hydrostatic pressure = 50 mm Hg, blood colloid osmotic pressure = 25 mm Hg, capsular hydrostatic pressure = 20 Hg.

For answers, see Answers Appendix.

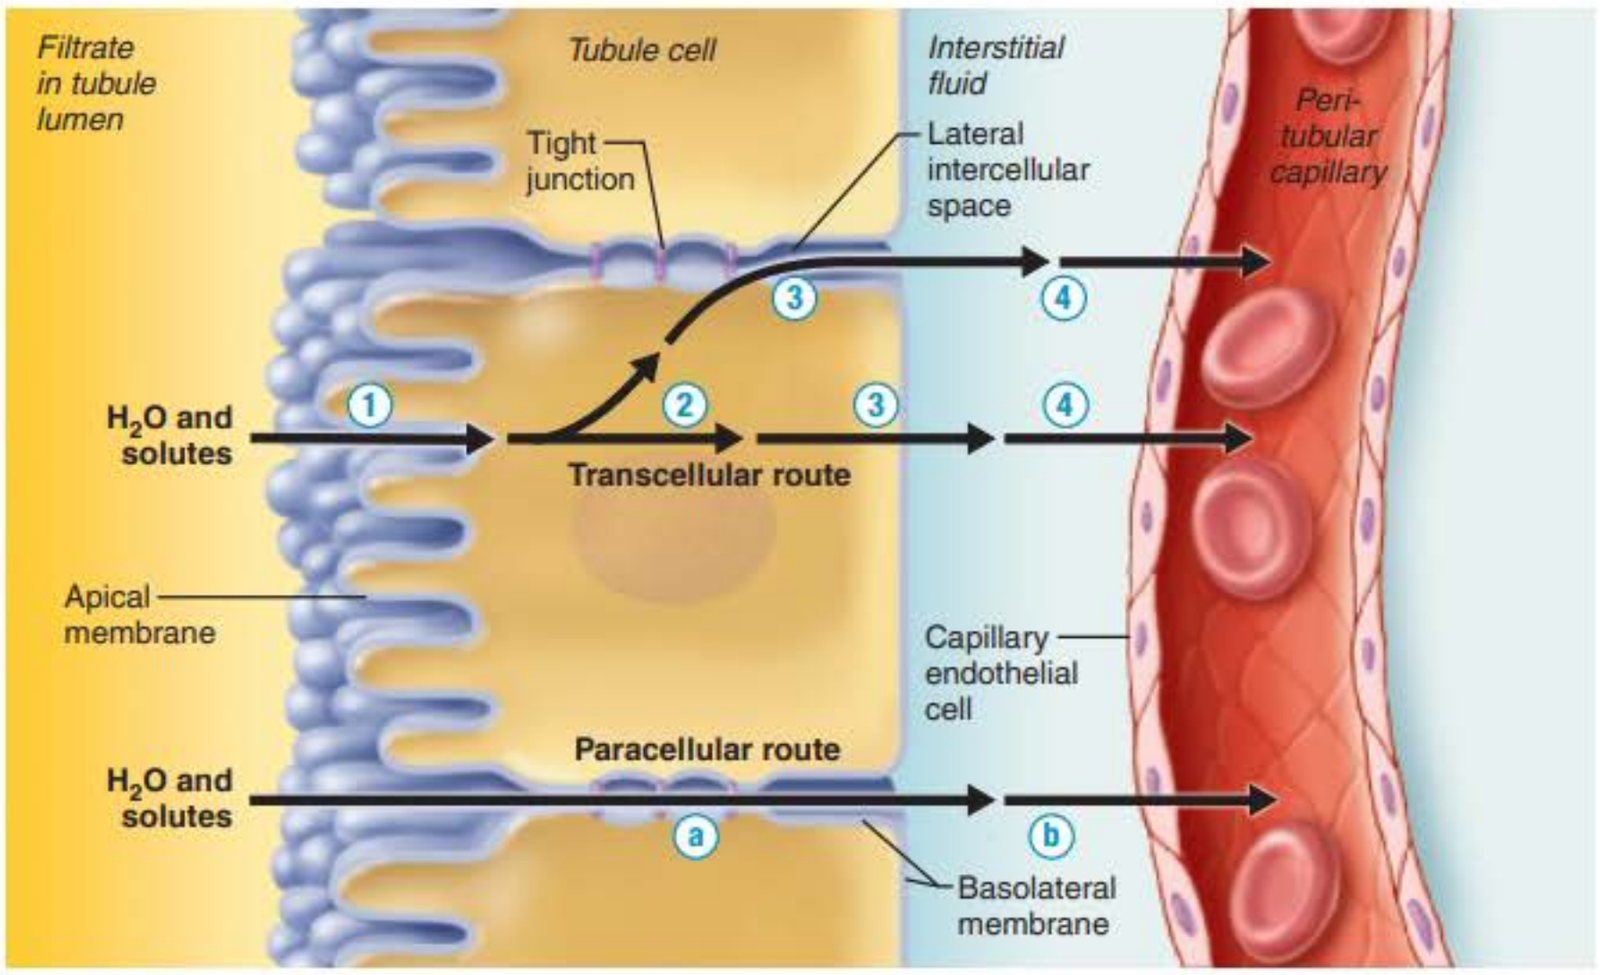
25

25.5 Urine formation, step 2: Most of the filtrate is reabsorbed into the blood

Learning Outcomes

- **Describe the mechanisms underlying water and solute reabsorption from the renal tubules into the peritubular capillaries.**
- **Describe how sodium and water reabsorption are regulated in the distal tubule and collecting duct.**

Our total plasma volume filters into the renal tubules about every 22 minutes, so all our plasma would drain away as urine in less than 30 minutes were it not for **tubular reabsorption**, which quickly reclaims most of the tubule contents and returns them to the blood.



The transcellular route involves:

(1) Transport across the apical membrane.

(2) Diffusion through the cytosol.

(3) Transport across the basolateral membrane. (Often involves the lateral intercellular spaces because membrane transporters transport ions into these spaces.)

(4) Movement through the interstitial fluid and into the capillary.

The paracellular route involves:

(a) Movement through leaky tight junctions, particularly in the proximal convoluted tubule.

(b) Movement through the interstitial fluid and into the capillary.

Figure 25.15 Tubular reabsorption occurs by transcellular and paracellular routes.
Generally, water and solutes move into the peritubular capillaries through intercellular clefts. For simplicity, transporters, ion channels, intercellular clefts, and aquaporins are not depicted.

Tubular reabsorption (shown schematically at right) is a selective *transepithelial process* that begins as soon as the filtrate enters the proximal tubules.

To reach the blood, reabsorbed substances follow either the *transcellular* or *paracellular route* (**Figure 25.15**). The transcellular route is just like the route we described for absorption in the gut (◀ p. 912). Transported substances move through the *apical membrane*, the cytosol, and the *basolateral membrane* of the tubule cell and then the endothelium of the peritubular capillaries. Movement of substances in the paracellular route—*between* the tubule cells—is limited by the tight junctions connecting these cells. In the proximal nephron, however, these tight junctions are "leaky" and allow water and some important ions (Ca^{2+}, Mg^{2+}, K^+, and some Na^+) to pass through the paracellular route.

Given healthy kidneys, virtually all organic nutrients such as glucose and amino acids are completely reabsorbed to maintain or restore normal plasma concentrations. In contrast, the reabsorption of water and many ions is continuously regulated and adjusted in response to hormonal signals. Depending on the substances transported, the reabsorption process may be *active* or *passive*.

- **Active tubular reabsorption** requires ATP either directly (primary active transport; ◀ p. 75) or indirectly (secondary active transport; ◀ pp. 75–76) for at least one of its steps.
- **Passive tubular reabsorption** encompasses diffusion, facilitated diffusion, and osmosis (◀ pp. 70–73)—processes in which substances move down their electrochemical gradients.

(You may wish to review these membrane transport processes before you proceed.)

Tubular Reabsorption of Sodium

Sodium ions are the single most abundant cation in the filtrate, and about 80% of the energy used for active transport is devoted to reabsorbing them. Sodium reabsorption is almost always active and via the transcellular route. Let's begin with the ATP-driven step.

Sodium Transport across the Basolateral Membrane

Na^+ is actively transported out of the tubule cell by *primary active transport*—a Na^+-K^+ ATPase pump in the basolateral membrane (**Figure 25.16** (1)). From there, the bulk flow of water sweeps Na^+ into adjacent peritubular capillaries. This bulk flow of water and solutes into the peritubular capillaries is rapid because the blood there has low hydrostatic pressure and high osmotic pressure (remember, most proteins remain in the blood instead of filtering out into the tubule).

Sodium Transport across the Apical Membrane

Active pumping of Na^+ from the tubule cells results in a strong electrochemical gradient that favors its entry at the apical face via *secondary active transport* (*cotransport*) carriers (Figure 25.16 (2), (3)) or via facilitated diffusion through channels (not illustrated). This occurs because (1) the pump maintains the intracellular Na^+ concentration at low levels, and (2) the K^+ pumped into the tubule cells almost immediately diffuses out into the

interstitial fluid via leakage channels, leaving the interior of the tubule cell with a net negative charge.

Because each tubule segment plays a slightly different role in reabsorption, the precise mechanism by which Na^+ is reabsorbed at the apical membrane varies.

Tubular Reabsorption of Nutrients, Water, and Ions

The reabsorption of Na^+ by primary active transport provides the energy and the means for reabsorbing almost every other substance, including water.

Complete an interactive tutorial: MasteringA&P® > Study Area > Interactive Physiology

Secondary Active Transport

Substances reabsorbed by *secondary active transport* (the "push" comes from the gradient created by Na^+-K^+ pumping at the basolateral membrane) include glucose, amino acids, some ions, and vitamins. In nearly all these cases, an apical carrier moves Na^+ down its concentration gradient as it cotransports another solute (Figure 25.16 ③). Cotransported solutes move across the basolateral membrane by facilitated diffusion via other transport proteins (not shown) before moving into the peritubular capillaries.

Passive Tubular Reabsorption of Water

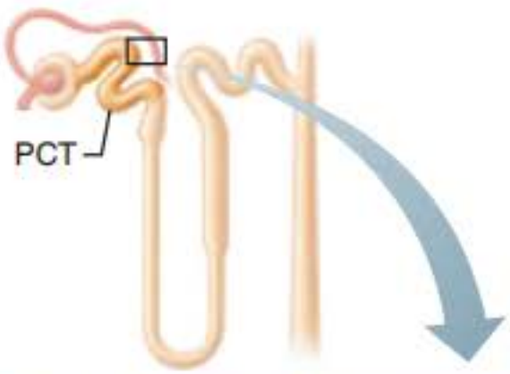
The movement of Na^+ and other solutes establishes a strong osmotic gradient, and water moves by osmosis into the peritubular capillaries. Transmembrane proteins called **aquaporins** (◀ p. 71) aid this process by acting as water channels across plasma membranes (Figure 25.16 ④).

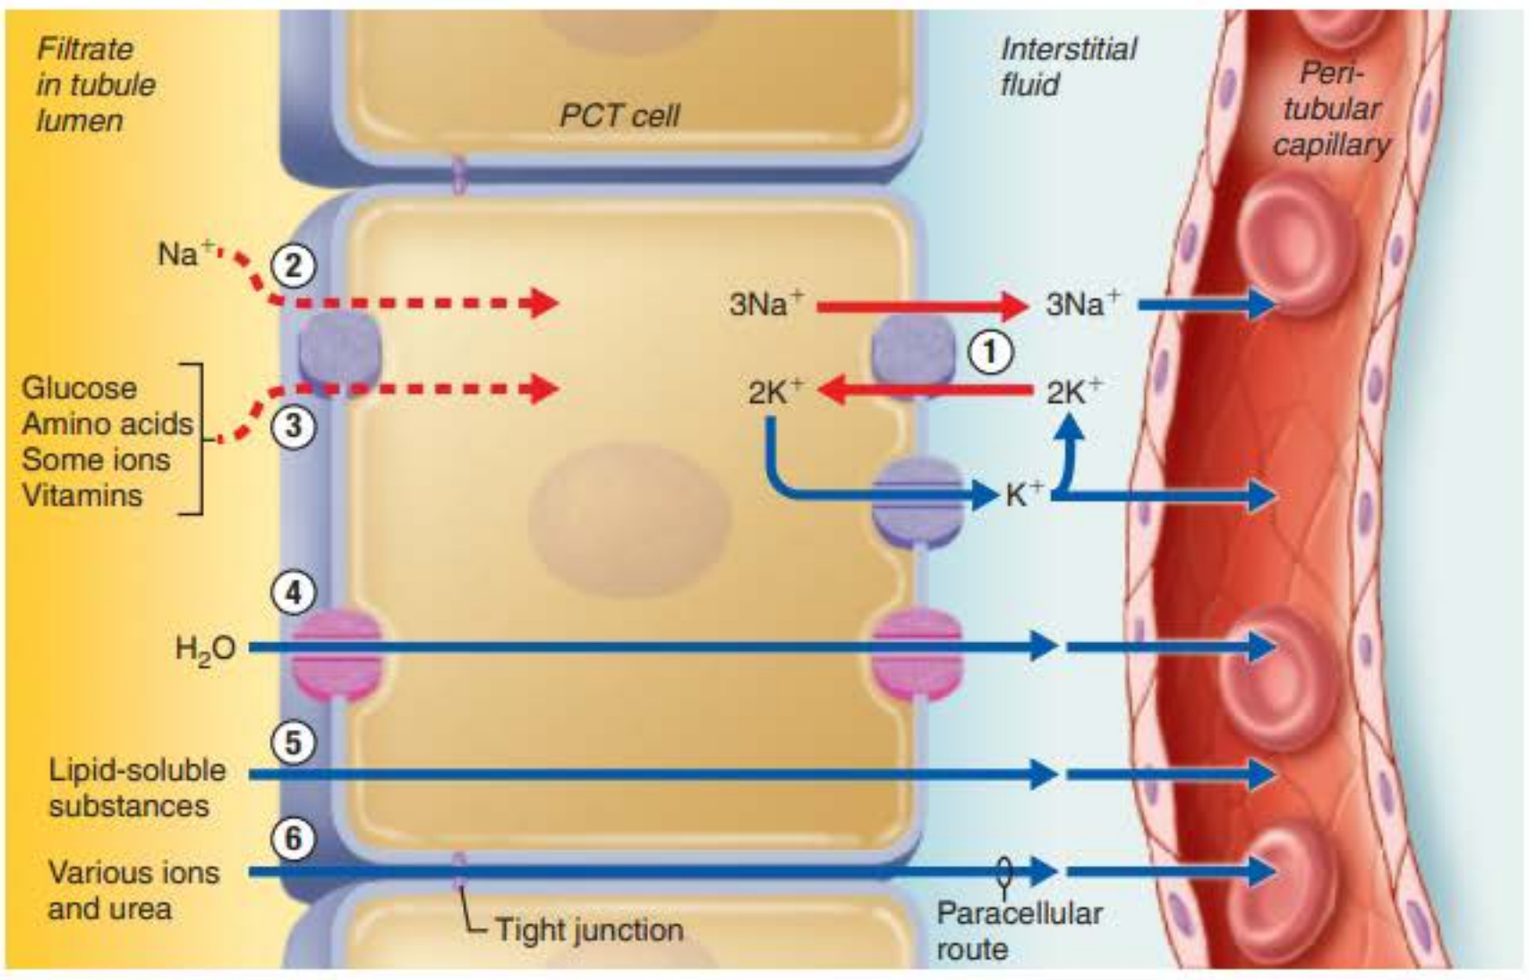
In continuously water-permeable regions of the renal tubules, such as the PCT, aquaporins are always present in the tubule cell membranes. Their presence "obliges" the body to absorb water in the proximal nephron regardless of its state of over- or underhydration. This water flow is referred to as **obligatory water reabsorption**.

Aquaporins are virtually absent in the apical membranes of the collecting duct unless antidiuretic hormone (ADH) is present. Water reabsorption that depends on ADH is called **facultative water reabsorption**.

Passive Tubular Reabsorption of Solutes

As water leaves the tubules, the concentration of solutes in the filtrate increases and, if able, they too follow their concentration gradients into the peritubular capillaries. This





① At the basolateral membrane, Na^+ is pumped into the interstitial space by the Na^+-K^+ ATPase. Active Na^+ transport creates concentration gradients that drive:

② "Downhill" Na^+ entry at the apical membrane.

③ Reabsorption of organic nutrients and certain ions by cotransport at the apical membrane.

④ Reabsorption of water by osmosis through aquaporins. Water reabsorption increases the concentration of the solutes that are left behind. These solutes can then be reabsorbed as they move down their gradients:

⑤ Lipid-soluble substances diffuse by the transcellular route.

⑥ Various ions (e.g., Cl^-, Ca^{2+}, K^+) and urea diffuse by the paracellular route.

Figure 25.16 Tubular reabsorption of water and nutrients uses active and passive transport. PCT cells (shown here) reabsorb 80% of the filtrate. Microvilli have been omitted for simplicity.

phenomenon—solutes following solvent—explains the passive reabsorption of a number of solutes present in the filtrate, such as lipid-soluble substances, certain ions, and some urea (Figure 25.16 ⑤, ⑥). It also explains in part why lipid-soluble drugs and environmental pollutants are difficult to excrete: Since lipid-soluble compounds can generally pass through membranes, they will follow their concentration gradients and be reabsorbed, even if this is not "desirable."

As Na^+ ions move through the tubule cells into the peritubular capillary blood, they also establish an electrical gradient that favors passive reabsorption of anions (primarily Cl^-) to restore electrical neutrality in the filtrate and plasma.

Transport Maximum

The transcellular transport systems for the various solutes are quite specific and *limited*. There is a **transport maximum (T_m)** for nearly every substance that is reabsorbed using a transport protein in the membrane. The T_m (reported in mg/min) reflects the number of transport proteins in the renal tubules available to ferry a particular substance. In general, there are plenty of transporters for substances such as glucose that need to be retained, and few or no transporters for substances of no use to the body.

When the transporters are saturated—that is, all bound to the substance they transport—the excess is excreted in urine. This is what happens in individuals who become hyperglycemic because of uncontrolled diabetes mellitus. As plasma levels of glucose approach and exceed 180 mg/dl, the glucose T_m is exceeded and large amounts of glucose may be lost in the urine even though the renal tubules are still functioning normally.

Reabsorptive Capabilities of the Renal Tubules and Collecting Ducts

Table 25.2 compares the reabsorptive abilities of various regions of the renal tubules and collecting ducts.

Proximal Convoluted Tubule

The entire renal tubule is involved in reabsorption to some degree, but the PCT cells are by far the most active reabsorbers and the events just described occur mainly in this tubular segment. Normally, the PCT reabsorbs *all* of the glucose and amino acids in the filtrate and 65% of the Na^+ and water. The bulk of the electrolytes are reabsorbed by the time the filtrate reaches the nephron loop. Nearly all of the uric acid and about half of the urea are reabsorbed in the proximal tubule, but both are later secreted back into the filtrate.

Nephron Loop

Beyond the PCT, the permeability of the tubule epithelium changes dramatically. Here, for the first time, water reabsorption is not coupled to solute reabsorption. Water can leave the descending limb of the nephron loop but *not* the ascending limb, where aquaporins are scarce or absent in the tubule cell membranes. These permeability differences play a vital role in the kidneys' ability to form dilute or concentrated urine.

The rule for water is that it leaves the descending (but not the ascending) limb of the nephron loop. The opposite is true for solutes. Virtually no solute reabsorption occurs in the descending limb, but solutes are reabsorbed both actively and passively in the ascending limb.

In the thin segment of the ascending limb, Na^+ moves passively down the concentration gradient created by water reabsorption. In the thick ascending limb, a Na^+-K^+-$2Cl^-$ symporter (◀ p. 76) is the main means of Na^+ entry at the apical surface. A Na^+-K^+ ATPase operates at the basolateral membrane to create

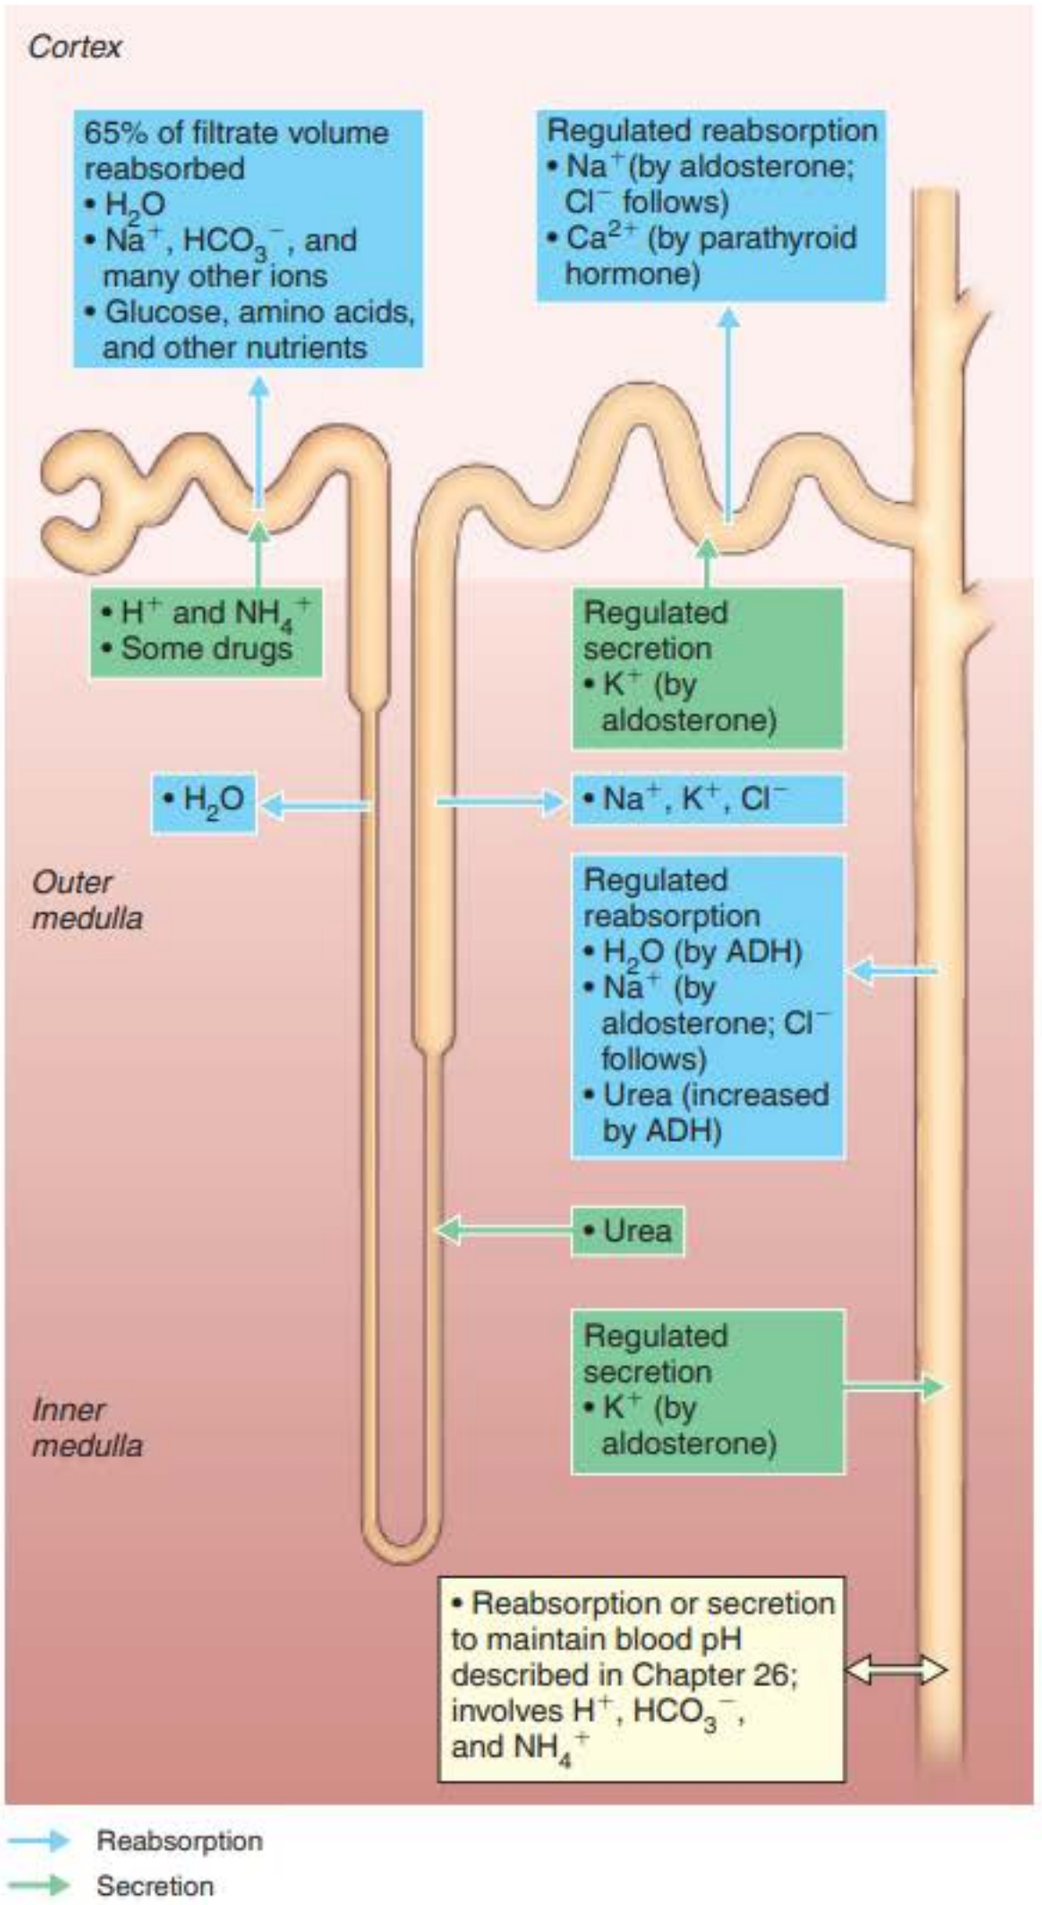


Figure 25.17 Summary of tubular reabsorption and secretion. The various regions of the renal tubule carry out reabsorption and secretion and maintain a gradient of osmolality within the medullary interstitial fluid. Color gradients represent varying osmolality at different points in the interstitial fluid.

Table 25.2 Reabsorption Capabilities of Different Segments of the Renal Tubules and Collecting Ducts

TUBULE SEGMENT	SUBSTANCE REABSORBED	MECHANISM
Proximal Convoluted Tubule (PCT)		
	Sodium ions (Na^+)	Primary active transport via basolateral Na^+-K^+ pump; crosses apical membrane through channels, symporters, or antiporters
	Virtually all nutrients (glucose, amino acids, vitamins, some ions)	Secondary active transport with Na^+
	Cl^-, K^+, Mg^{2+}, Ca^{2+}, and other ions	Passive paracellular diffusion driven by electrochemical gradient
	HCO_3^-	Secondary active transport linked to H^+ secretion and Na^+ reabsorption (see Chapter 26)
	Water	Osmosis; driven by solute reabsorption (obligatory water reabsorption)
	Lipid-soluble solutes	Passive diffusion driven by the concentration gradient created by reabsorption of water
	Urea	Primarily passive paracellular diffusion driven by chemical gradient
Nephron Loop		
Descending limb	Water	Osmosis
Ascending limb	Na^+, Cl^-, K^+	Secondary active transport of Cl^-, Na^+, and K^+ via Na^+-K^+-$2Cl^-$ cotransporter in thick portion; paracellular diffusion; Na^+-H^+ antiport
	Ca^{2+}, Mg^{2+}	Passive paracellular diffusion driven by electrochemical gradient
Distal Convoluted Tubule (DCT)		
	Na^+, Cl^-	Primary active Na^+ transport at basolateral membrane; secondary active transport at apical membrane via Na^+-Cl^- symporter and channels; aldosterone-regulated at distal portion
	Ca^{2+}	Passive uptake via PTH-modulated channels in apical membrane; primary and secondary active transport (antiport with Na^+) in basolateral membrane
Collecting Duct		
	Na^+, K^+, HCO_3^-, Cl^-	Primary active transport of Na^+ (requires aldosterone); passive paracellular diffusion of some Cl^-; cotransport of Cl^- and HCO_3^-; K^+ is both reabsorbed and secreted (aldosterone dependent), usually resulting in net K^+ secretion
	Water	Osmosis; controlled (facultative) water reabsorption; ADH required to insert aquaporins
	Urea	Facilitated diffusion in response to concentration gradient in the deep medulla region; recycles and contributes to medullary osmotic gradient

the ionic gradient that drives the symporter. The thick ascending limb also has Na^+-H^+ antiporters. In addition, some 50% of Na^+ passes via the paracellular route in this region.

Distal Convoluted Tubule and Collecting Duct

While reabsorption in the PCT and nephron loop does not vary with the body's needs, hormones fine-tune reabsorption in the DCT and collecting duct (**Figure 25.17**). Because most of the filtered water and solutes have been reabsorbed by the time the DCT is reached, only a small amount of the filtered load is subject to this fine tuning (e.g., about 10% of the originally filtered NaCl and 25% of the water). We introduce hormones that act at the DCT and collecting duct here but discuss them in more detail in Chapter 26.

- **Antidiuretic hormone (ADH).** As its name reveals, ADH inhibits *diuresis* (di″u-re′sis), or urine output. ADH makes the principal cells of the collecting ducts more permeable to water by causing aquaporins (◀ p. 71) to be inserted into their apical membranes. The amount of ADH determines the number of aquaporins, and so regulates the amount of water that is reabsorbed there. When the body is overhydrated, extracellular fluid osmolality decreases, decreasing ADH secretion by the posterior pituitary (◀ p. 613) and making the collecting ducts relatively impermeable to water. ADH also increases urea reabsorption by the collecting ducts, as we will describe later.
- **Aldosterone.** Aldosterone fine-tunes reabsorption of the remaining Na^+. Decreased blood volume or blood pressure, or high extracellular K^+ concentration (hyperkalemia), can cause the adrenal cortex to release aldosterone to the blood (◀ pp. 623–624). Except for hyperkalemia (which *directly* stimulates the adrenal cortex to secrete aldosterone), these conditions promote the renin-angiotensin-aldosterone mechanism (see Figure 25.14).

  Aldosterone targets the principal cells of the collecting ducts and cells of the distal portion of the DCT (prodding them to synthesize and retain more apical Na^+ and K^+ channels, and more basolateral Na^+-K^+ ATPases). As a result, little or no Na^+ leaves the body in urine. In the absence of aldosterone, these segments reabsorb much less Na^+ and about 2% of Na^+ filtered daily can be lost—an amount incompatible with life.

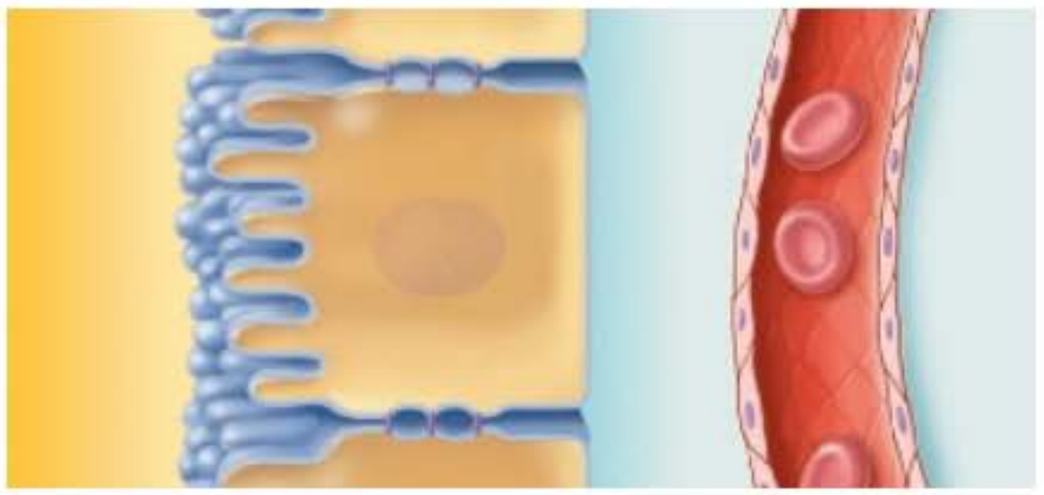
  Physiologically, aldosterone's role is to increase blood volume, and therefore blood pressure, by enhancing Na^+ reabsorption. In general, water follows Na^+ if aquaporins are present. Aldosterone also reduces blood K^+ concentrations because aldosterone-induced reabsorption of Na^+ is coupled to K^+ secretion in the principal cells of the collecting duct. That is, as Na^+ enters the cell, K^+ moves into the lumen.
- **Atrial natriuretic peptide (ANP).** In contrast to aldosterone, which acts to conserve Na^+, ANP reduces blood Na^+, thereby decreasing blood volume and blood pressure (◀ p. 624). Released by cardiac atrial cells when blood volume or blood pressure is elevated, ANP exerts several effects that lower blood Na^+ content, including direct inhibition of Na^+ reabsorption at the collecting ducts.
- **Parathyroid hormone (PTH).** Acting primarily at the DCT, PTH increases the reabsorption of Ca^{2+} (◀ p. 622).

Check Your Understanding

12. In which part of the nephron does most reabsorption occur?

13. How does the movement of Na^+ drive the reabsorption of water and solutes?

14. DRAW In the figure at right above, draw arrows to represent the pathway for transcellular reabsorption of Na^+. If transport proteins are required for this process, draw and label them in the appropriate locations. In each case, state whether the transport of Na^+ is primary active, secondary active, or passive.



15. MAKE CONNECTIONS Primary and secondary active transport processes are shown in Figure 25.16 (and were introduced in Chapter 3). How do they differ?

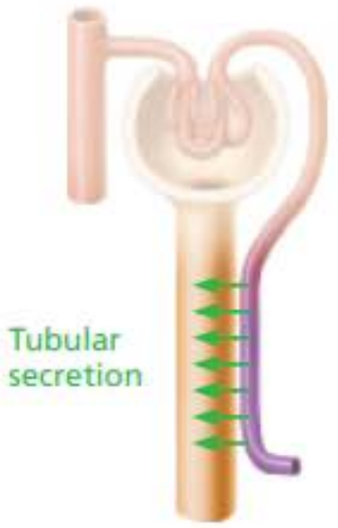
For answers, see Answers Appendix.

25.6 Urine formation, step 3: Certain substances are secreted into the filtrate

Learning Outcome

- **Describe the importance of tubular secretion and list several substances that are secreted.**

The most important way to clear plasma of unwanted substances is to simply not reabsorb them from the filtrate. Another way is **tubular secretion**—essentially, reabsorption in reverse (shown schematically at right). Tubular secretion moves *selected* substances [such as H^+, K^+, NH_4^+ (ammonium ion), creatinine, and certain organic acids and bases] from the peritubular capillaries through the tubule cells into the filtrate. Also, some substances (such as HCO_3^-) that are synthesized in the tubule cells are secreted.



The urine eventually excreted contains *both filtered and secreted substances*. With one major exception (K^+), the PCT is the main site of secretion, but the collecting ducts are also active (Figure 25.17).

Tubular secretion is important for:

- *Disposing of substances, such as certain drugs and metabolites, that are tightly bound to plasma proteins.* Because plasma proteins are generally not filtered, the substances they bind are not filtered and so must be secreted.
- *Eliminating undesirable substances or end products that have been reabsorbed by passive processes.* Urea and uric acid, two nitrogenous wastes, are both handled in this way. Urea handling in the nephron is complicated and will be discussed on p. 1000, but the net effect is that 40–50% of the urea in the filtrate is excreted.
- *Ridding the body of excess K^+.* Because virtually all K^+ present in the filtrate is reabsorbed in the PCT and ascending nephron loop, nearly all K^+ in urine comes from aldosterone-driven

active tubular secretion into the late DCT and collecting ducts.

- *Controlling blood pH.* When blood pH drops toward the acidic end of its homeostatic range, the renal tubule cells actively secrete more H^+ into the filtrate and retain and generate more HCO_3^- (a base). As a result, blood pH rises and the urine drains off the excess H^+. Conversely, when blood pH approaches the alkaline end of its range, Cl^- is reabsorbed instead of HCO_3^-, which is allowed to leave the body in urine. We will discuss the kidneys' role in pH homeostasis in more detail in Chapter 26.

Check Your Understanding

16. List several substances that are secreted into the kidney tubules.

For answers, see Answers Appendix.

25.7 The kidneys create and use an osmotic gradient to regulate urine concentration and volume

Learning Outcomes

- **Describe the mechanisms responsible for the medullary osmotic gradient.**
- **Explain how dilute and concentrated urine are formed.**

From day to day, and even hour to hour, our intake and loss of fluids can vary dramatically. For example, when you run on a hot summer day, you dehydrate as you rapidly lose fluid as sweat. On the other hand, if you drink a pitcher of lemonade while sitting on the porch, you may overhydrate. In response, the kidneys make adjustments to keep the solute concentration of body fluids constant at about 300 mOsm, the normal osmotic concentration of blood plasma. Maintaining constant osmolality of extracellular fluids is crucial for preventing cells, particularly in the brain, from shrinking or swelling from the osmotic movement of water.

Recall from Chapter 3 (pp. 71–73) that a solution's osmolality is the concentration of solute particles per kilogram of water. Because 1 osmol (equivalent to 1 mole of particles) is a fairly large unit, the milliosmol (mOsm) (mil″e-oz′mōl), equal to 0.001 osmol, is generally used. In the discussion that follows, we use mOsm to indicate mOsm/kg.

The kidneys keep the solute load of body fluids constant by regulating urine concentration and volume.

- When you dehydrate, your kidneys produce a small volume of concentrated urine.
- When you overhydrate, your kidneys produce a large volume of dilute urine.

The kidneys accomplish this feat using countercurrent mechanisms. In the kidneys, the term *countercurrent* means that fluid flows in opposite directions through adjacent segments of the same tube connected by a hairpin turn* (see *Focus on the Medullary Osmotic Gradient*, Focus Figure 25.1, pp. 996–997). This arrangement makes it possible to exchange materials between the two segments.

Two types of countercurrent mechanisms determine urine concentration and volume:

- The **countercurrent multiplier** is the interaction between the flow of filtrate through the ascending and descending limbs of the long nephron loops of juxtamedullary nephrons.
- The **countercurrent exchanger** is the flow of blood through the ascending and descending portions of the vasa recta.

These countercurrent mechanisms establish and maintain an osmotic gradient extending from the cortex through the depths of the medulla (**Figure 25.18**). This gradient—the **medullary osmotic gradient**—allows the kidneys to vary urine concentration dramatically.

How do the kidneys form the osmotic gradient? *Focus on the Medullary Osmotic Gradient* (**Focus Figure 25.1** on pp. 996–997) explores the answer to this question.

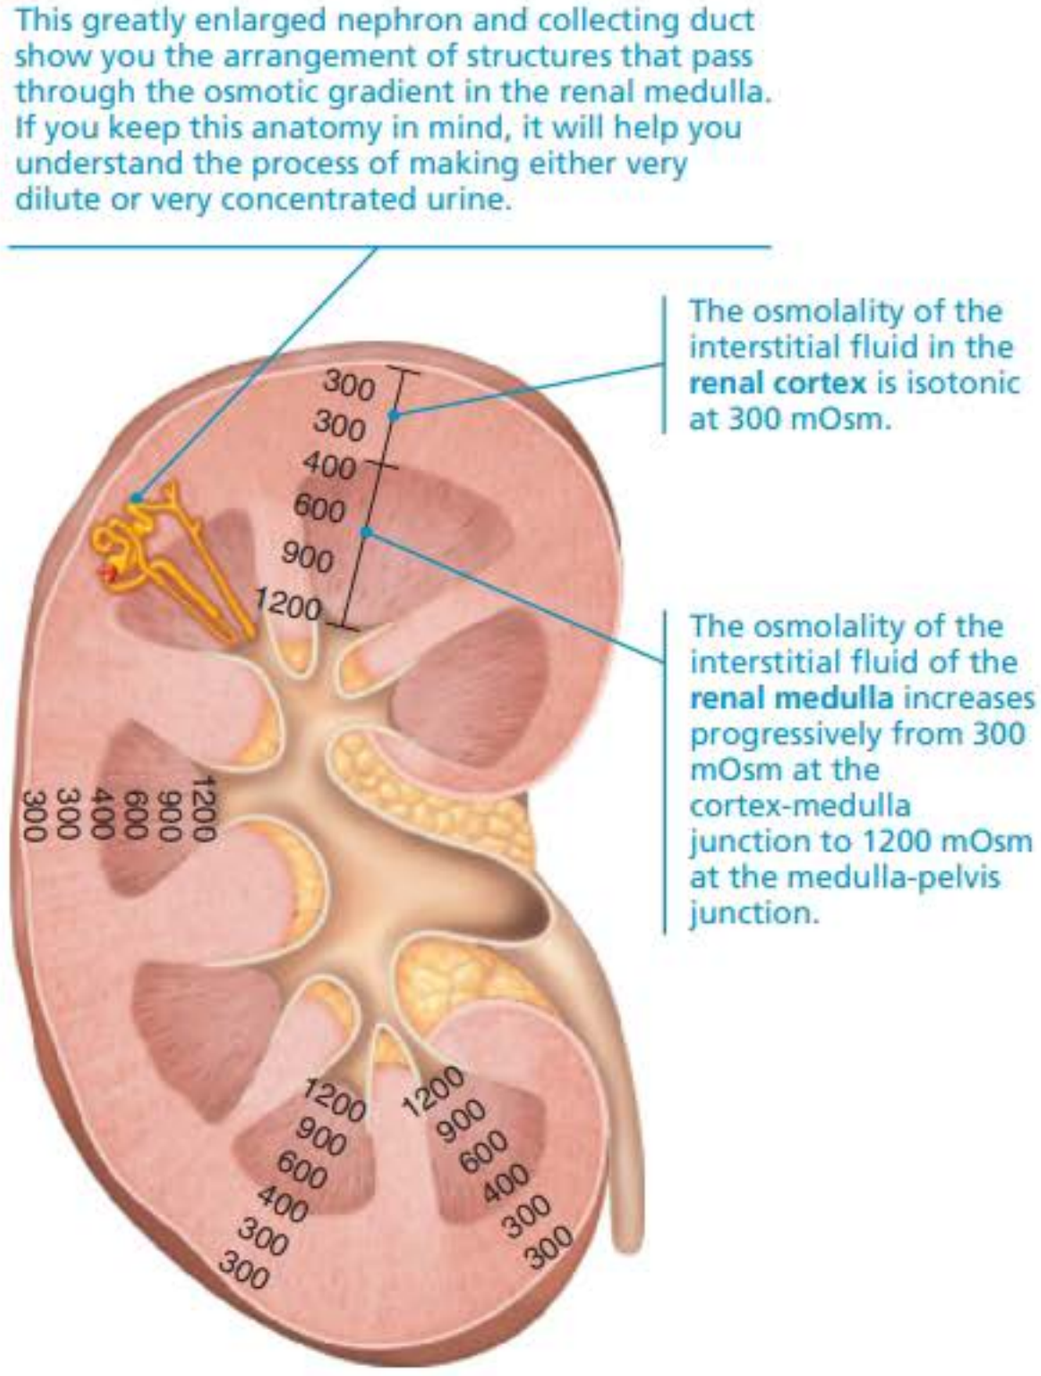


Figure 25.18 Osmotic gradient in the renal medulla.

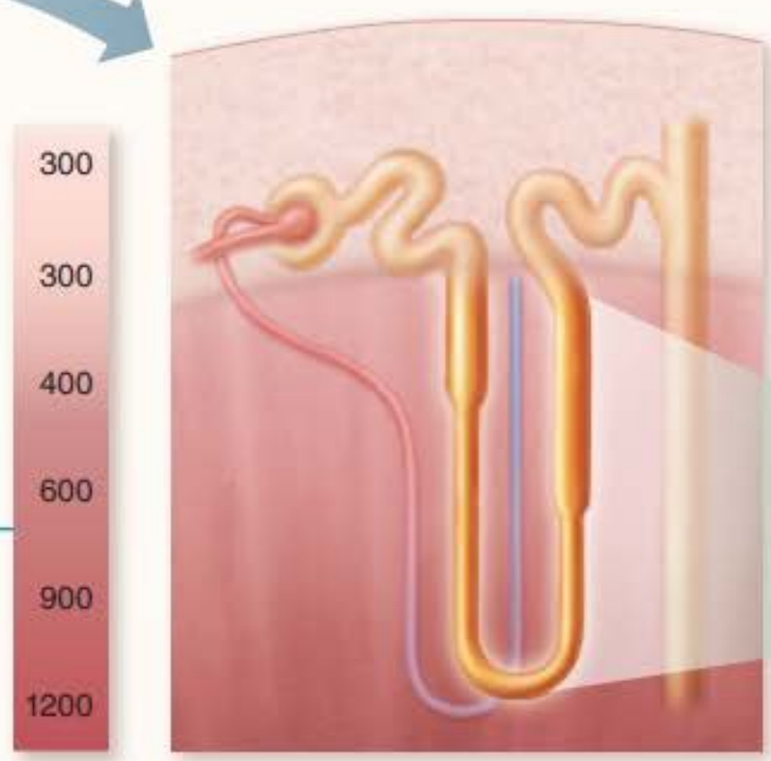
*The term "countercurrent" is commonly misunderstood to mean that the direction of fluid flow in the nephron loops is opposite that of the blood in the vasa recta. In fact, there is no one-to-one relationship between individual nephron loops and capillaries of the vasa recta as might be suggested by two-dimensional diagrams such as Focus Figure 25.1. Instead, there are many tubules and capillaries packed together like a bundle of straws. Each tubule is surrounded by many blood vessels, whose flow is not necessarily counter to flow in that tubule (see Figure 25.8).

(Text continues on p. 998.)

FOCUS FIGURE 25.1 Medullary Osmotic Gradient

Juxtamedullary nephrons create an osmotic gradient within the renal medulla that allows the kidney to produce urine of varying concentration.

The osmotic gradient: The osmolality (solute concentration) of the medullary interstitial fluid progressively increases from the 300 mOsm of normal body fluid to 1200 mOsm at the deepest part of the medulla.

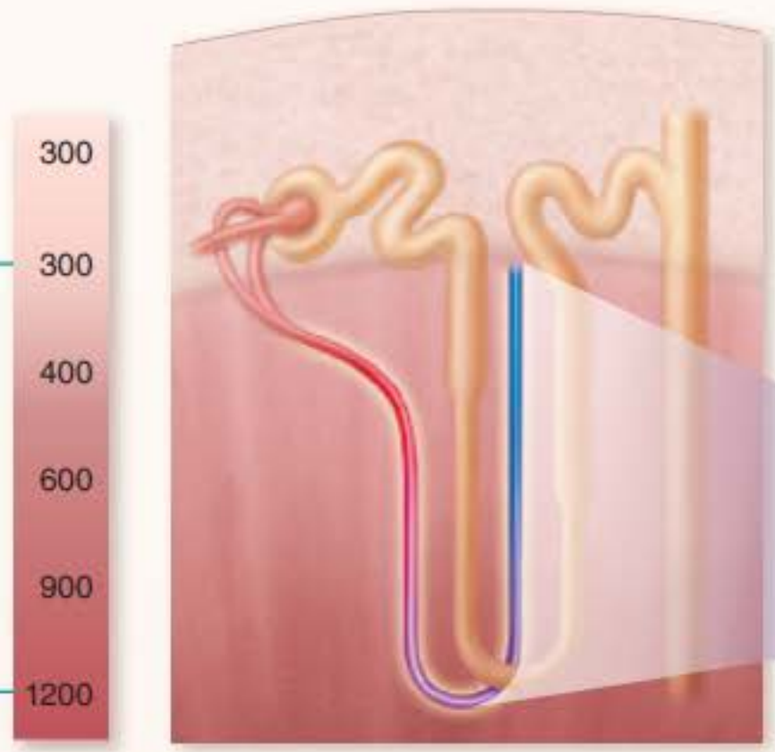


The big picture: Three key players interact with the medullary osmotic gradient.

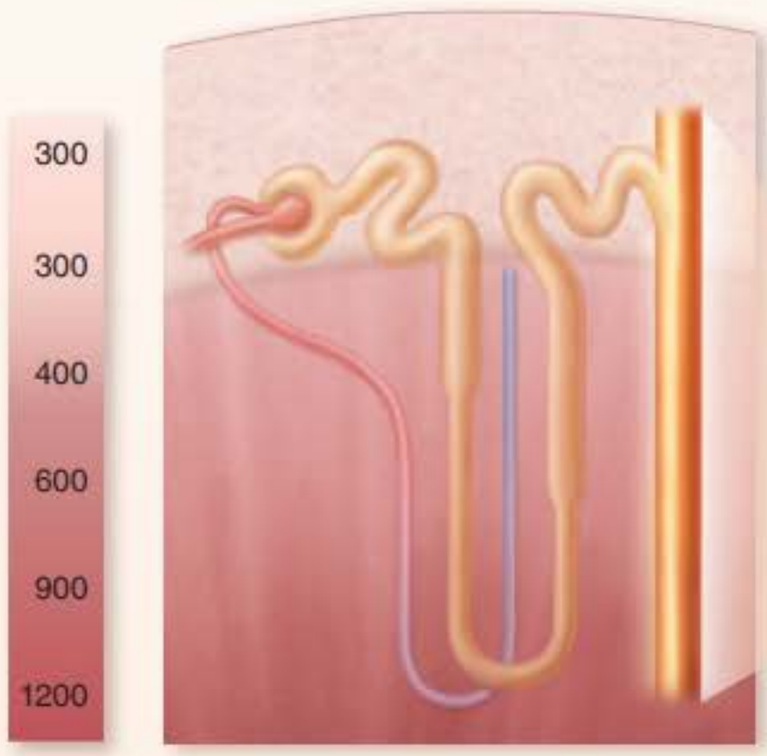
The **long nephron loops** of juxtamedullary nephrons *create* the gradient. They act as **countercurrent multipliers.**

Lower concentration of solutes

Higher concentration of solutes



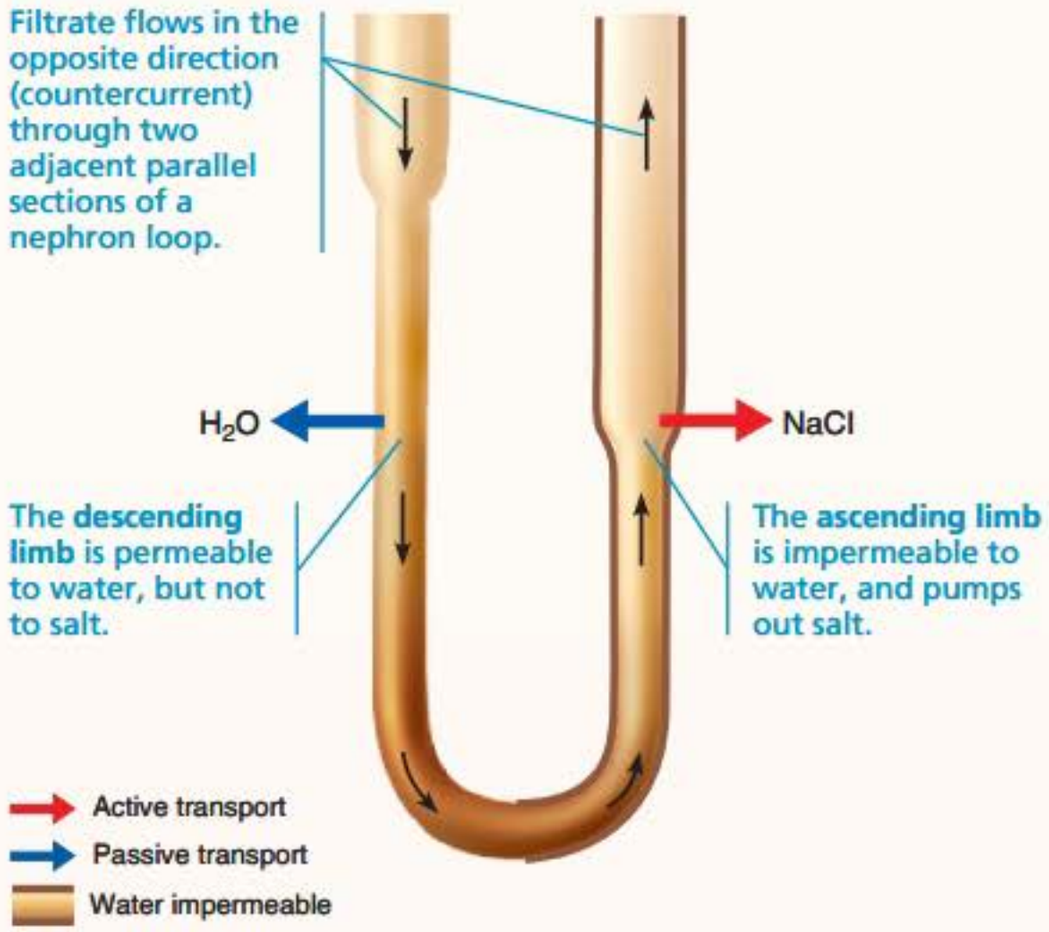
The **vasa recta** *preserve* the gradient. They act as **countercurrent exchangers** (see Figure 25.19).



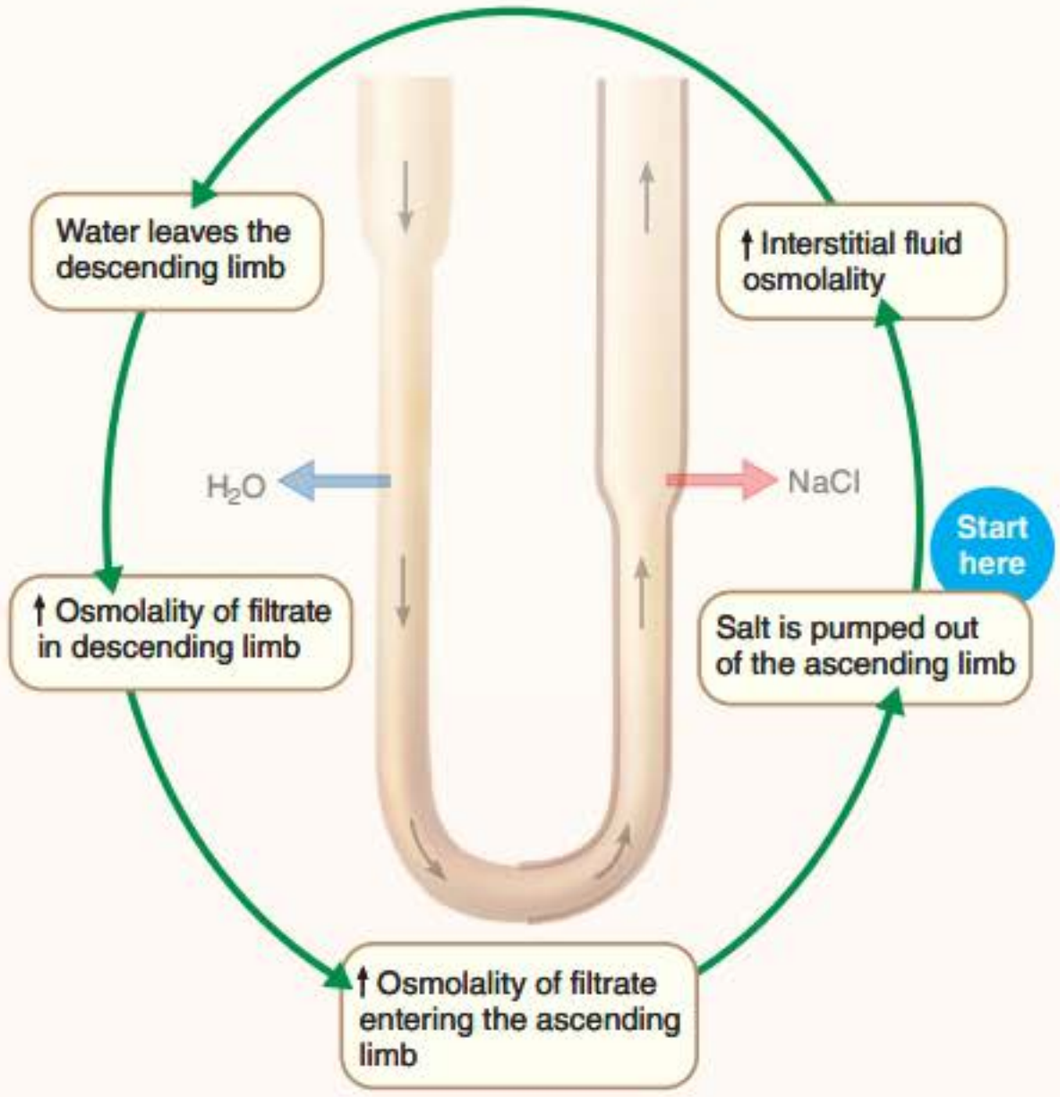
The **collecting ducts** of all nephrons *use* the gradient to adjust urine osmolality (see Figure 25.20).

Long nephron loops of juxtamedullary nephrons create the gradient.

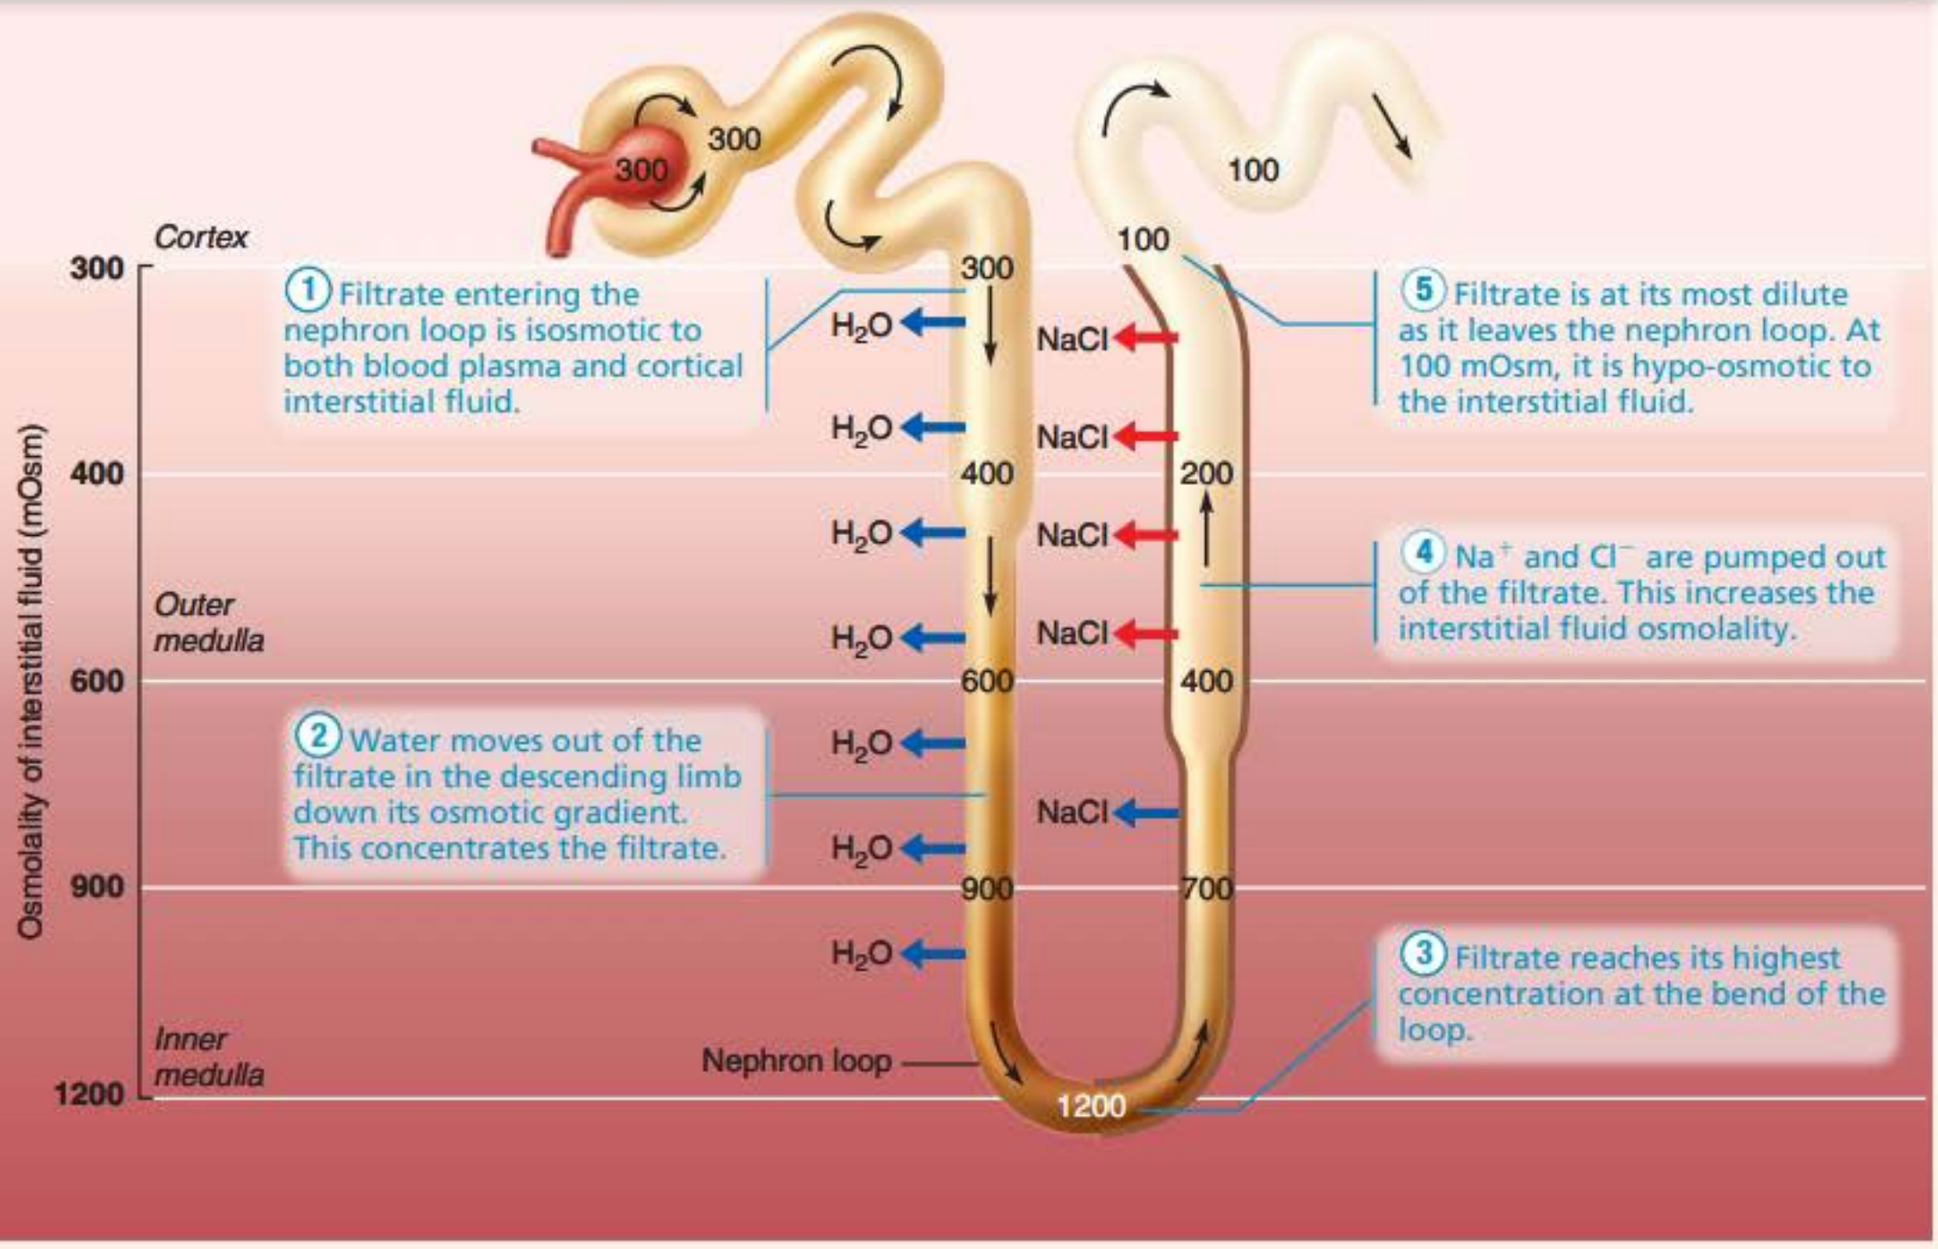
The countercurrent multiplier depends on three properties of the nephron loop to establish the osmotic gradient.



These properties establish a positive feedback cycle that uses the flow of fluid to multiply the power of the salt pumps.



As water and solutes are reabsorbed, the loop first concentrates the filtrate, then dilutes it.



The Countercurrent Multiplier

Take some time to study the mechanism of the countercurrent multiplier in Focus Figure 25.1 (pp. 996–997). The countercurrent multiplier depends on actively transporting solutes out of the ascending limb ("Start" of the positive feedback cycle).

Although the two limbs of the nephron loop are not in direct contact with each other, they are close enough to influence each other's exchanges with the interstitial fluid they share. The more NaCl the ascending limb extrudes, the more water diffuses out of the descending limb and the saltier the filtrate in the descending limb becomes. The ascending limb then uses the increasingly "salty" filtrate left behind in the descending limb to raise the osmolality of the medullary interstitial fluid even further. This establishes a positive feedback cycle that produces the high osmolality of the fluids in the descending limb and interstitial fluid.

Notice at the bottom of the right page of Focus Figure 25.1 that there is a constant difference in filtrate concentration (200 mOsm) between the two limbs of the nephron loop, and between the ascending limb and the interstitial fluid. This difference reflects the power of the ascending limb's NaCl pumps, which are just powerful enough to create a 200 mOsm difference between the inside and outside of the ascending limb. A 200 mOsm gradient by itself would not be enough to allow excretion of very concentrated urine. The beauty of this system lies in the fact that, because of countercurrent flow, the nephron loop is able to "multiply" these small changes in solute concentration into a gradient change along the vertical length of the loop (both inside and outside) that is closer to 900 mOsm (1200 mOsm – 300 mOsm).

Notice also that while much of the Na^+ and Cl^- reabsorption in the ascending limb is active (via Na^+-K^+-$2Cl^-$ cotransporters in the thick ascending limb), some is passive (mostly in the thin portion of the ascending limb).

Vasa recta preserve the gradient.

- **The vasa recta are highly permeable to water and solutes.**
- **Countercurrent exchanges occur between each section of the vasa recta and its surrounding fluid. As a result:**
  - The blood within the vasa recta remains nearly isosmotic to the surrounding fluid.
  - The vasa recta are able to reabsorb water and solutes into the general circulation without undoing the osmotic gradient created by the countercurrent multiplier.

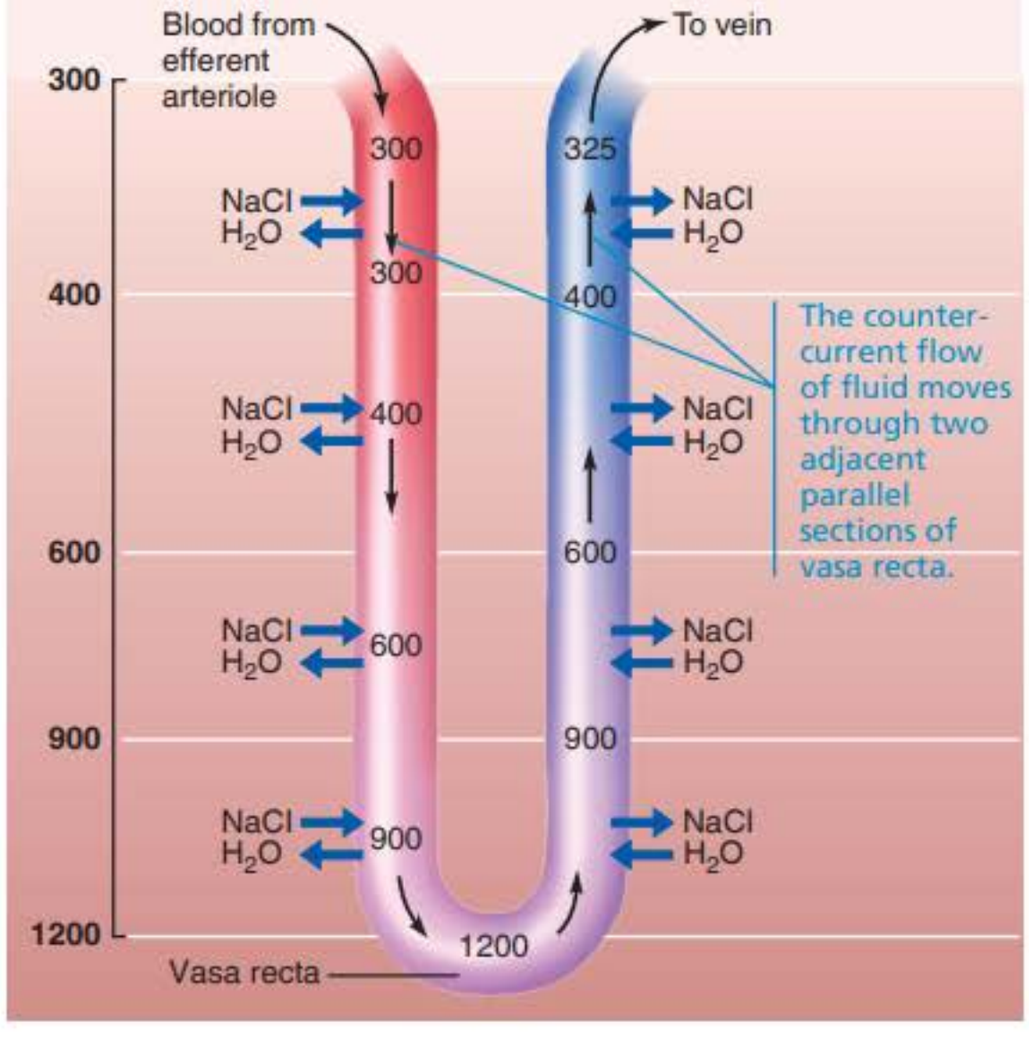


Figure 25.19 Countercurrent exchange.

The Countercurrent Exchanger

The vasa recta act as countercurrent exchangers (**Figure 25.19**). Countercurrent exchange does not create the medullary gradient, but preserves it by (1) preventing rapid removal of salt from the medullary interstitial space, and (2) removing reabsorbed water. As a result, blood leaving and reentering the cortex via the vasa recta has nearly the same solute concentration.

The water picked up by the ascending vasa recta includes not only water lost from the descending vasa recta, but also water reabsorbed from the nephron loop and collecting duct. As a result, the volume of blood at the end of the vasa recta is greater than at the beginning.

Formation of Dilute or Concentrated Urine

As we have just seen, the kidneys go to a great deal of trouble to create the medullary osmotic gradient. But for what purpose? Without this gradient, you would not be able to raise the concentration of urine above 300 mOsm—the osmolality of interstitial fluid. As a result, you would not be able to conserve water when you are dehydrated.

Figure 25.20 shows the body's response to either overhydration or dehydration and ADH's role in controlling the production of dilute or concentrated urine. When we are overhydrated, ADH production decreases (◀ p. 613) and the osmolality of urine falls as low as 100 mOsm. If aldosterone (not shown) is present, the DCT and collecting duct cells can remove Na^+ and selected other ions from the filtrate, making the urine that enters the renal pelvis even more dilute. The osmolality of urine can plunge as low as 50 mOsm, about one-sixth the concentration of glomerular filtrate or blood plasma.

When we are dehydrated, the posterior pituitary releases large amounts of ADH and the solute concentration of urine may rise as high as 1200 mOsm, the concentration of interstitial fluid in the deepest part of the medulla. With maximal ADH secretion, up to 99% of the water in the filtrate is reabsorbed and returned to the blood, and only half a liter per day of highly concentrated urine is excreted. The ability of our kidneys to produce such concentrated urine is critically tied to our ability to survive for a limited time without water.

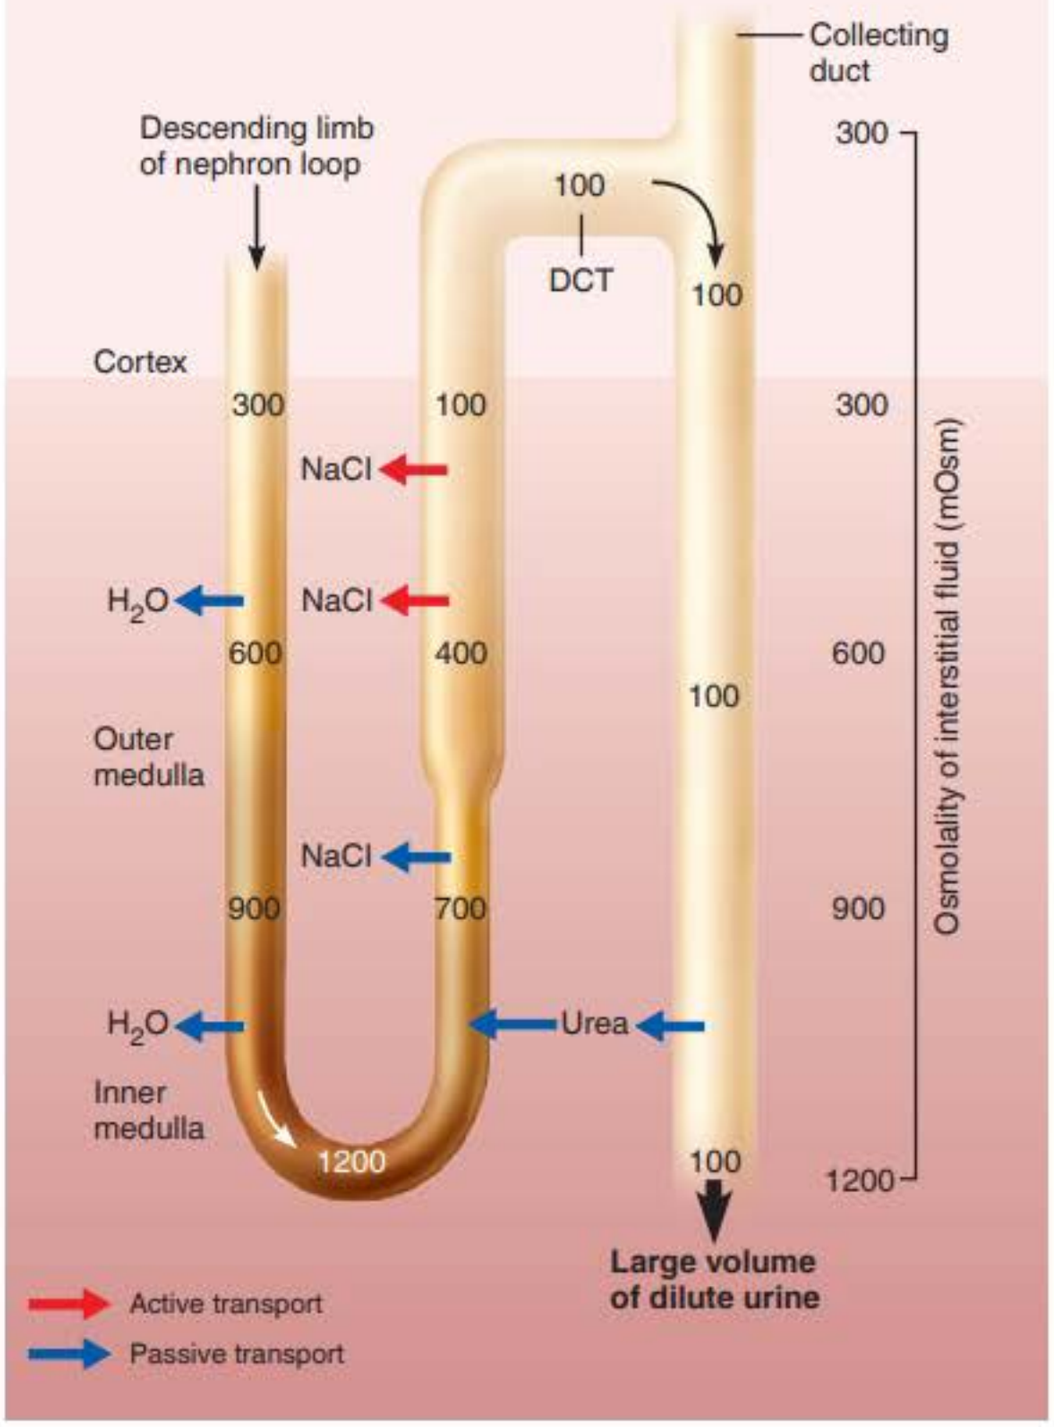
Collecting ducts use the gradient.

(a) If we were so overhydrated we had no ADH...

↓ Osmolality of extracellular fluids
↓
↓ ADH release from posterior pituitary
↓
↓ Number of aquaporins (H_2O channels) in collecting duct
↓
↓ H_2O reabsorption from collecting duct
↓
Large volume of dilute urine

(b) If we were so dehydrated we had maximal ADH...

↑ Osmolality of extracellular fluids
↓
↑ ADH release from posterior pituitary
↓
↑ Number of aquaporins (H_2O channels) in collecting duct
↓
↑ H_2O reabsorption from collecting duct
↓
Small volume of concentrated urine



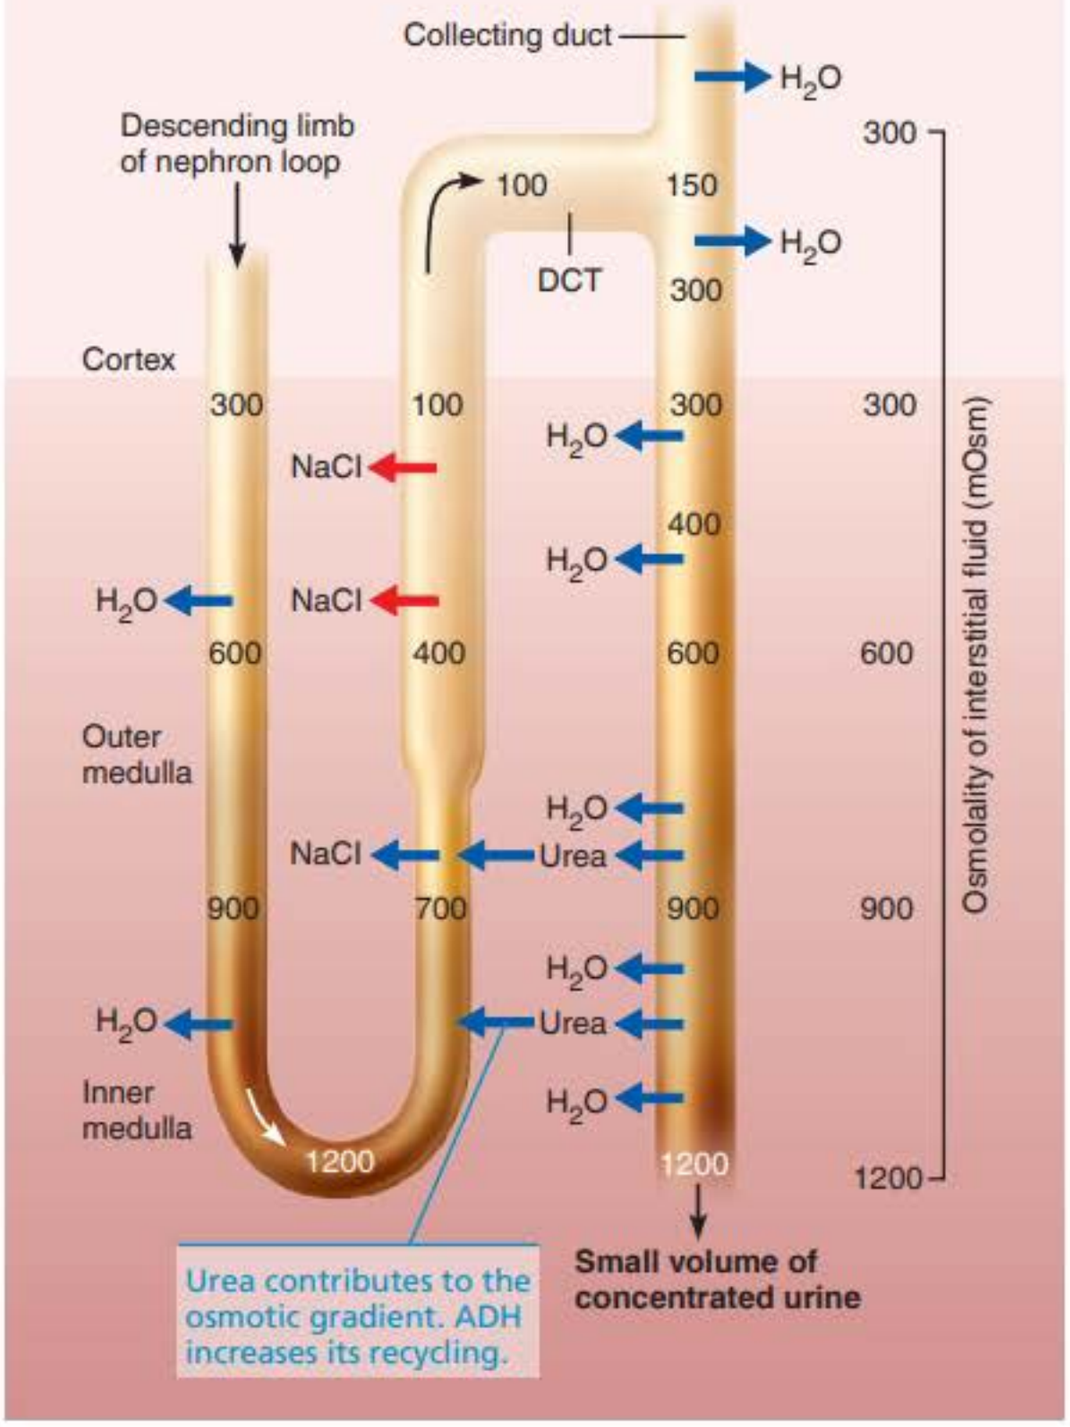


Figure 25.20 Mechanism for forming dilute or concentrated urine. Under the control of antidiuretic hormone (ADH), the collecting ducts fine-tune urine concentration using the medullary osmotic gradient.

Urea Recycling and the Medullary Osmotic Gradient

We're not quite done yet. There's one last piece of the puzzle left—urea. We usually think of urea as simply a metabolic waste product, but conserving water is so important that the kidneys actually use urea to help form the medullary gradient (Figure 25.20).

1. Urea enters the filtrate by facilitated diffusion in the ascending thin limb of the nephron loop.
2. As the filtrate moves on, the cortical collecting duct usually reabsorbs water, leaving urea behind.
3. When filtrate reaches the portion of the collecting duct in the deep medullary region, the now highly concentrated urea moves by facilitated diffusion out of the collecting duct into the interstitial fluid of the medulla. These movements form a pool of urea that recycles back into the ascending thin limb of the nephron loop. In this way, urea contributes substantially to the high osmolality in the medulla.

Antidiuretic hormone enhances urea transport out of the medullary collecting duct. When ADH is present, it increases urea recycling and strengthens the medullary osmotic gradient, allowing more concentrated urine to be formed.

Diuretics

There are several types of **diuretics**, chemicals that enhance urinary output. Alcohol encourages diuresis by inhibiting release of ADH. Other diuretics increase urine flow by inhibiting Na^+ reabsorption and the obligatory water reabsorption that normally follows. Examples include many drugs prescribed for hypertension (◀ p. 724) or the edema of congestive heart failure (◀ p. 700). Most diuretics inhibit Na^+-associated symporters. "Loop diuretics" (like furosemide) are powerful because they inhibit formation of the medullary gradient by acting at the ascending limb of the nephron loop. Thiazides are less potent and act at the DCT. An *osmotic diuretic* is a substance that is not reabsorbed and that carries water out with it (for example, the high blood glucose of a diabetes mellitus patient).

Check Your Understanding

17. Describe the special characteristics of the descending and ascending limbs of the nephron loop that cause the formation of the medullary osmotic gradient.
18. Under what conditions is ADH released from the posterior pituitary? What effect does ADH have on the collecting ducts?

For answers, see Answers Appendix.

25.8 Renal function is evaluated by analyzing blood and urine

Learning Outcomes

- **Define renal clearance and explain how this value summarizes the way a substance is handled by the kidney.**
- **Describe the normal physical and chemical properties of urine.**
- **List several abnormal urine components, and name the condition characterized by the presence of detectable amounts of each.**

Since the time of the ancient Greek Hippocrates, physicians have examined their patients' urine for signs of disease. **Urinalysis**, the analysis of urine, can aid in the diagnosis of diseases or detect illegal substances. However, to measure how well the kidneys are functioning, we need to analyze *both blood and urine*. Renal function can quickly be assessed by measuring levels of *nitrogenous wastes* in blood. But to precisely measure kidney function, we need to determine the renal clearance, which requires that both blood and urine be tested. Normal blood and urine values for various substances are found in Appendix F.

Renal Clearance

Renal clearance refers to the volume of plasma from which the kidneys clear (completely remove) a particular substance in a given time, usually 1 minute. Renal clearance tests are done to determine the GFR, which allows us to detect glomerular damage and follow the progress of renal disease.

The renal clearance rate (C) of any substance, in ml/min, is calculated from the equation

$$C = UV/P$$

where

U = concentration of the substance in urine (mg/ml)

V = flow rate of urine formation (ml/min)

P = concentration of the substance in plasma (mg/ml)

Because it is freely filtered and neither reabsorbed nor secreted by the kidneys, *inulin* (in′u-lin) is the substance used to determine the GFR. Inulin is a plant polysaccharide that has a renal clearance value equal to the GFR. When inulin is infused such that its plasma concentration is 1 mg/ml (P = 1 mg/ml), then generally U = 125 mg/ml, and V = 1 ml/min. Therefore, its renal clearance is $C = (125 \times 1)/1 = 125$ ml/min, meaning that in 1 minute the kidneys have cleared all the inulin present in 125 ml of plasma.

The clearance value tells us about the net handling of a substance by the kidneys. There are three possible cases:

- A clearance value less than that of inulin means that the substance is reabsorbed. For example, C is normally 70 ml/min for urea, meaning that of the 125 ml of glomerular filtrate formed each minute, approximately 70 ml is completely cleared of urea, while the urea in the remaining 55 ml is recovered and returned to the plasma. If C is zero (such as for glucose in healthy individuals), reabsorption is complete or the substance is not filtered.
- If C is equal to that of inulin, there is no net reabsorption or secretion.
- If C is greater than that of inulin, the tubule cells are secreting the substance into the filtrate. This is the case with most drug metabolites. Knowing a drug's renal clearance value is essential because if it is high, the drug dosage must also be high and administered frequently to maintain a therapeutic level.

Creatinine, which has a *C* value of 140 ml/min, is freely filtered but also secreted in small amounts. Nevertheless, its measured blood value is often used to give an estimate of GFR. This is convenient because creatinine does not need to be intravenously infused into the patient as does inulin.

HOMEOSTATIC IMBALANCE 25.4 — CLINICAL

Chronic renal disease, defined as a GFR of less than 60 ml/min for at least three months, often develops silently over many years. Filtrate formation decreases gradually, nitrogenous wastes accumulate in the blood, and blood pH drifts toward the acidic range. The leading cause of chronic renal disease is diabetes mellitus (44% of new cases), with hypertension a close second (28% of new cases). Other causes include repeated kidney infections, physical trauma, and heavy metal poisoning.

In **renal failure** (GFR < 15 ml/min), filtrate formation decreases or stops completely. The clinical syndrome associated with renal failure is called **uremia** (literally "urine in the blood") and includes fatigue, anorexia, nausea, mental changes, and muscle cramps.

While uremia was once attributed to accumulation of nitrogenous wastes (particularly urea), we now know that urea is not especially toxic. Rather, this multiorgan failure is caused by the interplay of multiple factors. These include ionic and hormonal imbalances (including anemia due to lack of erythropoietin; ◀ p. 648), as well as metabolic abnormalities and accumulation of various toxic molecules that interfere with normal metabolism.

Current treatment options are hemodialysis or a kidney transplant. **Hemodialysis** uses an "artificial kidney" apparatus, passing the patient's blood through a membrane tubing that is permeable only to selected substances. The tubing is immersed in a solution that differs slightly from normal cleansed plasma. As blood circulates through the tubing, substances such as nitrogenous wastes and K^+ present in the blood (but not in the bath) diffuse out of the blood into the surrounding solution. Meanwhile, substances to be added to the blood, mainly buffers for H^+ (and glucose for malnourished patients), move from the bathing solution into the blood. In this way, hemodialysis retains or adds needed substances, while removing wastes and excess ions.

Urine

Chemical Composition

Water accounts for about 95% of urine volume; the remaining 5% consists of solutes. The largest component of urine by weight, apart from water, is **urea**, which is derived from the normal breakdown of amino acids. Other **nitrogenous wastes** in urine include **uric acid** (an end product of nucleic acid metabolism) and **creatinine** (a metabolite of creatine phosphate, which is found in large amounts in skeletal muscle tissue where it stores energy to regenerate ATP; ◀ p. 304).

Normal solute constituents of urine, in order of decreasing concentration, are urea, Na^+, K^+, PO_4^{3-}, SO_4^{2-}, creatinine, and uric acid. Much smaller but highly variable amounts of Ca^{2+}, Mg^{2+}, and HCO_3^- are also present.

Unusually high concentrations of any solute, or the presence of abnormal substances such as plasma proteins, WBCs (pus), or bile pigments, may indicate pathology (**Table 25.3**). (Normal urine values are listed in Appendix F.)

Physical Characteristics

Color and Transparency Freshly voided urine is clear and pale to deep yellow. Its yellow color is due to **urochrome** (u′rokrōm), a pigment that results when the body destroys hemoglobin. The more concentrated the urine, the deeper the color.

An abnormal color (such as pink, brown, or a smoky tinge) may result from eating certain foods (beets, rhubarb) or from the presence of bile pigments or blood in the urine. Additionally, some commonly prescribed drugs and vitamin supplements alter the color of urine. Cloudy urine may indicate a urinary tract infection.

Odor Fresh urine is slightly aromatic, but if allowed to stand, it develops an ammonia odor as bacteria metabolize its urea solutes. Some drugs and vegetables alter the odor of urine, as do some diseases. For example, in uncontrolled diabetes mellitus the urine smells fruity because of its acetone content.

Table 25.3 Abnormal Urinary Constituents

SUBSTANCE	NAME OF CONDITION	POSSIBLE CAUSES
Glucose	Glycosuria	Diabetes mellitus
Proteins	Proteinuria, albuminuria	Nonpathological: excessive physical exertion, pregnancy Pathological (over 150 mg/day): glomerulonephritis (see Related Clinical Terms on p. 1008), severe hypertension, heart failure, often an initial sign of renal disease
Ketone bodies	Ketonuria	Excessive formation and accumulation of ketone bodies, as in starvation and untreated diabetes mellitus
Hemoglobin	Hemoglobinuria	Various: transfusion reaction, hemolytic anemia, severe burns, etc.
Bile pigments	Bilirubinuria	Liver disease (hepatitis, cirrhosis) or obstruction of bile ducts from liver or gallbladder
Erythrocytes	Hematuria	Bleeding urinary tract (due to trauma, kidney stones, infection, or cancer)
Leukocytes (pus)	Pyuria	Urinary tract infection

pH Urine is usually slightly acidic (around pH 6), but changes in body metabolism or diet may cause the pH to vary from about 4.5 to 8.0. A predominantly *acidic* diet that contains large amounts of protein and whole wheat products produces acidic urine. A vegetarian (*alkaline*) diet, bacterial infection of the urinary tract, or prolonged drainage of the stomach via a nasogastric tube all cause the urine to become alkaline.

Specific Gravity The ratio of the mass of a substance to the mass of an equal volume of distilled water is its **specific gravity**. Because urine is water plus solutes, a given volume has a greater mass than the same volume of distilled water. The specific gravity of distilled water is 1.0 and that of urine ranges from 1.001 to 1.035, depending on its solute concentration.

Check Your Understanding

19. What are the three major nitrogenous wastes excreted in the urine?

20. PREDICT What would you expect the normal clearance value for amino acids to be? Explain.

For answers, see Answers Appendix.

25.9 The ureters, bladder, and urethra transport, store, and eliminate urine

Learning Outcomes

- **Describe the general location, structure, and function of the ureters, urinary bladder, and urethra.**
- **Compare the course, length, and functions of the male urethra with those of the female.**
- **Define micturition and describe its neural control.**

The kidneys form urine continuously and the ureters transport it to the bladder. It is usually stored in the bladder until its release through the urethra in a process called *micturition*.

25

Ureters

The **ureters** are slender tubes that convey urine from the kidneys to the bladder (Figures 25.1, 25.2, and 25.23). Each ureter begins at the level of L_2 as a continuation of the renal pelvis. From there, it descends behind the peritoneum and runs obliquely through the posterior bladder wall. This arrangement prevents backflow of urine because any increase in bladder pressure compresses and closes the distal ends of the ureters.

Histologically, the ureter wall has three layers (**Figure 25.21**). From the inside out:

- The *mucosa* contains a transitional epithelium (◀ p. 123) that is continuous with the mucosae of the kidney pelvis superiorly and the bladder medially.
- The *muscularis* is composed chiefly of two smooth muscle sheets: the internal longitudinal layer and the external circular layer. An additional smooth muscle layer, the external longitudinal layer, appears in the lower third of the ureter.
- The *adventitia* covering the ureter's external surface is typical fibrous connective tissue.

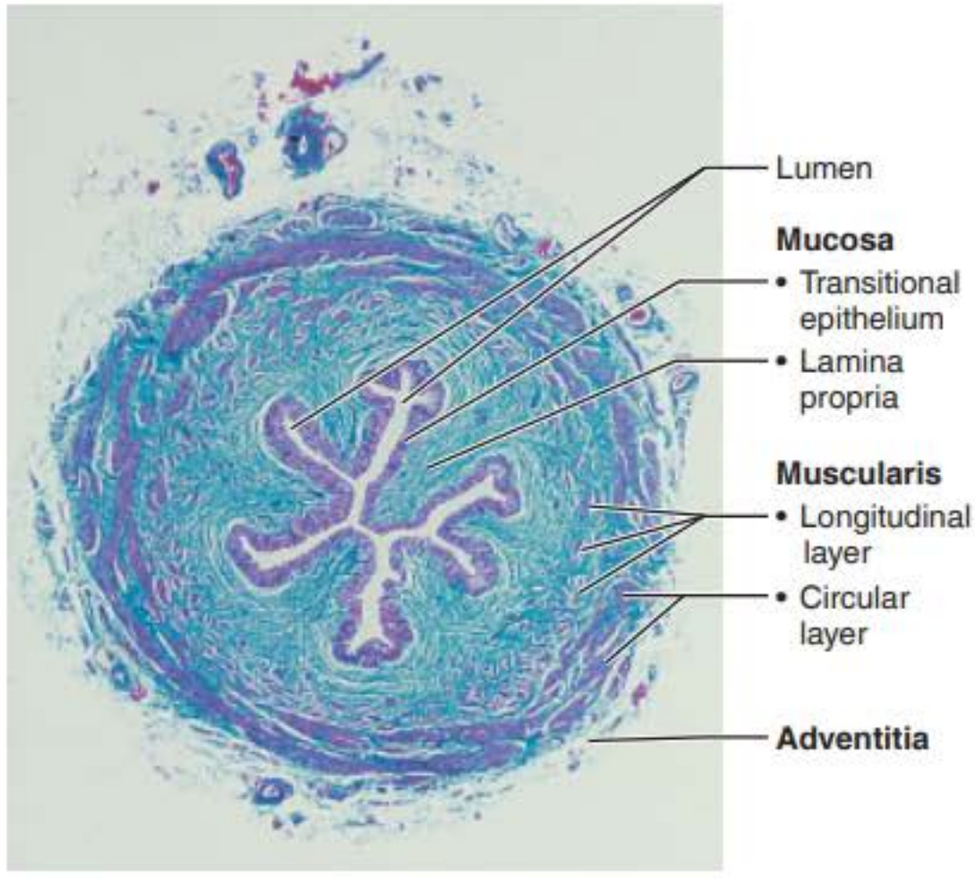

Figure 25.21 Cross section of the ureter wall (10×). The prominent mucosal folds seen in an empty ureter stretch and flatten to accommodate large pulses of urine.

Practice Histology questions:
MasteringA&P® > Study Area > Lab Tools > PAL

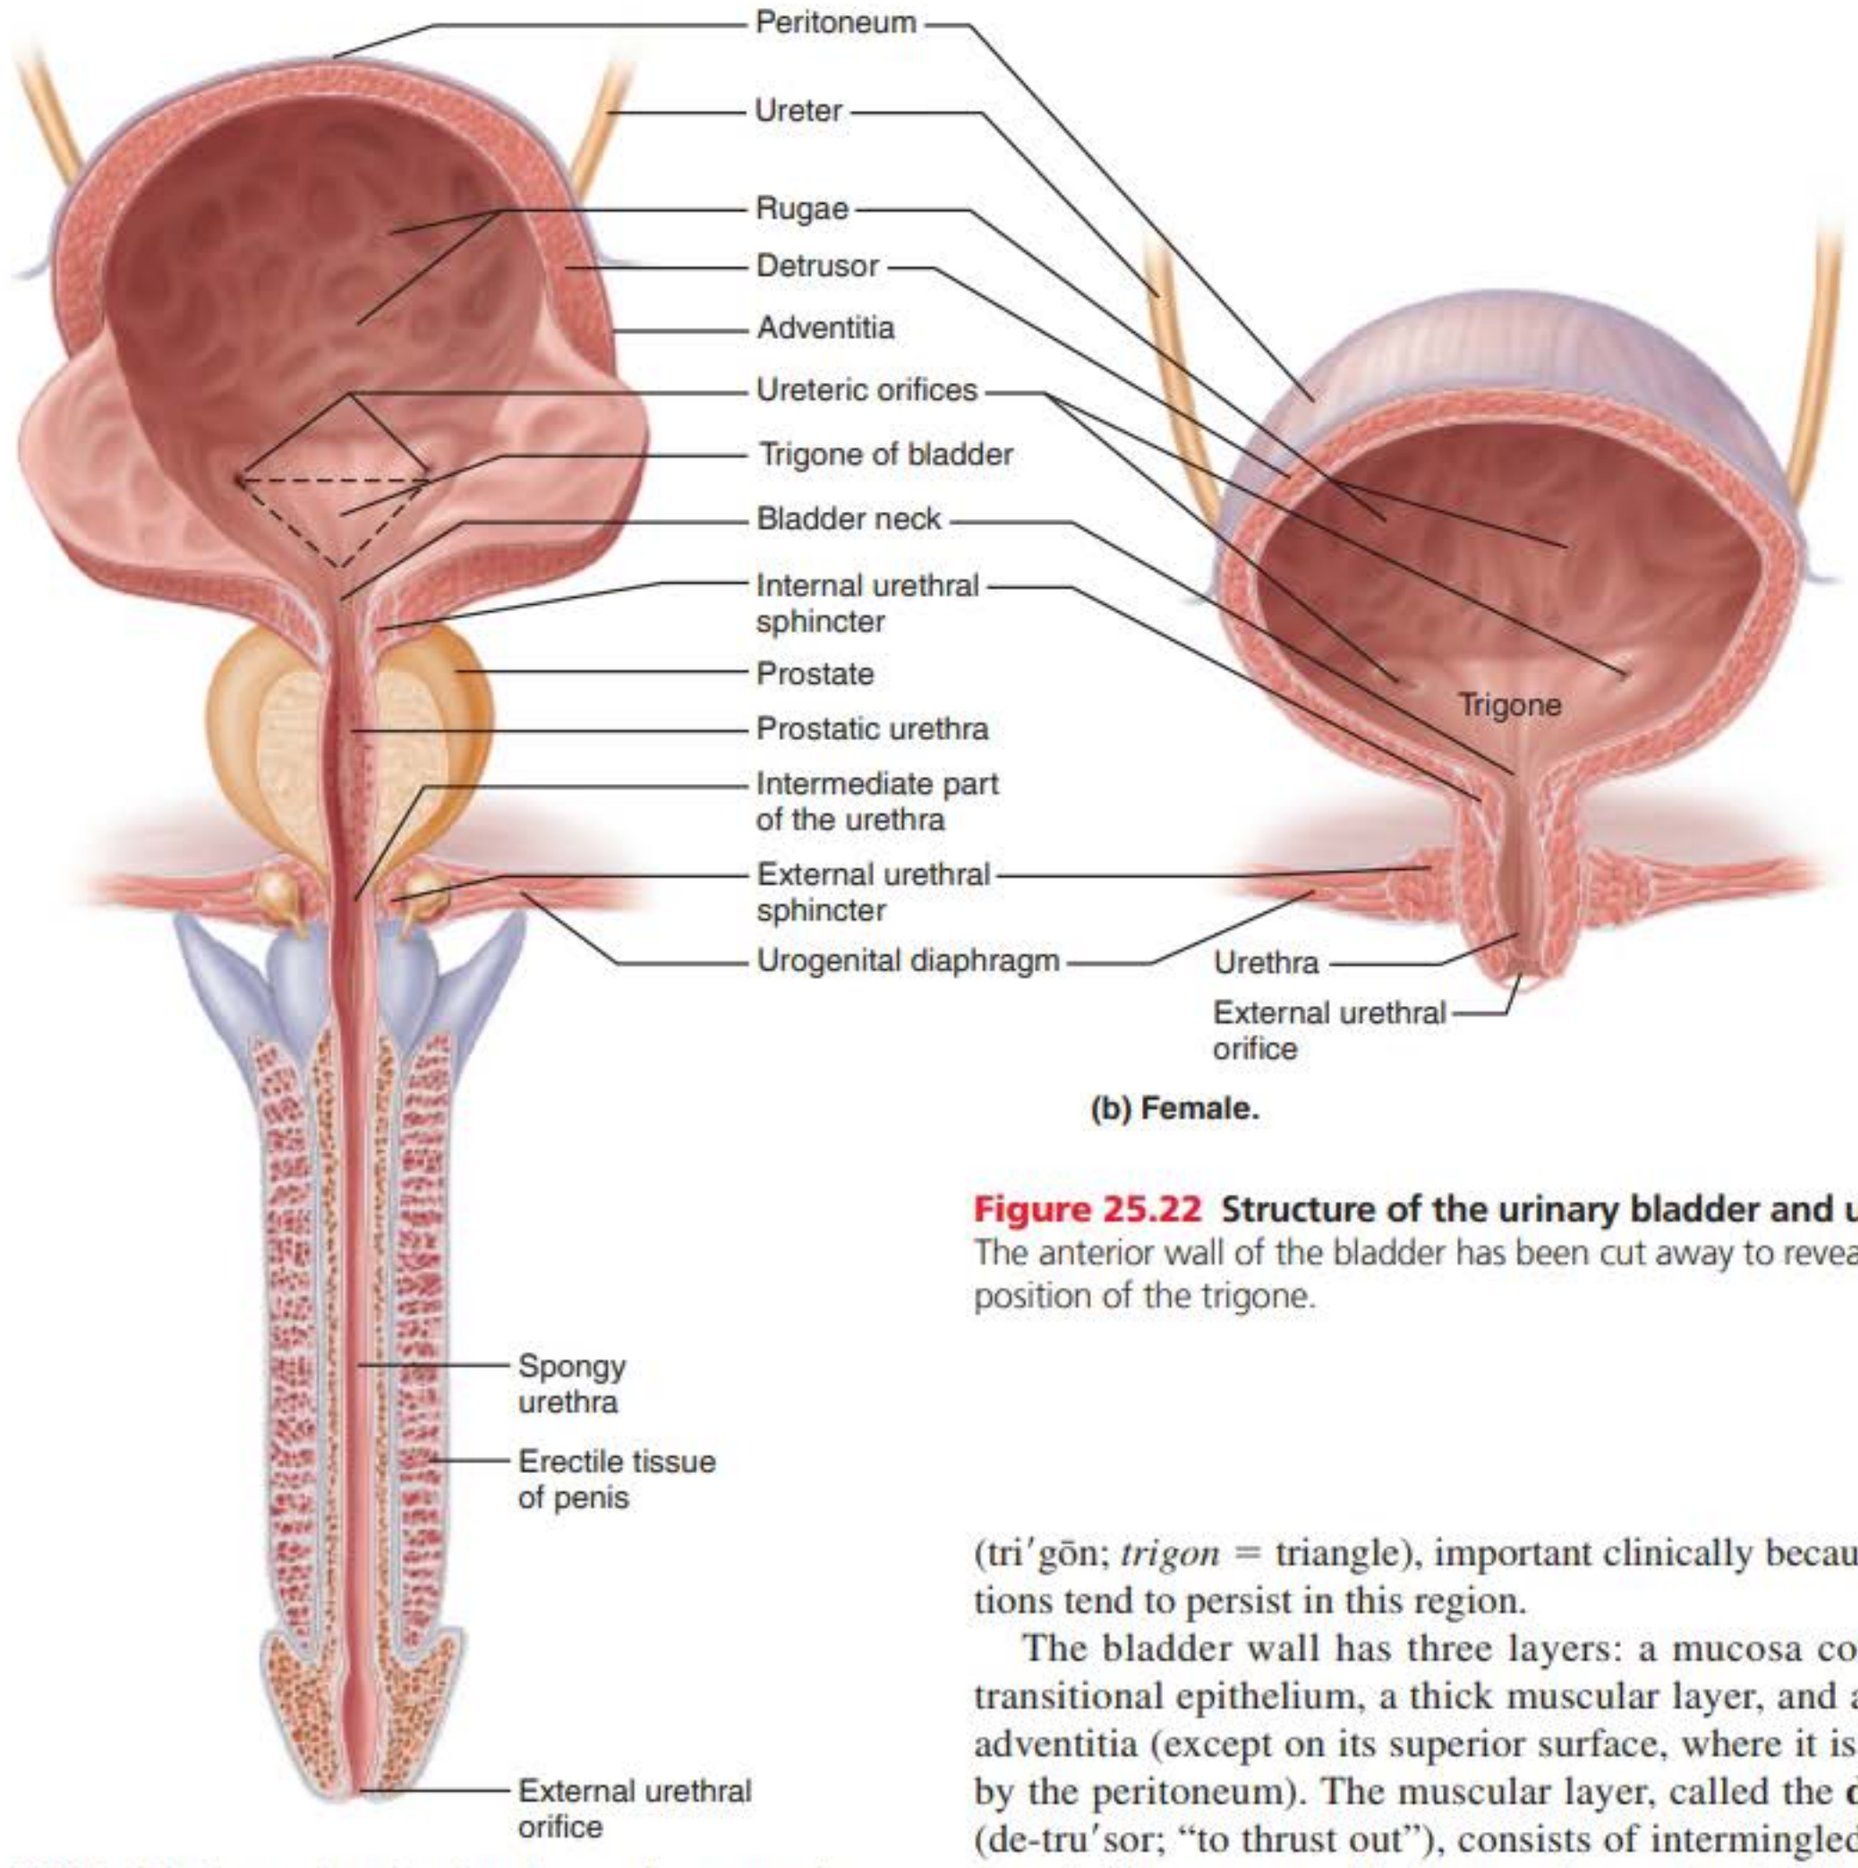
The ureter plays an active role in transporting urine. Incoming urine distends the ureter and stimulates its muscularis to contract, propelling urine into the bladder. (Urine does *not* reach the bladder through gravity alone.) The strength and frequency of the peristaltic waves are adjusted to the rate of urine formation. Both sympathetic and parasympathetic fibers innervate each ureter, but neural control of peristalsis appears to be insignificant compared to the way ureteral smooth muscle responds to stretch.

HOMEOSTATIC IMBALANCE 25.5 — CLINICAL

When calcium or magnesium salts or uric acid are concentrated in urine, they may crystallize and precipitate as "kidney stones," or **renal calculi** (kal′ku-li; *calculus* = little stone). If stones obstruct urine flow, they cause excruciating pain radiating from the flank to the abdomen. *Nephrolithiasis* (*litho* = stone; *iasis* = condition) refers to calculi in the kidney, whereas *ureterolithiasis* refers to calculi lodged in the ureters.

While most small calculi pass without intervention, larger calculi or those that lodge in the ureter can be removed endoscopically or surgically. Many calculi, especially those in the kidney, can be treated by *lithotripsy*, a noninvasive procedure that uses acoustic wave energy to break stones into smaller pieces that may be passed more easily.

Obesity and elevated blood calcium are risk factors for the formation of renal calculi. The best way to prevent recurrence is to maintain dilute urine by adequate hydration.



(a) **Male.** The long male urethra has three regions: prostatic, intermediate, and spongy.

(b) **Female.**

Figure 25.22 Structure of the urinary bladder and urethra. The anterior wall of the bladder has been cut away to reveal the position of the trigone.

Urinary Bladder

The **urinary bladder** is a smooth, collapsible, muscular sac that stores urine temporarily.

Urinary Bladder Anatomy

The bladder is located retroperitoneally on the pelvic floor just posterior to the pubic symphysis. The prostate (part of the male reproductive system) lies inferior to the bladder neck, which empties into the urethra. In females, the bladder is anterior to the vagina and uterus (see Figure 27.15 on p. 1061).

The interior of the bladder has openings for both ureters and the urethra (**Figure 25.22**). The smooth, triangular region of the bladder base outlined by these three openings is the **trigone** (tri′gōn; *trigon* = triangle), important clinically because infections tend to persist in this region.

The bladder wall has three layers: a mucosa containing transitional epithelium, a thick muscular layer, and a fibrous adventitia (except on its superior surface, where it is covered by the peritoneum). The muscular layer, called the **detrusor** (de-tru′sor; "to thrust out"), consists of intermingled smooth muscle fibers arranged in inner and outer longitudinal layers and a middle circular layer.

Urine Storage Capacity

The bladder is very distensible. When empty, the bladder collapses into its basic pyramidal shape. Its walls are thick and the mucosa is thrown into folds (*rugae*). As urine accumulates, the bladder expands, becomes pear shaped, and rises superiorly in the abdominal cavity. The transitional epithelium and muscular wall stretch and thin, and rugae disappear. These changes allow the bladder to store more urine without a significant rise in internal pressure.

Usually, a moderately full bladder holds approximately 500 ml (1 pint) of urine. However, if urine flow has been partially obstructed for a long time (as by an enlarged prostate), then the bladder can become enlarged to hold more than twice that amount. When tense with urine, it can be palpated well above the pubic symphysis.

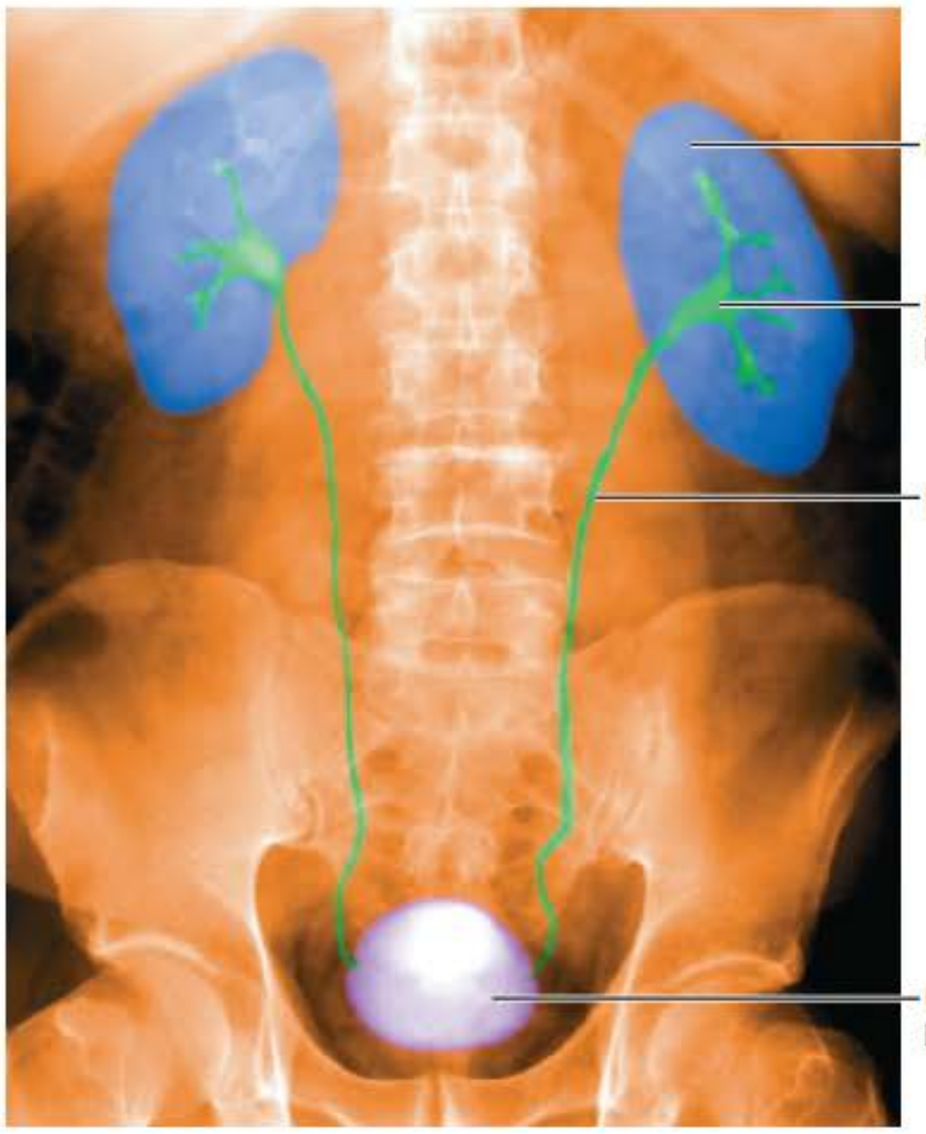


Figure 25.23 Pyelogram. This X-ray image was obtained using a contrast medium to show the ureters, kidneys, and urinary bladder. (Artificially colored.)

The urinary bladder and ureters can be seen in a special X ray called a pyelogram (**Figure 25.23**).

Urethra

The **urethra** is a thin-walled muscular tube that drains urine from the bladder and conveys it out of the body. The epithelium of its mucosal lining is mostly pseudostratified columnar epithelium. However, near the bladder it becomes transitional epithelium, and near the external opening it changes to a protective stratified squamous epithelium.

At the bladder-urethra junction, the detrusor smooth muscle thickens to form the **internal urethral sphincter** (Figure 25.22). This involuntary sphincter, controlled by the autonomic nervous system, keeps the urethra closed when urine is not being passed and prevents leaking between voiding.

The **external urethral sphincter** surrounds the urethra as it passes through the *urogenital diaphragm*. This sphincter is formed of skeletal muscle and is voluntarily controlled. The *levator ani* muscle of the pelvic floor also serves as a voluntary constrictor of the urethra (◀ Table 10.7, pp. 348–349).

The length and functions of the urethra differ in the two sexes. In females the urethra is only 3–4 cm (1.5 inches) long and fibrous connective tissue binds it tightly to the anterior vaginal wall. Its external opening, the **external urethral orifice**, lies anterior to the vaginal opening and posterior to the clitoris.

In males the urethra is approximately 20 cm (8 inches) long and has three regions.

- The **prostatic urethra**, about 2.5 cm (1 inch) long, runs within the prostate.
- The **intermediate part of the urethra** (or *membranous urethra*), which runs through the urogenital diaphragm, extends about 2 cm from the prostate to the beginning of the penis.
- The **spongy urethra**, about 15 cm long, passes through the penis and opens at its tip via the **external urethral orifice**.

The male urethra has a double function: It carries semen as well as urine out of the body. We discuss its reproductive function in Chapter 27.

HOMEOSTATIC IMBALANCE 25.6 — CLINICAL

Urinary tract infection (UTI) is a common problem, with up to 50% of women experiencing a UTI during their lives. The location of the female urethra near the anus predisposes it to colonization by fecal bacteria. Sexual activity and the use of spermicides increase the risk. In both men and women, catheterization or any condition that obstructs the normal flow of urine also predisposes an individual to acquiring a UTI.

Infection of the urinary bladder, or *cystitis*, causes urinary *frequency* (increased voiding) and *dysuria* (painful urination). The urine may be blood tinged or foul smelling. If the infection ascends to the kidney, the more serious *pyelonephritis* (see p. 977) results, accompanied by fever, back pain, and other symptoms of systemic illness. After the offending bacteria are identified by culturing the urine, antibiotics are used to treat the problem.

Micturition

Micturition (mik″tu-rish′un; *mictur* = urinate), also called **urination** or *voiding*, is the act of emptying the urinary bladder. For micturition to occur, three things must happen simultaneously: (1) the detrusor must contract, (2) the internal urethral sphincter must open, and (3) the external urethral sphincter must open.

The detrusor and its internal urethral sphincter are composed of smooth muscle and are innervated by both the parasympathetic and sympathetic nervous systems, which have opposing actions. The external urethral sphincter, in contrast, is skeletal muscle, and therefore is innervated by the somatic nervous system.

How are the three events required for micturition coordinated? Micturition is most easily understood in infants where a spinal reflex coordinates the process. As urine accumulates, distension of the bladder activates stretch receptors in its walls. Impulses from the activated receptors travel via visceral afferent fibers to the sacral region of the spinal cord. Visceral afferent impulses, relayed by sets of interneurons, excite parasympathetic neurons and inhibit sympathetic neurons (**Figure 25.24**). As a result, the detrusor contracts and the internal sphincter opens. Visceral afferent impulses also decrease the firing rate of somatic efferents that normally keep the external urethral sphincter closed. This allows the sphincter to relax so urine can flow.

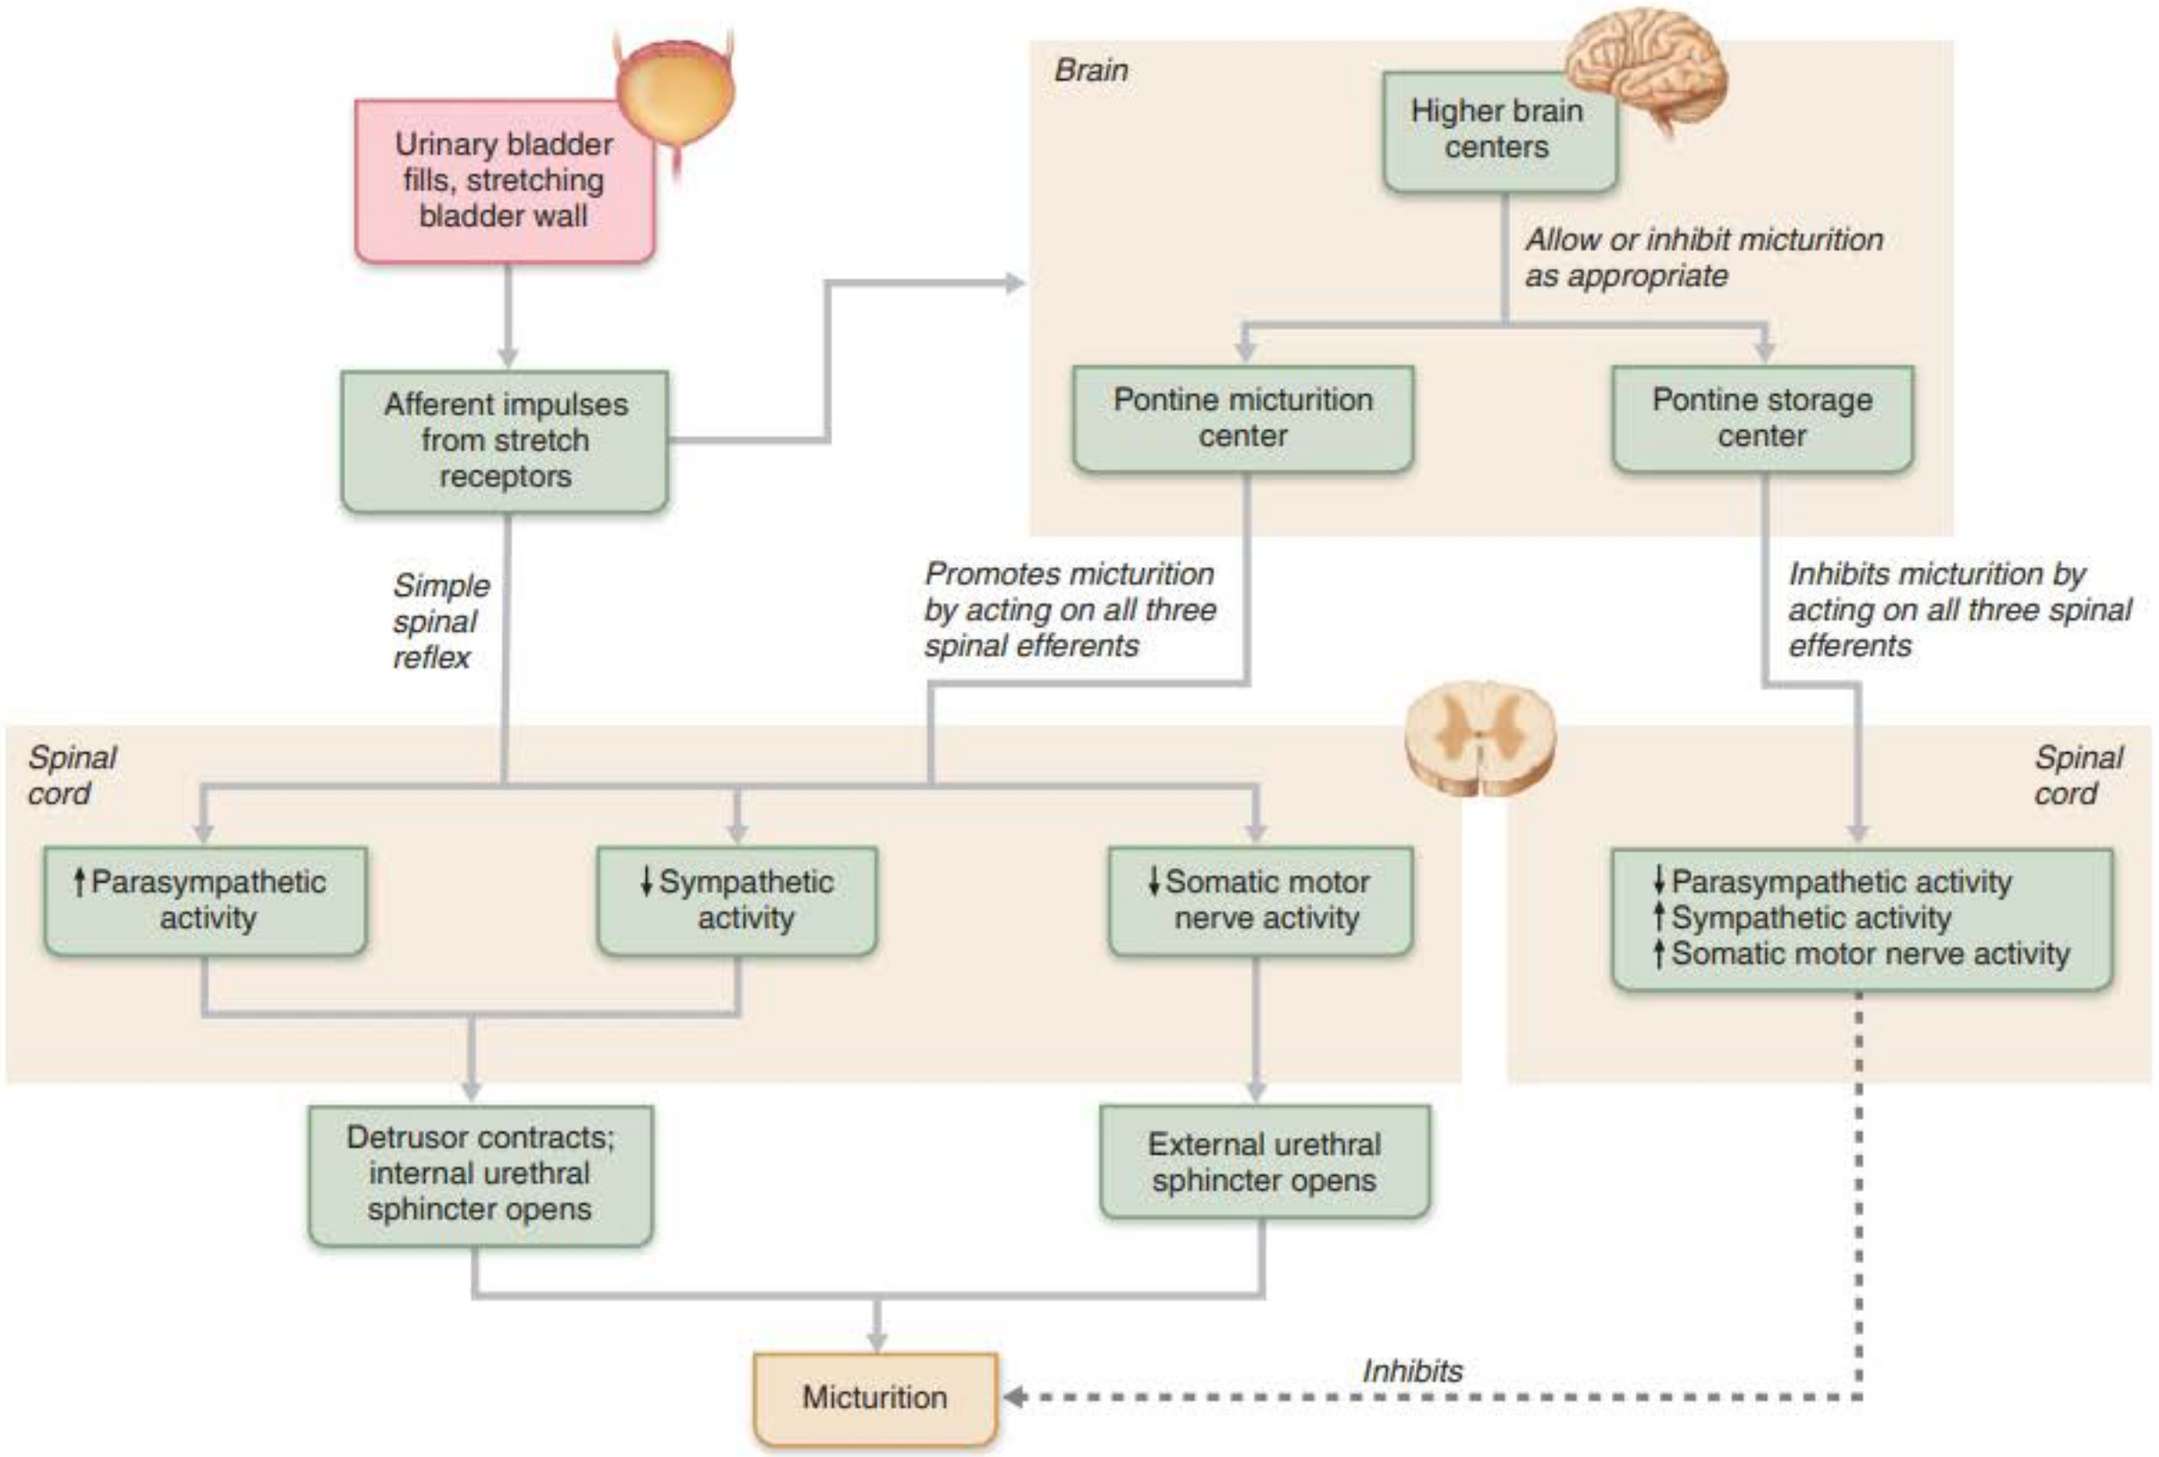

Figure 25.24 Control of micturition.

Between ages 2 and 3, descending circuits from the brain have matured enough to begin to override reflexive urination. The pons (◀ p. 452) has two centers that participate in control of micturition. The *pontine storage center* inhibits micturition, whereas the *pontine micturition center* promotes this reflex. Afferent impulses from bladder stretch receptors are relayed to the pons, as well as to higher brain centers that provide the conscious awareness of bladder fullness.

Lower bladder volumes primarily activate the pontine storage center, which inhibits urination by suppressing parasympathetic and enhancing sympathetic output to the bladder. When a person chooses not to void, reflex bladder contractions subside within a minute or so and urine continues to accumulate. Because the external sphincter is voluntarily controlled, we can choose to keep it closed and postpone bladder emptying temporarily. After additional urine has collected, the micturition reflex occurs again and, if urination is delayed again, is damped once more.

The urge to void gradually becomes greater and greater, and micturition usually occurs before urine volume exceeds 400 ml. After normal micturition, only about 10 ml of urine remains in the bladder.

HOMEOSTATIC IMBALANCE 25.7 — CLINICAL

In adults, **urinary incontinence** (the inability to control urination) is usually a result of weakened pelvic muscles following childbirth or surgery, physical pressure during pregnancy, or nervous system problems. In *stress incontinence*, a sudden increase in intra-abdominal pressure (during laughing and coughing) forces urine through the external sphincter. This condition is common during pregnancy when the heavy uterus stretches the muscles of the pelvic floor and the urogenital diaphragm (◀ p. 348) that support the external sphincter. In *overflow incontinence*, urine dribbles from the urethra whenever the bladder overfills.

In **urinary retention**, the bladder is unable to expel its contained urine. Urinary retention is common after general anesthesia (it takes a little time for the detrusor to regain its activity). Urinary retention in men often reflects hypertrophy of the prostate, which narrows the urethra, making it difficult to void. When urinary retention is prolonged, a slender drainage tube called a **catheter** (kath′ĕ-ter) must be inserted through the urethra to drain the urine and prevent bladder trauma from excessive stretching.

successively higher sources. Although the lower blood vessels usually degenerate, they sometimes persist, and for this reason multiple renal arteries are common. The metanephric kidneys excrete urine by the third month of fetal life, and most of the amniotic fluid that surrounds a developing fetus is fetal urine. Nonetheless, the fetal kidneys do not work nearly as hard as they will after birth because exchange through the placenta allows the mother's urinary system to clear most of the undesirable substances from the fetal blood.

As the metanephros is developing, the cloaca subdivides to form the future rectum and anal canal and the **urogenital sinus**, into which the urinary and genital ducts empty. The urinary bladder and the urethra then develop from the urogenital sinus (Figure 25.25b–d).

HOMEOSTATIC IMBALANCE 25.8 CLINICAL

Three of the most common congenital abnormalities of the urinary system are horseshoe kidney, hypospadias, and polycystic kidney.

When ascending from the pelvis the kidneys are very close together, and in 1 out of 600 people they fuse across the midline, forming a single, U-shaped *horseshoe kidney*. This condition is usually asymptomatic, but it may be associated with other kidney abnormalities, such as obstructed drainage, that increase the risk of frequent kidney infections.

Hypospadias (hi″po-spa′de-as), found in male infants only, is the most common congenital abnormality of the urethra. It occurs when the urethral orifice is located on the ventral surface of the penis. This problem may be corrected surgically when the child is around 12 months old.

Polycystic kidney disease (*PKD*) is a group of disorders characterized by the presence of many fluid-filled cysts in the kidneys. These interfere with renal function, ultimately leading to renal failure. These disorders can be grouped into two general forms based on their pattern of inheritance:

- *Autosomal dominant PKD*, the less severe form, is much more common, affecting 1 in 500 people. The cysts develop so gradually that they produce no symptoms until about 40 years of age.
- *Autosomal recessive PKD* is more severe and much less common, affecting 1 in 20,000 people. Almost half of newborns with recessive PKD die just after birth, and survivors generally develop renal failure in early childhood.

Because its bladder is very small and its kidneys are less able to concentrate urine for the first two months, a newborn baby voids 5 to 40 times daily, depending on fluid intake. By 2 months, infants void approximately 400 ml/day, and the amount steadily increases until adolescence, when adult urine output (about 1500 ml/day) is achieved.

Incontinence is normal in infants because their nervous systems have not matured enough to control the external urethral sphincter. Reflex voiding occurs each time a baby's bladder fills enough to activate the stretch receptors. Control of the voluntary urethral sphincter goes hand in hand with nervous system development. By 15 months, most toddlers know when they have voided. By 24 months, some children are ready to begin toilet training. Daytime control usually is achieved first. It is unrealistic to expect complete nighttime control before age 4.

From childhood through late middle age, most urinary system problems are infectious conditions. *Escherichia coli* bacteria are normal residents of the digestive tract and generally cause no problems there, but these bacteria account for 80% of all urinary tract infections. *Sexually transmitted infections* can also inflame the urinary tract and clog some of its ducts. Childhood streptococcal infections such as strep throat and scarlet fever, if not treated promptly, may cause long-term inflammatory renal damage.

Only about 3% of elderly people have histologically normal kidneys, and kidney function declines with advancing age. The kidneys shrink as the nephrons decrease in size and number, and the tubule cells become less efficient. By age 80, the GFR of healthy seniors is only about 70% that of young adults. Diabetics are particularly at risk for renal disease, accounting for almost half of new cases.

Loss of bladder tone with age can cause an annoying increase in frequency of micturition. *Nocturia* (nok-tu′re-ah), the need to get up during the night to urinate, plagues almost two-thirds of this population. Many people eventually experience incontinence, which can usually be treated with exercise, medications, or surgery.

RELATED CLINICAL TERMS

Bladder cancer Bladder cancer, three times more common in men than in women, accounts for about 2% of all cancer deaths. It usually involves neoplasms of the bladder's lining epithelium and may be induced by carcinogens from the environment or the workplace that end up in urine. Smoking, exposure to industrial chemicals, and arsenic in drinking water have also been linked to bladder cancer. Blood in the urine is a common warning sign.

Cystocele (sis′to-sēl; *cyst* = a sac, the bladder; *cele* = hernia, rupture) Herniation of the urinary bladder into the vagina; a common result of tearing of the pelvic floor muscles during childbirth.

Cystoscopy (sis-tos′ko-pe; *cyst* = bladder; *scopy* = observation) Procedure in which a thin viewing tube is threaded into the bladder through the urethra to examine the bladder's mucosal surface.

Diabetes insipidus (in-sĭ′pĭ-dus; *insipid* = tasteless, bland) See Chapter 16, p. 614. Nephrogenic diabetes insipidus is due to lack of ADH receptors in the collecting duct.

Glomerulonephritis (GN) (glo-mer″u-lo-nef-ri′tis) Inflammation of the glomeruli, leading to increased permeability of the filtration membrane. In some cases, circulating immune complexes (antibodies bound to foreign substances, such as streptococcal bacteria) become trapped in the glomerular basement membranes. In other cases, immune responses are mounted against one's own kidney tissues, leading to glomerular damage. In either case, the inflammatory response that follows damages the filtration membrane, allowing blood proteins and even blood cells to pass into the renal tubules and into the urine. As the osmotic pressure of blood drops, fluid seeps from the bloodstream into the tissue spaces, causing bodywide edema. Renal shutdown requiring dialysis may occur temporarily, but normal renal function usually returns within a few months. If permanent glomerular damage occurs, acute GN becomes chronic GN and ultimately renal failure results.

Intravenous pyelogram (IVP) (pi′ĕ-lo-gram; *pyelo* = kidney pelvis; *gram* = written) An X ray of the kidneys and ureters obtained after intravenous injection of a contrast medium (as in Figure 25.23).

Nephrotoxin A substance (heavy metal, organic solvent, or bacterial toxin) that is toxic to the kidneys.

Nocturnal enuresis (NE) (en″u-re′sis) An inability to control urination at night during sleep; bed-wetting. In children over 6, called primary NE if control has never been achieved and secondary NE if control was achieved and then lost. Secondary NE often has psychological causes. Primary NE is more common and results from a combination of inadequate nocturnal ADH production, unusually sound sleep, or a small bladder capacity. Synthetic ADH often corrects the problem.

Renal infarct Area of dead, or necrotic, renal tissue due to blockage of the vascular supply to the kidney or hemorrhage. A common cause of localized renal infarct is an obstructed interlobar artery. Because interlobar arteries do not anastomose, their obstruction leads to ischemic necrosis of the portions of the kidney they supply.

Urologist (u-rol′o-jist) Physician who specializes in diseases of urinary structures in both sexes and in diseases of the reproductive tract of males.

CHAPTER SUMMARY

25.1 The kidneys have three distinct regions and a rich blood supply (pp. 975–978)

Location and External Anatomy (pp. 975–976)

1. The paired kidneys are retroperitoneal in the superior lumbar region.
2. A fibrous capsule, a perirenal fat capsule, and renal fascia surround each kidney. The perirenal fat capsule helps hold the kidneys in position.

Internal Gross Anatomy (pp. 976–977)

3. A kidney has a superficial cortex, a deeper medulla consisting mainly of medullary pyramids, and a medial pelvis. Extensions of the pelvis (calyces) surround and collect urine draining from the apices of the medullary pyramids.

Blood and Nerve Supply (pp. 977–978)

4. The kidneys receive 25% of the total cardiac output per minute.
5. The vascular pathway through a kidney is as follows: renal artery → segmental arteries → interlobar arteries → arcuate arteries → cortical radiate arteries → afferent arterioles → glomeruli → efferent arterioles → peritubular capillary beds → cortical radiate veins → arcuate veins → interlobar veins → renal vein.
6. The nerve supply of the kidneys is derived from the renal plexus.

25.2 Nephrons are the functional units of the kidney (pp. 978–983)

1. Nephrons are the structural and functional units of the kidneys.
2. Each nephron consists of a glomerulus (a high-pressure capillary bed), a glomerular capsule, and a renal tubule that is continuous with the capsule. Subdivisions of the renal tubule (from the glomerular capsule) are the proximal convoluted tubule, nephron loop, and distal convoluted tubule. A second capillary bed, the low-pressure peritubular capillary bed, is closely associated with the renal tubule of each nephron.
3. The more numerous cortical nephrons are located almost entirely in the cortex; only a small part of their nephron loop penetrates into the medulla. Glomeruli of juxtamedullary nephrons are located near the cortex-medulla junction, and their nephron loops dip deeply into the medulla. Instead of directly forming peritubular capillaries, the efferent arterioles of many juxtamedullary nephrons form unique bundles of straight vessels, called vasa recta, that serve tubule segments in the medulla. Juxtamedullary nephrons and the vasa recta play an important role in establishing the medullary osmotic gradient.
4. Collecting ducts receive urine from many nephrons and help concentrate urine. They form the medullary pyramids.
5. The juxtaglomerular complex is at the point of contact between the afferent arteriole and the most distal part of the ascending limb of the nephron loop. It consists of the granular cells, the macula densa, and extraglomerular mesangial cells.

25.3 Overview: Filtration, absorption, and secretion are the key processes of urine formation (pp. 983–984)

1. Functions of the nephrons include glomerular filtration, tubular reabsorption, and tubular secretion. Via these functional processes, the kidneys regulate the volume, composition, and pH of the blood, and eliminate nitrogenous metabolic wastes.

25.4 Urine formation, step 1: The glomeruli make filtrate (pp. 984–989)

1. The filtration membrane consists of the fenestrated glomerular endothelium, the intervening basement membrane, and the podocyte-containing visceral layer of the glomerular capsule. It permits free passage of substances smaller than (most) plasma proteins.
2. The glomeruli function as filters. High glomerular blood pressure (55 mm Hg) occurs because the glomeruli are fed and drained by arterioles, and the afferent arterioles are larger in diameter than the efferent arterioles.
3. About one-fifth of the plasma flowing through the kidneys is filtered from the glomeruli into the glomerular capsule.
4. Usually about 10 mm Hg, the net filtration pressure (NFP) is determined by the relationship between forces favoring filtration (glomerular hydrostatic pressure) and forces that oppose it (capsular hydrostatic pressure and blood colloid osmotic pressure).

5. The glomerular filtration rate (GFR) is directly proportional to the net filtration pressure and is about 125 ml/min (180 L/day).
6. Intrinsic renal control, or renal autoregulation, enables the kidneys to maintain a relatively constant renal blood flow and glomerular filtration rate. Intrinsic control involves a myogenic mechanism and a tubuloglomerular feedback mechanism mediated by the macula densa.
7. Extrinsic control of GFR, via nerves and hormones, maintains blood pressure. Strong sympathetic nervous system activation causes constriction of the afferent arterioles, which decreases filtrate formation.
8. The renin-angiotensin-aldosterone mechanism raises systemic blood pressure by generating angiotensin II. Renin is released from granular cells in response to (1) direct sympathetic nervous system stimulation, (2) paracrines released by the macula densa, and (3) reduced stretch of granular cell membranes.

Complete an interactive tutorial: MasteringA&P® > Study Area > Interactive Physiology > Urinary System > Glomerular Filtration

25.5 Urine formation, step 2: Most of the filtrate is reabsorbed into the blood (pp. 989–994)

1. During tubular reabsorption, needed substances are removed from the filtrate by the tubule cells and returned to the peritubular capillary blood. The primary active transport of Na^+ by a Na^+-K^+ ATPase pump at the basolateral membrane accounts for Na^+ reabsorption and establishes the electrochemical gradient that drives the reabsorption of most other solutes and H_2O. Na^+ enters at the apical surface of the tubule cell via facilitated diffusion through channels or as part of a cotransport mechanism.
2. Passive tubular reabsorption is driven by electrochemical gradients established by active reabsorption of sodium ions. Water, many ions, and various other substances (for example, urea) are reabsorbed passively by diffusion via transcellular or paracellular pathways.
3. Secondary active tubular reabsorption occurs by cotransport with Na^+ via transport proteins. Transport of such substances is limited by the number of carriers available. Actively reabsorbed substances include glucose, amino acids, and some ions.
4. The proximal tubule cells are most active in reabsorption. Most of the nutrients, 65% of the water and sodium ions, and the bulk of actively transported ions are reabsorbed in the proximal convoluted tubules.
5. Reabsorption of additional sodium ions and water occurs in the distal tubules and collecting ducts and is hormonally controlled. Aldosterone increases the reabsorption of sodium; antidiuretic hormone (ADH) enhances water reabsorption by the collecting ducts.

Complete an interactive tutorial: MasteringA&P® > Study Area > Interactive Physiology > Urinary System > Tubular Reabsorption and Secretion

25.6 Urine formation, step 3: Certain substances are secreted into the filtrate (pp. 994–995)

1. Tubular secretion adds substances to the filtrate (from the blood or tubule cells). It is an active process that is important in eliminating drugs, certain wastes, and excess ions and in maintaining the acid-base balance of the blood.

25.7 The kidneys create and use an osmotic gradient to regulate urine concentration and volume (pp. 995–1000)

1. The graduated hyperosmolality of the medullary fluids (largely due to the cycling of NaCl and urea) ensures that the filtrate reaching the distal convoluted tubule is dilute (hypo-osmolar). This allows urine with osmolalities ranging from 50 to 1200 mOsm to be formed.
   - The descending limb of the nephron loop is permeable to water, which leaves the filtrate and enters the medullary interstitial space. The filtrate and medullary fluid at the bend of the nephron loop are hyperosmolar.
   - The ascending limb is impermeable to water. Na^+ and Cl^- move out of the filtrate into the interstitial space, passively in the thin portion and actively in the thick portion. The filtrate becomes more dilute.
   - As filtrate flows through the collecting ducts in the inner medulla, urea diffuses into the interstitial space. From here, urea reenters the ascending thin limb and is recycled.
   - The blood flow in the vasa recta is sluggish, and the contained blood equilibrates with the medullary interstitial fluid. Hence, blood exiting the medulla in the vasa recta is nearly isotonic to blood plasma and the high solute concentration of the medulla is maintained.
2. In the absence of antidiuretic hormone, dilute urine is formed because the dilute filtrate reaching the collecting duct is simply allowed to pass from the kidneys.
3. When extracellular fluid osmolality rises, blood levels of antidiuretic hormone rise, and the collecting ducts become more permeable to water. Water moves out of the filtrate as it flows through the hyperosmotic medullary areas. Consequently, more concentrated urine is produced, and in smaller amounts.

25.8 Renal function is evaluated by analyzing blood and urine (pp. 1000–1002)

Renal Clearance (pp. 1000–1001)

1. Renal clearance is the volume of plasma that is completely cleared of a particular substance per minute. Studies of renal clearance provide information about renal function or the course of renal disease.
2. Renal failure has serious consequences: The kidneys are unable to concentrate urine, acid-base and electrolyte imbalances occur, and nitrogenous wastes accumulate in the blood.

Urine (pp. 1001–1002)

3. Urine is 95% water; solutes include nitrogenous wastes (urea, uric acid, and creatinine) and various ions (always sodium, potassium, sulfate, and phosphate).
4. Substances not normally found in urine include glucose, proteins, erythrocytes, leukocytes, hemoglobin, and bile pigments.
5. Urine is typically clear, yellow, aromatic, and slightly acidic. Its specific gravity ranges from 1.001 to 1.035.

25.9 The ureters, bladder, and urethra transport, store, and eliminate urine (pp. 1002–1006)

Ureters (p. 1002)

1. The ureters are slender tubes running retroperitoneally from each kidney to the bladder. They conduct urine by peristalsis from the renal pelvis to the urinary bladder.

Urinary Bladder (pp. 1003–1004)

2. The urinary bladder, which functions to store urine, is a distensible muscular sac that lies posterior to the pubic symphysis. It has two inlets (ureters) and one outlet (urethra) that outline the trigone. In males, the prostate surrounds the bladder outlet.
3. The bladder wall consists of a mucosa containing transitional epithelium; a three-layered detrusor; and an adventitia.

Urethra (p. 1004)

4. The urethra is a muscular tube that conveys urine from the bladder to the body exterior.
5. Where the urethra leaves the bladder, it is surrounded by an internal urethral sphincter, an involuntary smooth muscle sphincter. Where it passes through the urogenital diaphragm, the voluntary external urethral sphincter is formed by skeletal muscle.
6. In females the urethra is 3–4 cm long and conducts only urine. In males it is 20 cm long and conducts both urine and semen.

Micturition (pp. 1004–1005)

7. Micturition is emptying of the bladder.
8. Accumulating urine stretches the bladder wall, which initiates the micturition reflex. In infants, this is a simple spinal reflex: Parasympathetic fibers are excited (and sympathetic fibers inhibited), causing the detrusor to contract and the internal urethral sphincter to open. In adults, pontine storage and micturition centers can override this simple reflex.
9. Because the external sphincter is voluntarily controlled, micturition can usually be delayed temporarily.

Developmental Aspects of the Urinary System (pp. 1006–1007)

1. Three sets of kidneys (pronephric, mesonephric, and metanephric) develop from the intermediate mesoderm. The metanephros excretes urine by the third month of development.
2. Common congenital abnormalities are horseshoe kidney, hypospadias, and polycystic kidney disease (PKD).
3. The kidneys of newborns are less able to concentrate urine; their bladder is small and voiding is frequent. Neuromuscular maturation generally allows toilet training for micturition to begin by 24 months of age.
4. The most common urinary system problems in children and young to middle-aged adults are bacterial infections.
5. With age, nephrons are lost, the filtration rate decreases, and tubule cells become less efficient at concentrating urine.
6. Bladder capacity and tone decrease with age, leading to frequent micturition and (often) incontinence. Urinary retention is a common problem of elderly men.

REVIEW QUESTIONS

To access additional practice questions using your smartphone, tablet, or computer: MasteringA&P® > Study Area > Practice Tests & Quizzes

Level 1 Remember/Understand

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. The lowest blood concentration of nitrogenous waste occurs in the **(a)** hepatic vein, **(b)** inferior vena cava, **(c)** renal artery, **(d)** renal vein.
2. The glomerular capillaries differ from other capillary networks in the body because they **(a)** have a larger area of anastomosis, **(b)** are derived from and drain into arterioles, **(c)** are not made of endothelium, **(d)** are sites of filtrate formation.
3. Damage to the renal medulla would interfere *first* with the functioning of the **(a)** glomerular capsules, **(b)** distal convoluted tubules, **(c)** collecting ducts, **(d)** proximal convoluted tubules.
4. Which is reabsorbed by the proximal convoluted tubule cells? **(a)** Na^+, **(b)** K^+, **(c)** amino acids, **(d)** all of the above.
5. Glucose is not normally found in the urine because it **(a)** does not pass through the walls of the glomerulus, **(b)** is kept in the blood by colloid osmotic pressure, **(c)** is reabsorbed by the tubule cells, **(d)** is removed by the body cells before the blood reaches the kidney.
6. Filtration at the glomerulus is inversely related to **(a)** water reabsorption, **(b)** capsular hydrostatic pressure, **(c)** arterial blood pressure, **(d)** acidity of the urine.
7. Tubular reabsorption **(a)** of glucose and many other substances is a T_m-limited active transport process, **(b)** of chloride is always linked to the passive transport of Na^+, **(c)** is the movement of substances from the blood into the nephron, **(d)** of sodium occurs only in the proximal tubule.
8. If a freshly voided urine sample contains excessive amounts of urochrome, it has **(a)** an ammonia-like odor, **(b)** a pH below normal, **(c)** a dark yellow color, **(d)** a pH above normal.
9. Which of the following is/are true about ADH? **(a)** It promotes obligatory water reabsorption, **(b)** it is secreted in response to an increase in extracellular fluid osmolality, **(c)** it causes insertion of aquaporins in the PCT, **(d)** it promotes Na^+ reabsorption.
10. What is the importance of the perirenal fat capsule that surrounds the kidney?
11. Define micturition and describe the micturition reflex.

Level 2 Apply/Analyze

12. Describe the mechanisms that contribute to renal autoregulation.
13. Describe the mechanisms of extrinsic regulation of GFR, and their physiological role.
14. Describe what is involved in active and passive tubular reabsorption.
15. Explain how the peritubular capillaries are adapted for receiving reabsorbed substances.
16. Explain the process and purpose of tubular secretion.
17. How does urinary bladder anatomy support its storage function?
18. Describe the changes that occur in kidney and bladder anatomy and physiology in old age.

Level 3 Evaluate/Synthesize

19. Trace the pathway a creatinine molecule takes from a glomerulus to the urethra. Name every microscopic or gross structure it passes through on its journey.
20. Explain the important differences between blood plasma and glomerular filtrate, and relate the differences to the structure of the filtration membrane.
21. How does aldosterone modify the chemical composition of urine?
22. Explain why the filtrate becomes hypotonic as it flows through the ascending limb of the nephron loop. Also explain why the filtrate at the bend of the nephron loop (and the interstitial fluid of the deep portions of the medulla) is hypertonic.

23. Mrs. Bigda, a 60-year-old woman, was brought to the hospital by the police after falling to the pavement. She is found to have alcoholic hepatitis. She is put on a salt- and protein-restricted diet and diuretics are prescribed to manage her ascites (accumulated fluid in the peritoneal cavity). How will diuretics reduce this excess fluid? Name and describe the mechanisms of action of three types of diuretics. Why is her diet salt-restricted?
24. While repairing a frayed utility wire, Kevin, an experienced lineman, slips and falls to the ground. Medical examination reveals a fracture of his lower spine and transection of the lumbar region of the spinal cord. How will Kevin's micturition be controlled from this point on? Will he ever again feel the need to void? Will there be dribbling of urine between voidings? Explain the reasoning behind all your responses.
25. Patty, aged 55, is awakened by excruciating pain that radiates from her right abdomen to the loin and groin regions on the same side. The pain is not continuous but recurs at intervals of 3 to 4 minutes. Diagnose her problem, and cite factors that might favor its occurrence.
26. Why are renal failure patients undergoing dialysis at risk for anemia and osteoporosis? What medications or supplements could you give them to prevent these problems?

CLINICAL CASE STUDY

32-Year-Old Diabetic Male on a Diuretic

Let's return to Kyle Boulard, whom we met in the previous chapter. Mr. Boulard has recovered from his acute diabetic crisis. The last update on his chart before he is discharged includes the following:

- BP 150/95, HR 75, temperature 37.2°C
- Urine: pH 6.9, negative for glucose and ketones; 24-hour urine collection reveals 170 mg albumin in urine per day

Mr. Boulard is prescribed a thiazide diuretic and an angiotensin converting enzyme (ACE) inhibitor. He is counseled on the importance of taking his medications regularly and keeping his outpatient follow-up appointments.

1. What is albumin? Is it normally found in the urine? What does its presence suggest?
2. ✚ NCLEX-STYLE Mr. Boulard's blood pressure is quite high. How would this affect his nephron function? Choose the statement below that is most accurate.
   a. The kidneys normally increase their rate of filtration when blood pressure increases.
   b. The kidneys normally increase their rate of reabsorption when blood pressure increases.
   c. The kidneys normally increase both their rate of filtration and reabsorption when blood pressure increases.
   d. The kidneys release more renin when blood pressure increases, activating the renin-angiotensin-aldosterone pathway.
3. Where and how do thiazide diuretics act in the kidneys and how does this reduce blood pressure?

At his two-week appointment at the outpatient clinic, Mr. Boulard complains of fatigue, weakness, muscle cramps, and irregular heartbeats. A physical examination and lab tests produce the following observations:

- BP 133/90, HR 75, temperature 37.3°C
- Blood K^+ 2.9 mEq/L (normal 3.5–5.5 mEq/L); blood Na^+ 135 mEq/L (normal 135–145 mEq/L)
- Urine K^+ 55 mEq/L (normal <40 mEq/L); urine Na^+ 21 mEq/L (normal >20 mEq/L)

4. What is Mr. Boulard's main problem at this point? Explain how the thiazide diuretic might have caused this problem.

When asked about his medications, Mr. Boulard admits that he did not fill his ACE inhibitor prescription because it was too expensive. He could only afford the thiazide medications along with his insulin.

5. How do ACE inhibitors reduce blood pressure?
6. ✚ NCLEX-STYLE You've counseled Mr. Boulard about how to prevent recurrence of his hypokalemia. Which of the statements he makes indicates a need for further instruction?
   a. "There's lots of potassium in fruits and vegetables, so I'll eat more bananas."
   b. "There's lots of potassium in regular table salt, so I'll just use more."
   c. "I guess I need to come in regularly and have potassium levels checked."
   d. "Maybe I should take a potassium supplement."

26 Fluid, Electrolyte, and Acid-Base Balance

In this chapter, you will learn that

The composition and volume of body fluids is tightly regulated

by first examining

26.1 Body fluid compartments

and

Body fluid composition

looking closer at

26.2 Water balance and ECF osmolality

26.3 Electrolyte balance

including

26.4 Acid-base balance

controlled by

Chemical buffer systems

Respiratory regulation

using

Respiratory system Ch. 22

26.5 Renal regulation

using

Urinary system Ch. 25

and asking

26.6 What happens when things go wrong?

and finally, exploring

Developmental Aspects of Fluid, Electrolyte, and Acid-Base Balance

Have you ever wondered why on some days you don't urinate for hours at a time, while on others it seems like you void every few minutes? Or why on occasion you cannot seem to quench your thirst? These situations reflect one of the body's most important functions: maintaining fluid, electrolyte, and acid-base balance.

Cell function depends not only on a continuous supply of nutrients and removal of metabolic wastes, but also on the physical and chemical homeostasis of the surrounding fluids. The French physiologist Claude Bernard recognized this truth with style in 1857 when he said, "It is the fixity of the internal environment which is the condition of free and independent life."

In this chapter, we first examine the composition and distribution of fluids in the internal environment and then consider the roles of various body organs and functions in establishing, regulating, and altering this balance.

26.1 Body fluids consist of water and solutes in three main compartments

Learning Outcomes

- **List the factors that determine body water content and describe the effect of each factor.**
- **Indicate the relative fluid volume and solute composition of the fluid compartments of the body.**
- **Contrast the overall osmotic effects of electrolytes and nonelectrolytes.**
- **Describe factors that determine fluid shifts in the body.**

Body Water Content

Not all bodies contain the same amount of water. Total body water is a function not only of age and body mass but also of sex and the relative amount of body fat. Infants, with their low body fat and low bone mass, are 73% or more water. (This high level of hydration accounts for their "dewy" skin, like that of a freshly picked peach.) After infancy total body water declines throughout life, accounting for only about 45% of body mass in old age.

A healthy young man is about 60% water, and a healthy young woman about 50%. This difference between the sexes reflects the fact that females have relatively more body fat and less skeletal muscle than males. Of all body tissues, adipose tissue is *least* hydrated (less than 20% water)—even bone contains more water than does fat. In contrast, skeletal muscle is about 75% water, so people with greater muscle mass have proportionately more body water.

Fluid Compartments

Water occupies two main **fluid compartments** within the body (**Figure 26.1**). Almost two-thirds by volume is in the **intracellular fluid (ICF) compartment**, which actually consists of trillions of tiny individual "compartments": the cells. In an adult male of average size (70 kg, or 154 lb), ICF accounts for about 25 L of the 40 L of body water.

The remaining one-third or so of body water is outside cells, in the **extracellular fluid (ECF) compartment**. The ECF

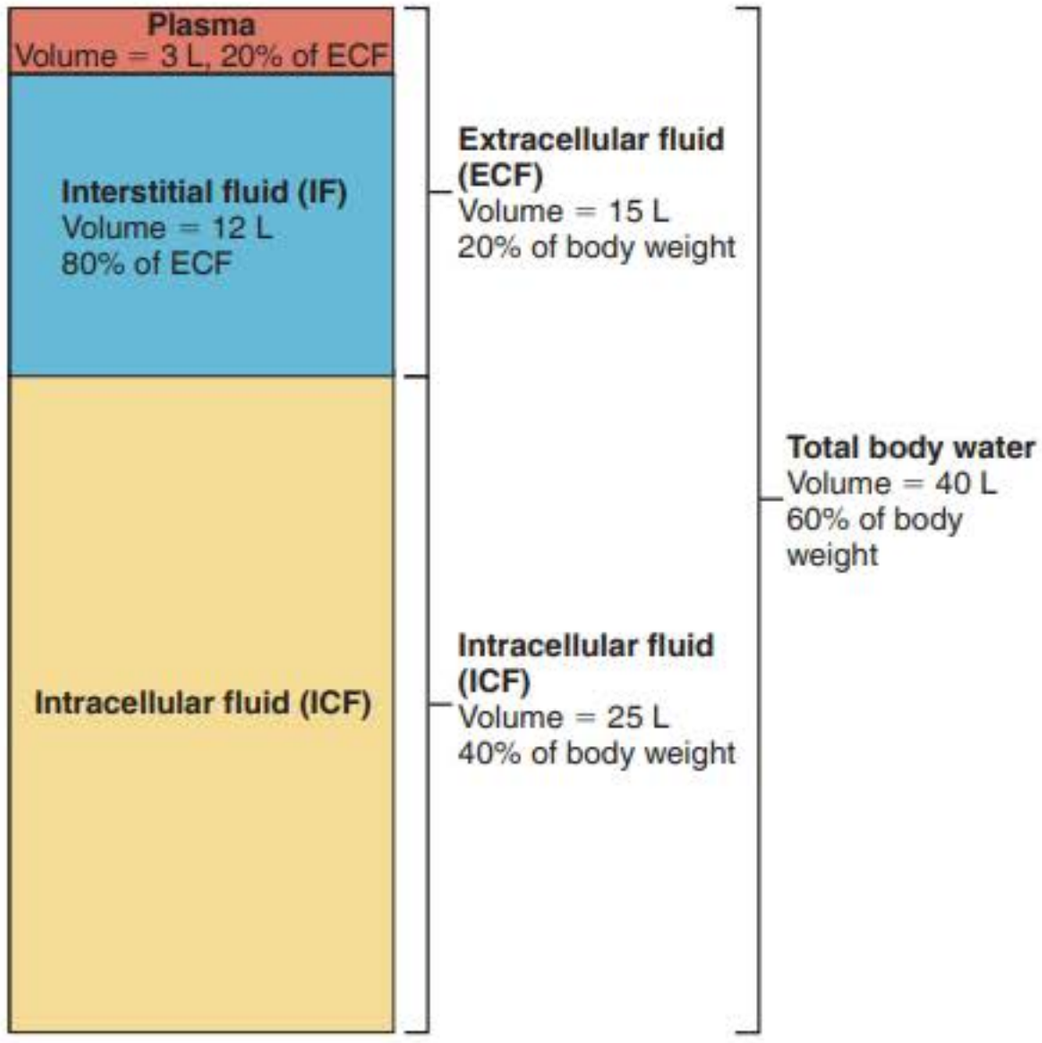

Figure 26.1 The major fluid compartments of the body.
[Values are for a 70-kg (154-lb) male.]

constitutes the body's "internal environment" referred to by Claude Bernard and is the external environment of each cell. As Figure 26.1 shows, the ECF compartment is divisible into two subcompartments: (1) **plasma**, the fluid portion of blood, and (2) **interstitial fluid (IF)**, the fluid in the microscopic spaces between tissue cells. There are numerous other examples of ECF that are distinct from both plasma and interstitial fluid—lymph, cerebrospinal fluid, humors of the eye, synovial fluid, serous fluid, gastrointestinal secretions—but most of these are similar to IF and are usually considered part of it.

Composition of Body Fluids

Water serves as the *universal solvent* in which a variety of solutes are dissolved. Solutes may be classified broadly as *electrolytes* and *nonelectrolytes*.

Electrolytes and Nonelectrolytes

Electrolytes are chemical compounds that dissociate into *ions* in water. (See Chapter 2, ◀ p. 39, if you need to review these concepts of chemistry.) Because ions are charged particles, they can conduct an electrical current—and so have the name *electrolyte*. Typically, electrolytes include inorganic salts, both inorganic and organic acids and bases, and some proteins.

In contrast, **nonelectrolytes** have bonds (usually covalent bonds) that prevent them from dissociating in solution. For this reason, no electrically charged species are created when nonelectrolytes dissolve in water. Most nonelectrolytes are organic molecules—glucose, lipids, creatinine, and urea, for example.

All dissolved solutes contribute to the osmotic activity of a fluid. However, electrolytes have much greater osmotic power than nonelectrolytes because each electrolyte molecule dissociates into at least two ions. For example, a molecule of sodium chloride (NaCl) contributes twice as many solute particles as glucose (which remains undissociated), and a molecule of magnesium chloride ($MgCl_2$) contributes three times as many:

$NaCl \rightarrow Na^+ + Cl^-$ (electrolyte; two particles)

$MgCl_2 \rightarrow Mg^{2+} + 2Cl^-$ (electrolyte; three particles)

glucose → glucose (nonelectrolyte; one particle)

Regardless of the type of solute particle, water moves according to osmotic gradients—from an area of lesser osmolality to an area of greater osmolality. For this reason, electrolytes have the greatest ability to cause fluid shifts.

Electrolyte concentrations of body fluids are usually expressed in **milliequivalents per liter (mEq/L)**, a measure of the number of electrical charges in 1 liter of solution. We can compute the concentration of electrical charges contributed by any ion using the equation

$$\text{mEq/L} = \frac{\text{ion concentration (mg/L)}}{\text{atomic weight of ion (mg/mmol)}} \times \begin{matrix}\text{no. of}\\ \text{electrical}\\ \text{charges on}\\ \text{one ion}\end{matrix}$$

(Recall from p. 30 that 1 millimole (mmol) = 0.001 mole.)

For example, to calculate the mEq/L of sodium or calcium ions in solution in plasma, we would determine the normal concentration of these ions in plasma, look up their atomic weights in the periodic table (see Appendix E), and plug these values into the equation:

$$Na^+: \quad \frac{3300 \text{ mg/L}}{23 \text{ mg/mmol}} \times 1 = 143 \text{ mEq/L}$$

$$Ca^{2+}: \quad \frac{100 \text{ mg/L}}{40 \text{ mg/mmol}} \times 2 = 5 \text{ mEq/L}$$

Notice that for ions with a single charge, 1 mEq is equal to 1 mmol, which, when dissolved in 1 kg of water, produces 1 mOsm (see p. 995). On the other hand, 1 mEq of ions with a double charge (like calcium) is equal to 1/2 mOsm. In either case, 1 mEq provides the same amount of charge.

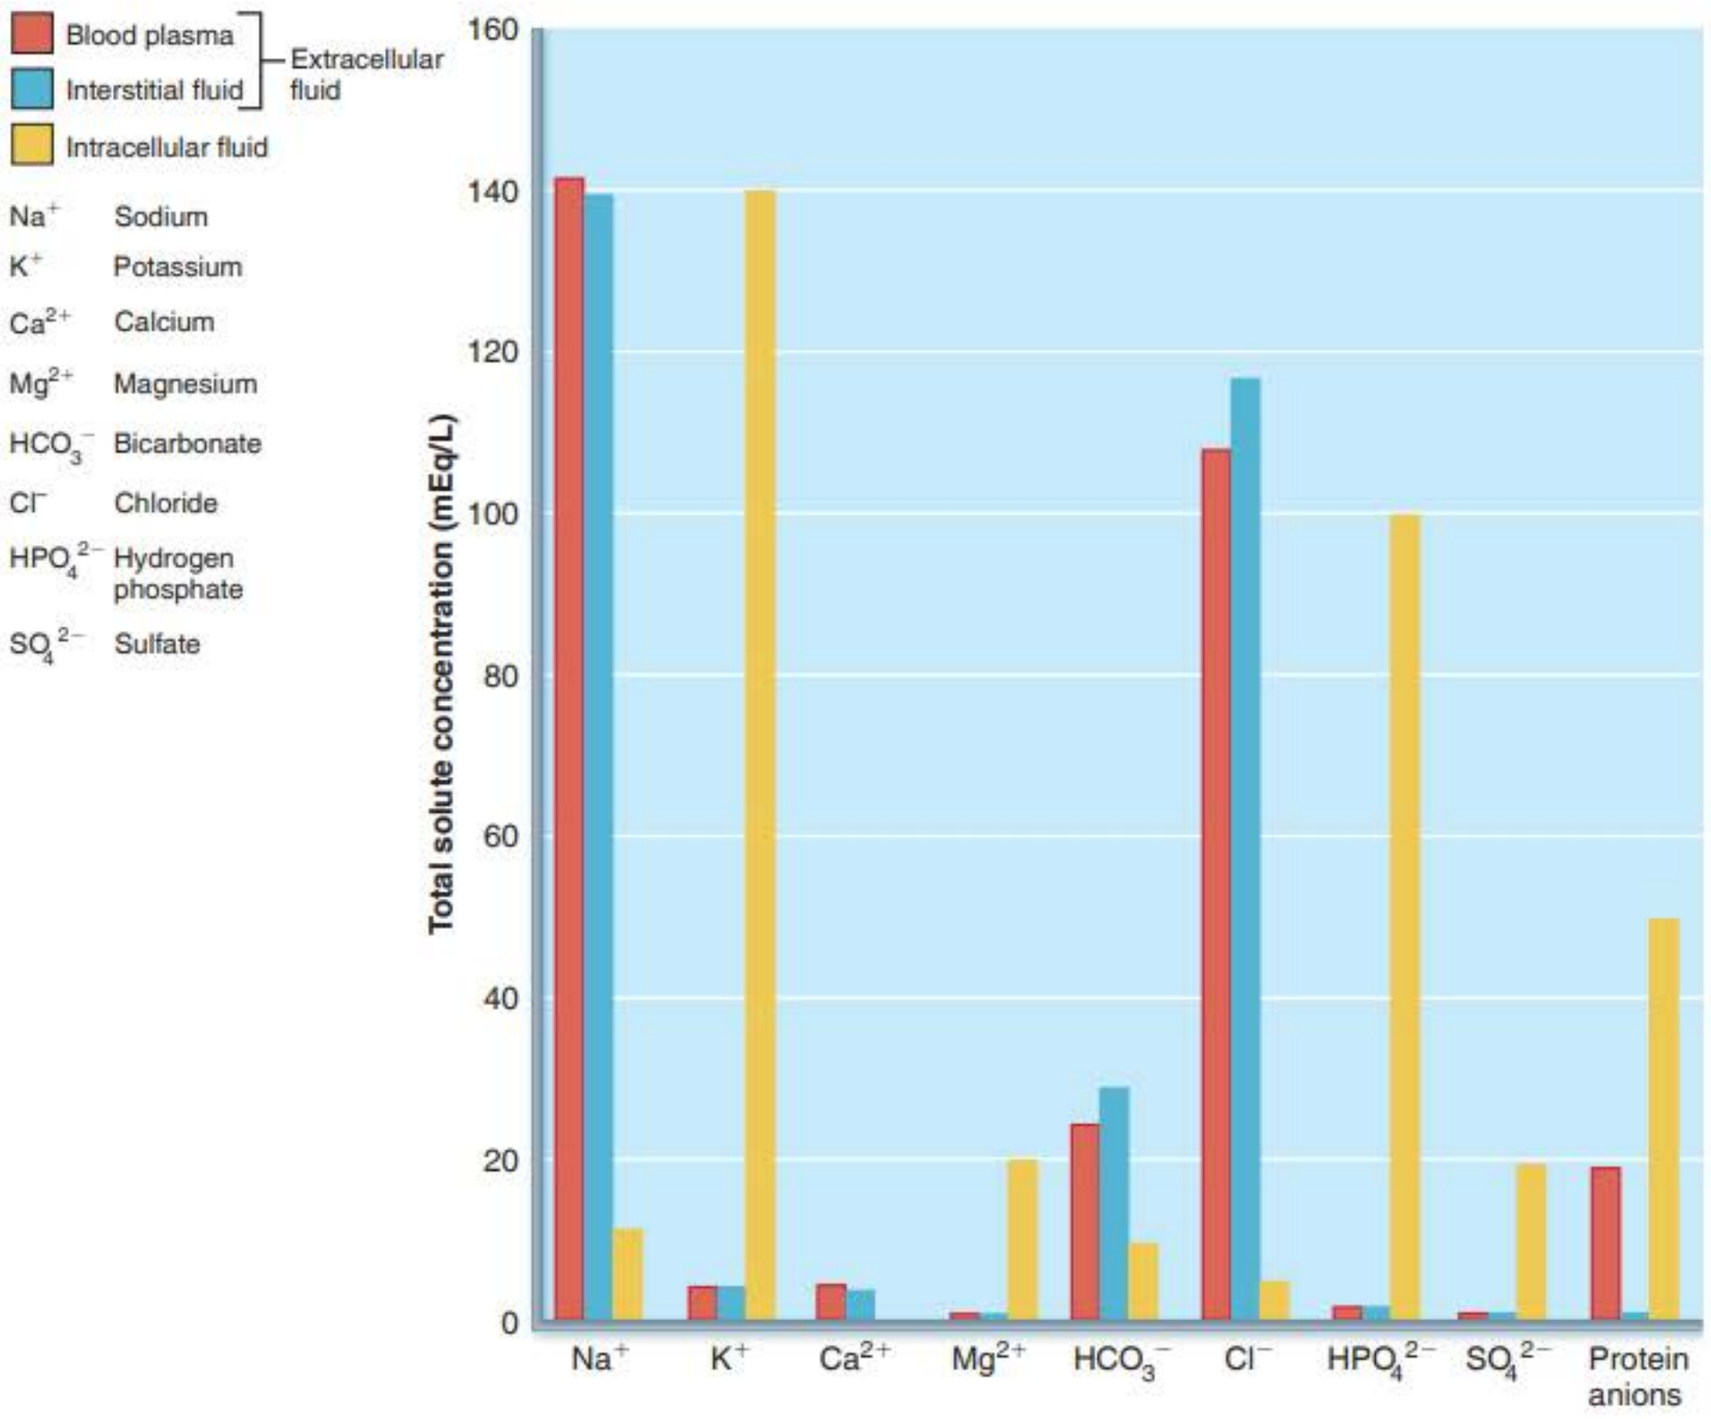

Figure 26.2 Electrolyte composition of blood plasma, interstitial fluid, and intracellular fluid. The very low intracellular Ca^{2+} concentration (10^{-7} *M*) does not include Ca^{2+} stores sequestered inside organelles. The high concentration of intracellular HPO_4^{2-} includes large amounts bound to intermediate metabolites, proteins, and lipids.

Comparison of Extracellular and Intracellular Fluids

A quick glance at the bar graphs in **Figure 26.2** reveals that each fluid compartment has a distinctive pattern of electrolytes. Except for the relatively high protein content in plasma (◀ p. 644), however, the extracellular fluids are very similar. Their chief cation is sodium, and their major anion is chloride. However, plasma contains somewhat fewer chloride ions than interstitial fluid because the nonpenetrating plasma proteins are normally anions and plasma is electrically neutral.

In contrast to extracellular fluids, the ICF contains only small amounts of Na^+ and Cl^-. Its most abundant cation is potassium, and its major anion is HPO_4^{2-}. Cells also contain substantial quantities of soluble proteins (about three times the amount found in plasma).

Notice that sodium and potassium ion concentrations in ECF and ICF are nearly opposite (Figure 26.2). The characteristic distribution of these ions on the two sides of cellular membranes reflects the activity of cellular ATP-dependent sodium-potassium pumps, which keep intracellular Na^+ concentrations low and K^+ concentrations high (◀ p. 75).

Electrolytes are the most abundant solutes in body fluids and determine most of their chemical and physical reactions, but they do not constitute the *bulk* of dissolved solutes in these fluids. Instead, the bulk of these fluids consists of large molecules such as proteins and some nonelectrolytes (phospholipids, cholesterol, and triglycerides). These account for about 90% of the mass of dissolved solutes in plasma, 60% in the IF, and 97% in the ICF.

Fluid Movement among Compartments

Osmotic and hydrostatic pressures regulate the continuous exchange and mixing of body fluids. Although water moves freely among the compartments along osmotic gradients, solutes are unequally distributed because of their size, electrical charge, or dependence on transport proteins. *Anything that changes the solute concentration in any compartment leads to net water flows.*

Figure 26.3 summarizes the exchanges of gases, solutes, and water across the body's borders and between the three fluid compartments within the body. In general, substances must pass through both the plasma and IF to reach the ICF. In the lungs, gastrointestinal tract, and kidneys, exchanges between the "outside world" and the plasma occur almost continuously. These exchanges alter plasma composition and volume, with plasma serving as the "highway" for delivering substances throughout the body. Compensating adjustments between the plasma and the other two fluid compartments follow quickly so that balance is restored.

Recall that:

- **Exchanges between plasma and IF occur across capillary walls.** We described the pressures driving these fluid movements in *Focus on Bulk Flow across Capillary Walls* (◀ **Focus Figure 19.1, pp. 732–733**). To recap, the hydrostatic pressure of blood forces nearly protein-free plasma out of the blood into the interstitial space. This filtered fluid is then almost completely reabsorbed into the bloodstream in response to the colloid osmotic pressure of plasma proteins. Under normal circumstances, lymphatic vessels pick up the small net leakage that remains behind in the interstitial space and return it to the blood.

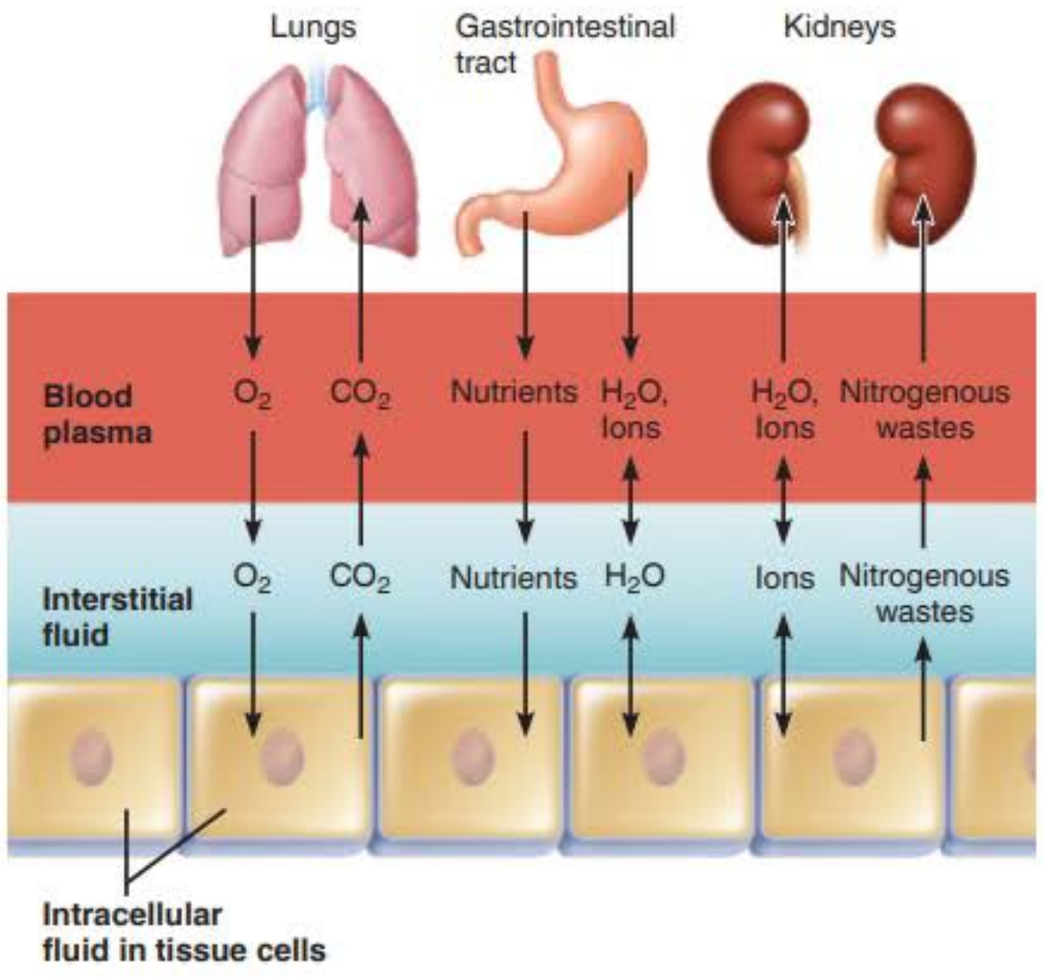

Figure 26.3 Exchange of gases, nutrients, water, and wastes between the three fluid compartments of the body.

- **Exchanges between the IF and ICF occur across plasma membranes.** As described in Chapter 3 (◀ **pp. 68–78**), exchanges across the plasma membrane depend on its permeability properties. As a general rule, two-way osmotic flow of water is substantial. But ion fluxes are restricted and, in most cases, ions move selectively by active transport or through channels. Movements of nutrients, respiratory gases, and wastes are typically unidirectional. For example, glucose and oxygen move into the cells and metabolic wastes move out.

Many factors can change ECF and ICF volumes. Because water moves freely between compartments, however, the osmolalities of all body fluids are equal (except during the first few minutes after a change occurs in one of the fluids). Increasing the ECF solute content (mainly the NaCl concentration) causes osmotic and volume changes in the ICF—namely, a shift of water out of the cells. Conversely, decreasing ECF osmolality causes water to move into the cells. Thus, ECF solute concentration determines ICF volume.

It is important for you to understand the concepts above, because they underlie all events that control fluid balance in the body.

Check Your Understanding

1. Which do you have more of, extracellular or intracellular fluid? Plasma or interstitial fluid?
2. What is the major cation in the ECF? In ICF? What are the intracellular anion counterparts of ECF's chloride ions?
3. PREDICT You eat salty pretzels without drinking. What happens to the volume of your extracellular fluid? Explain.

For answers, see Answers Appendix.

26.2 Both intake and output of water are regulated

Learning Outcomes

- **List the routes by which water enters and leaves the body.**
- **Describe feedback mechanisms that regulate water intake and hormonal controls of water output in urine.**
- **Explain the importance of obligatory water losses.**
- **Describe possible causes and consequences of dehydration and of hypotonic hydration.**

For the body to remain properly hydrated, water intake must equal water output. *Water intake* varies widely from person to person and is strongly influenced by habit, but is typically about 2500 ml a day in adults (**Figure 26.4**). Most water enters the body through ingested liquids and solid foods. Body water produced by cellular metabolism is called **metabolic water** or **water of oxidation**.

Water output occurs by several routes. Water that vaporizes out of the lungs in expired air or diffuses directly through the skin is called **insensible water loss**. Any measurable water loss is called **sensible water loss**. This includes water lost as urine (about 60%), obvious sweat, and in feces.

Healthy people have a remarkable ability to maintain the osmolality of their body fluids within very narrow limits (280–300 mOsm). A rise in plasma osmolality triggers (1) thirst, which prompts us to drink water, and (2) release of antidiuretic hormone (ADH; ◀ p. 613), which causes the kidneys to conserve water and excrete concentrated urine. On the other hand, a decline in osmolality inhibits both thirst and ADH release, and the latter prompts the kidneys to excrete large volumes of dilute urine.

In the body, water and Na^+ are closely tied together. In fact, Na^+ acts as a powerful "water magnet." However, the ADH and thirst mechanisms controlling osmolality regulate water *independently* of sodium. Later, we will describe mechanisms that regulate Na^+ and water *together* for the purpose of maintaining blood volume and pressure.

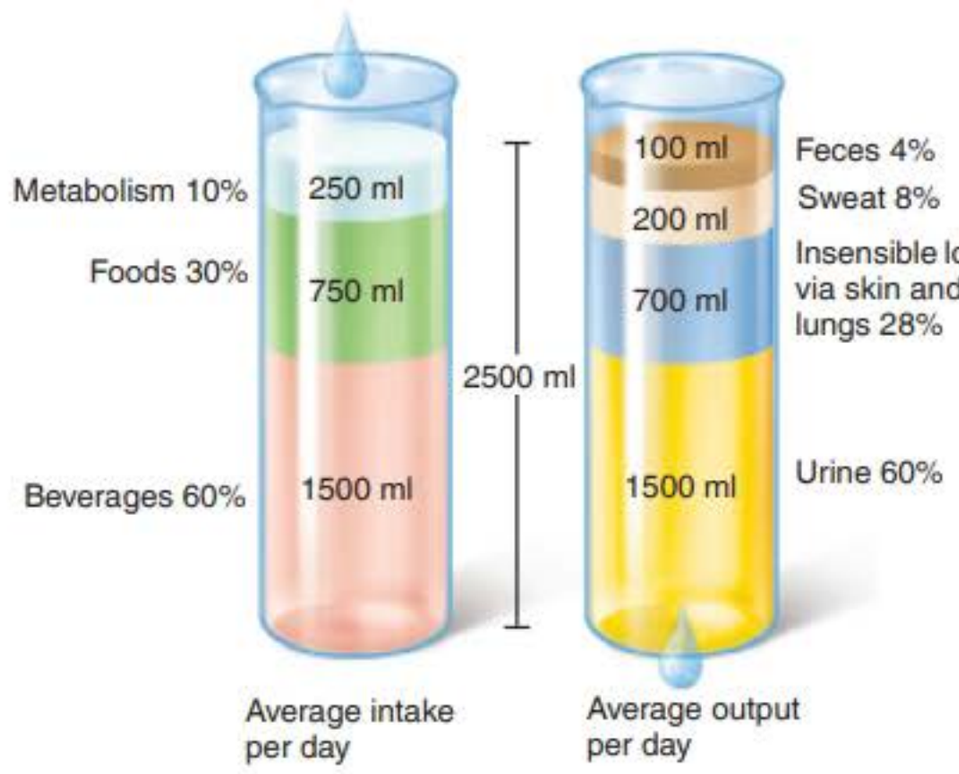

Figure 26.4 Major sources of water intake and output. When intake and output are in balance, the body is adequately hydrated.

Regulation of Water Intake

The **thirst mechanism** is the driving force for water intake. It is governed by the hypothalamic *thirst center* (◀ p. 449), which is activated by various stimuli (**Figure 26.5**):

- *Osmoreceptors*. Hypothalamic *osmoreceptors* detect ECF osmolality through changes in plasma membrane stretch that result from gaining or losing water. An increase in osmolality of only 1–2% activates these osmoreceptors.

- *Dry mouth*. When the blood's osmotic pressure increases, the salivary glands produce less saliva because the osmotic gradient drawing water from the blood into the salivary ducts is reduced.
- *A decrease in blood volume (or pressure)*. A substantial decrease in blood volume or pressure (5–10%, as in hemorrhage) also triggers the thirst mechanism. These changes in volume or pressure are signaled by baroreceptors that directly activate the thirst center, and by angiotensin II as we described in Chapter 19 (◀ p. 723).

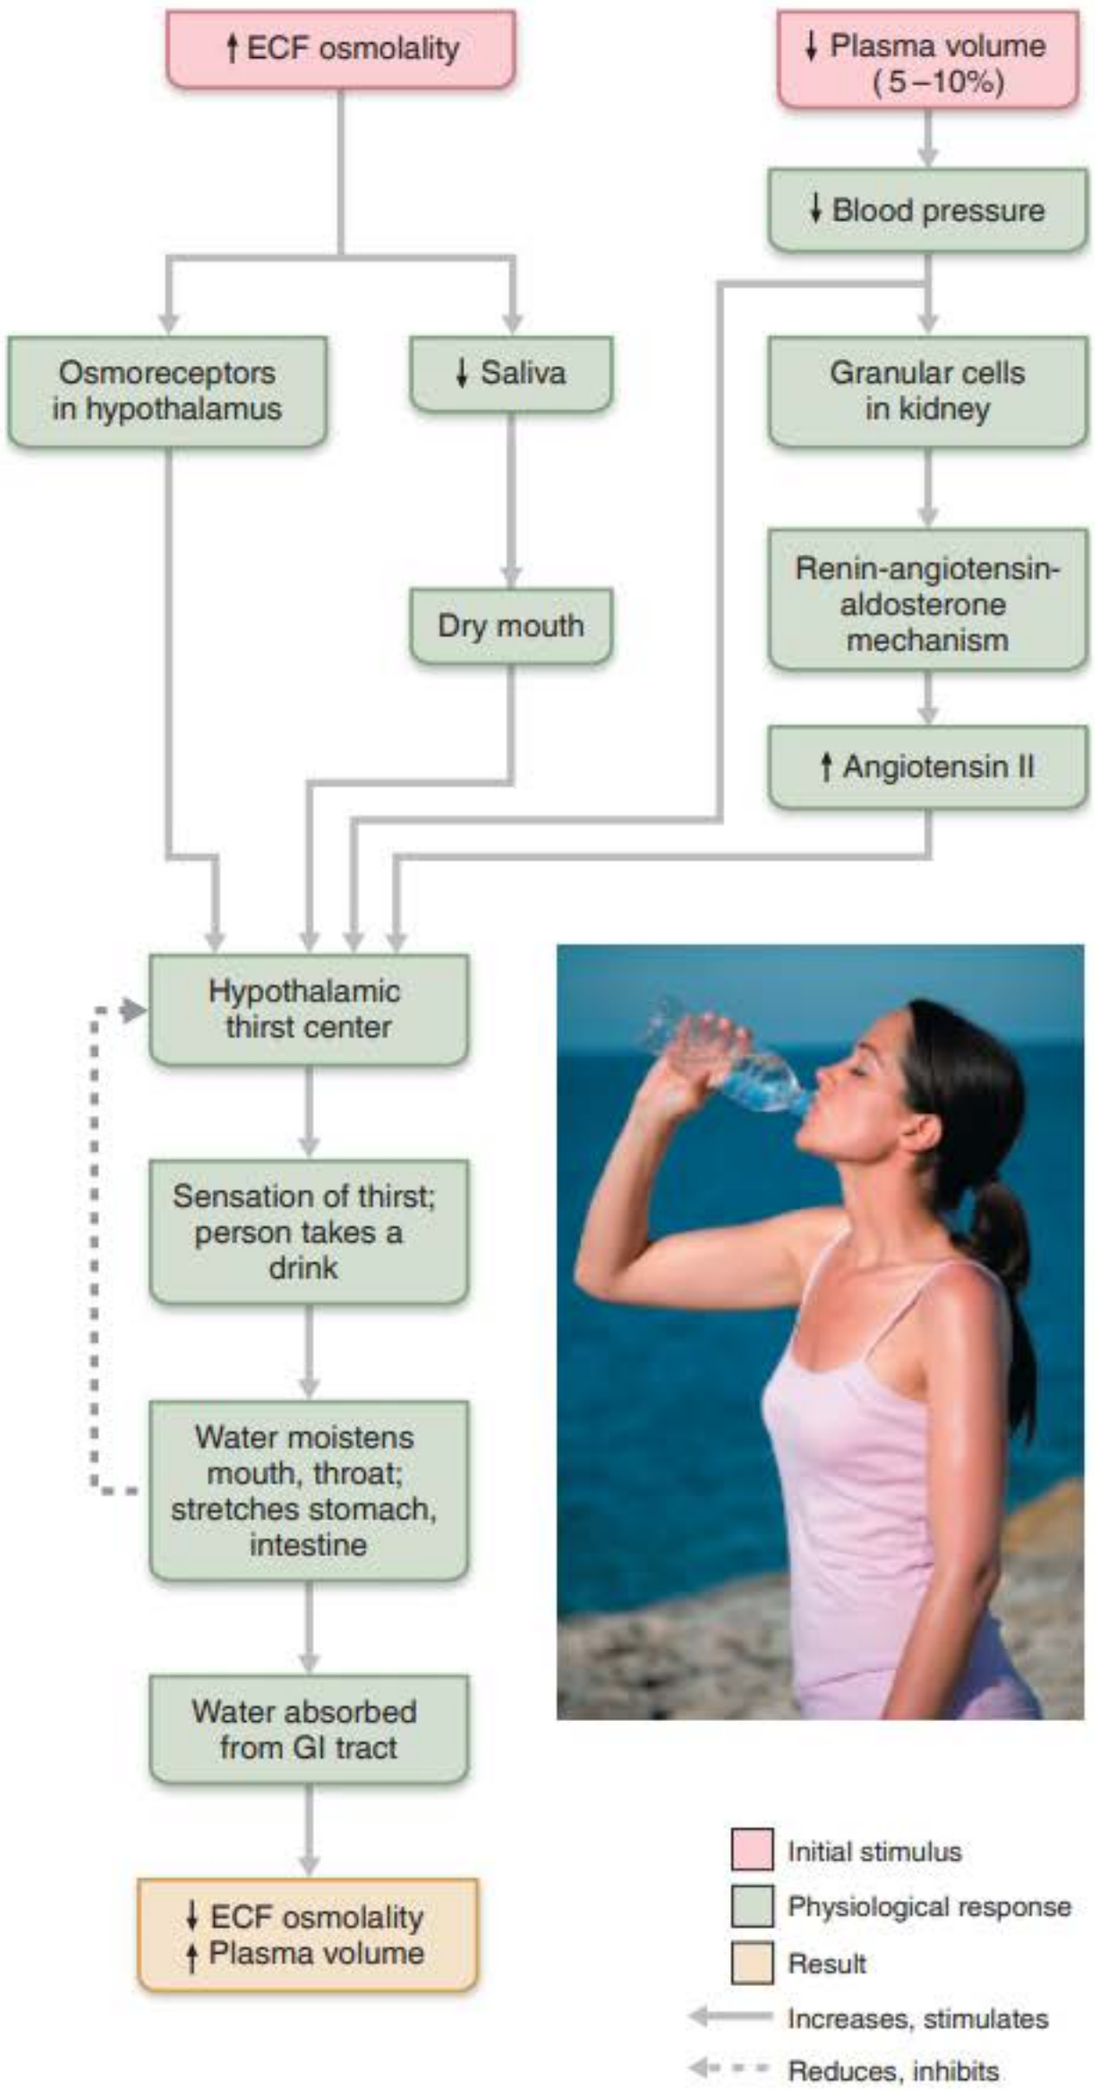

Figure 26.5 The thirst mechanism for regulating water intake. Only large volume changes (5–10% of plasma volume) activate the thirst mechanism. Osmolality changes are the normal stimuli.

Collectively, these events cause a subjective sensation of thirst, which motivates us to get a drink. This mechanism explains why some bars provide free *salty* snacks to their patrons.

Curiously, thirst is quenched almost as soon as we begin drinking water, even though the water has yet to be absorbed into the blood. How does this happen? Incoming liquid moistens the mucosa of the mouth and throat and activates osmoreceptors and stretch receptors in the stomach and small intestine, providing feedback signals that inhibit the thirst center. Premature quenching of thirst prevents us from drinking more than we need and overdiluting our body fluids, and allows time for the osmotic changes to come into play as regulatory factors.

As effective as thirst is, it is not always a reliable indicator of need. This is particularly true during athletic events, when thirst can be satisfied long before sufficient liquids have been drunk to maintain the body in top form. Additionally, elderly or confused people may not recognize or heed thirst signals. In contrast, fluid-overloaded renal or cardiac patients may feel thirsty despite their condition.

Regulation of Water Output

Output of certain amounts of water is unavoidable. Such **obligatory water losses** help to explain why we cannot survive for long without drinking. Even the most heroic conservation efforts by the kidneys cannot compensate for zero water intake. Obligatory water loss includes the *insensible water losses* described above, as well as *sensible water loss* of at least 500 ml per day in urine plus the water that accompanies undigested food residues in feces.

Obligatory water loss in urine reflects the fact that human kidneys must normally flush 600 mmol per day of urine solutes (end products of metabolism and so forth) out of the body in water. The maximum concentration of urine is about 1200 mOsm, so at least 500 ml of water must be excreted.

Beyond obligatory water loss, the solute concentration and volume of urine excreted depend on fluid intake, diet, and water loss via other avenues. For example, if you sweat profusely on a hot day, you have to excrete much less urine than usual to maintain water balance. Normally, the kidneys begin to eliminate excess water about 30 minutes after it is ingested. This delay reflects the time required to inhibit ADH release. Diuresis reaches a peak about 1 hour after drinking and declines to its lowest level after 3 hours.

Influence of Antidiuretic Hormone (ADH)

The amount of water reabsorbed in the renal collecting ducts is proportional to ADH release (◀ Figure 25.20, p. 999). When ADH levels are low, most of the water reaching the collecting ducts is not reabsorbed because the lack of aquaporins in the apical membranes of the principal cells prevents the movement of water. Instead, the water simply flows on by. The result is dilute urine and a reduced volume of body fluids. When ADH

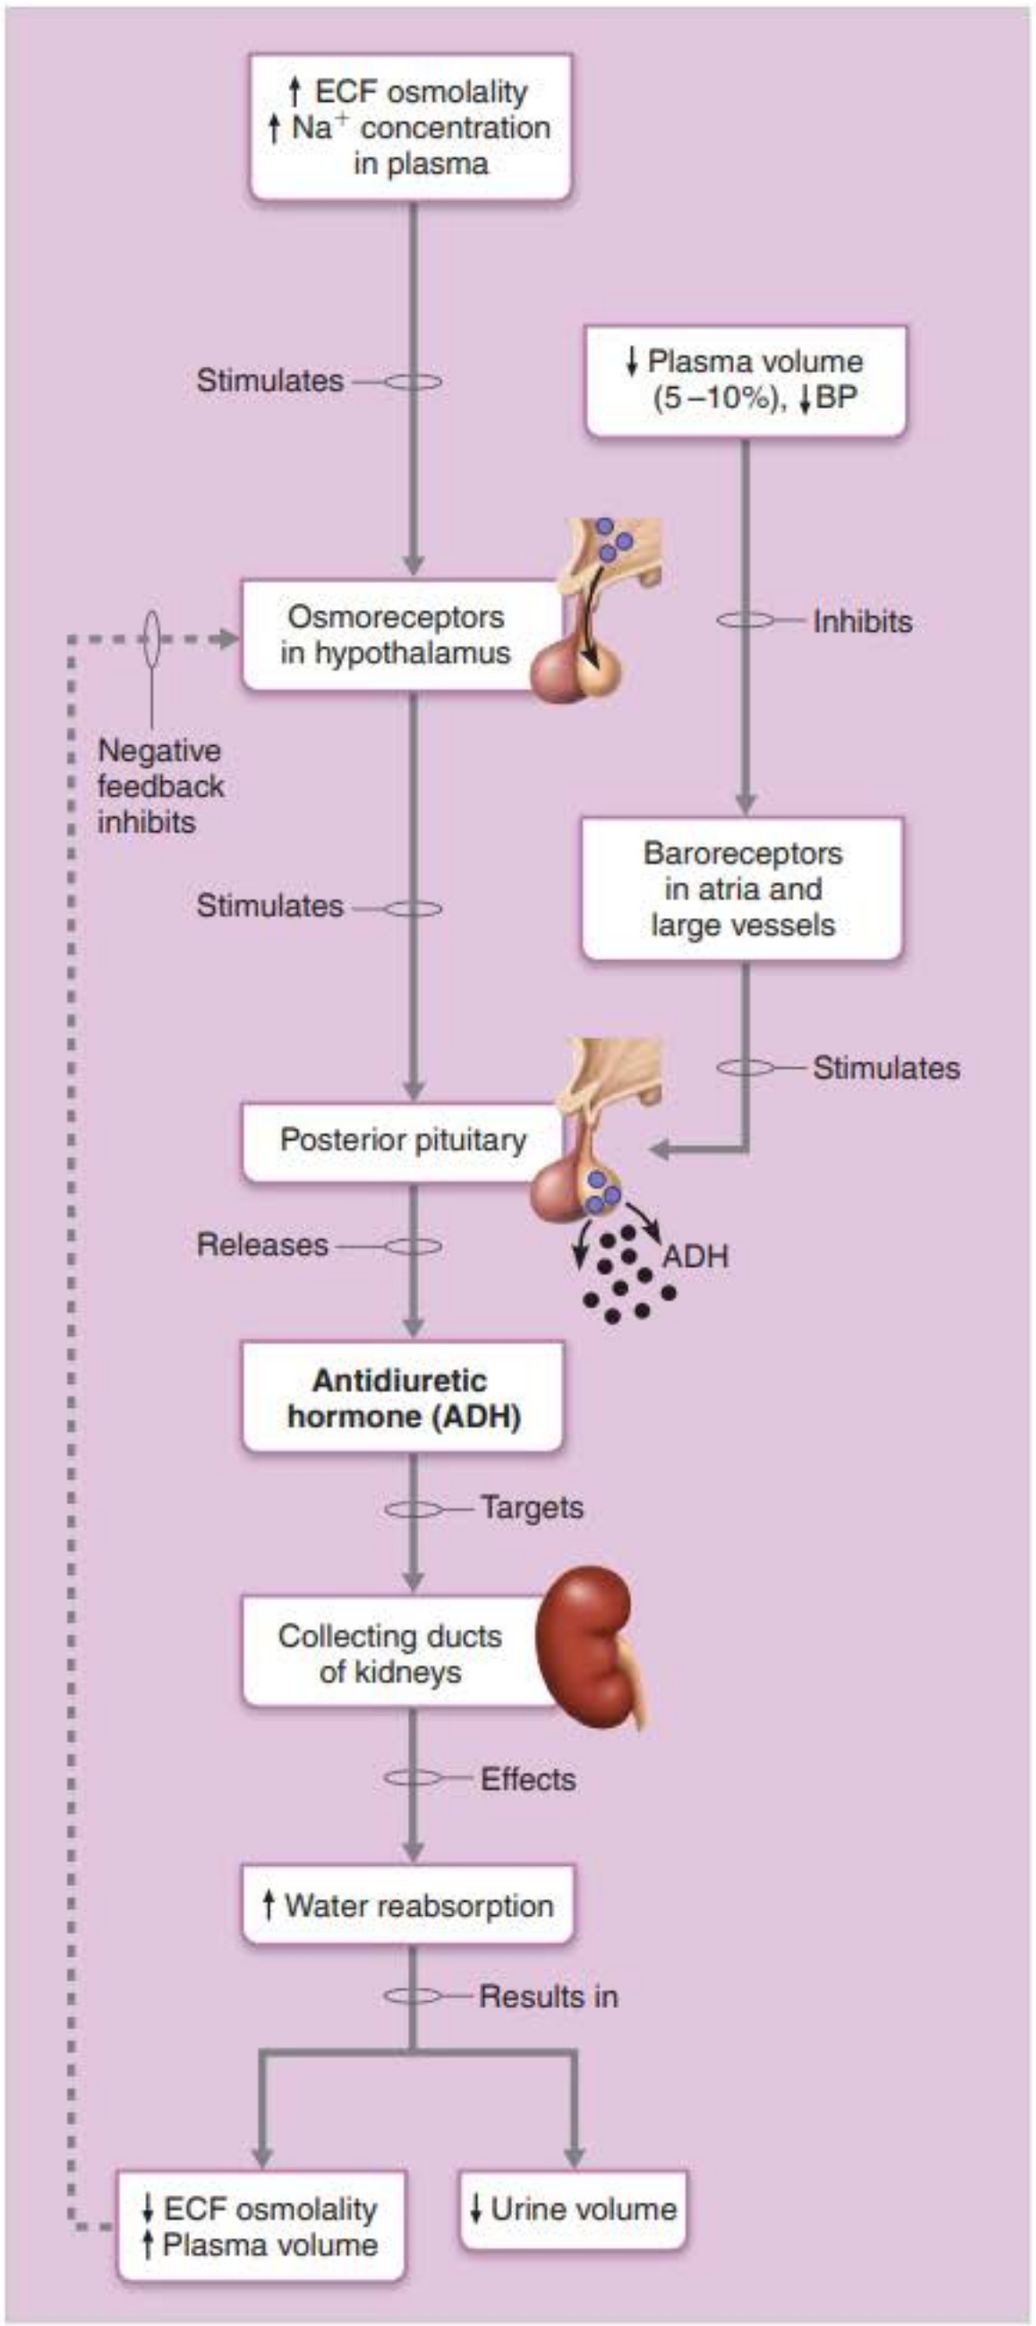

Figure 26.6 Mechanisms and consequences of ADH release.
(Vasoconstrictor effects of ADH are not shown.)

levels are high, aquaporins are inserted in the principal cell apical membranes, nearly all of the filtered water is reabsorbed, and a small volume of concentrated urine is excreted (**Figure 26.6**).

Osmoreceptors of the hypothalamus sense the ECF solute concentration and trigger or inhibit ADH release from the posterior pituitary accordingly (◀ p. 613). An increase in ECF osmolality prompts ADH release by stimulating the hypothalamic osmoreceptors. In contrast, a decrease in ECF osmolality inhibits ADH release and allows more water to be excreted in urine, restoring normal blood osmolality.

Large changes in blood volume or blood pressure also influence ADH secretion. A decrease in blood pressure increases ADH release both directly via baroreceptors in the atria and various blood vessels, and indirectly via the renin-angiotensin-aldosterone mechanism (◀ pp. 722–723).

The key word here is "large" because changes in ECF osmolality are much more important as day-to-day stimulatory or inhibitory factors. Factors that greatly reduce blood volume and so trigger ADH release include excessive sweating, vomiting, or diarrhea; severe blood loss; traumatic burns; and prolonged fever. Under these conditions, high concentrations of ADH also act to constrict arterioles, directly increasing blood pressure—this accounts for its other name: *vasopressin*. For a summary of how renal mechanisms involving ADH, aldosterone, and angiotensin II tie into overall controls of blood volume and blood pressure, see Figure 26.10 (p. 1024). However, remember that the main thrust of ADH is to maintain ECF osmolality.

Disorders of Water Balance CLINICAL

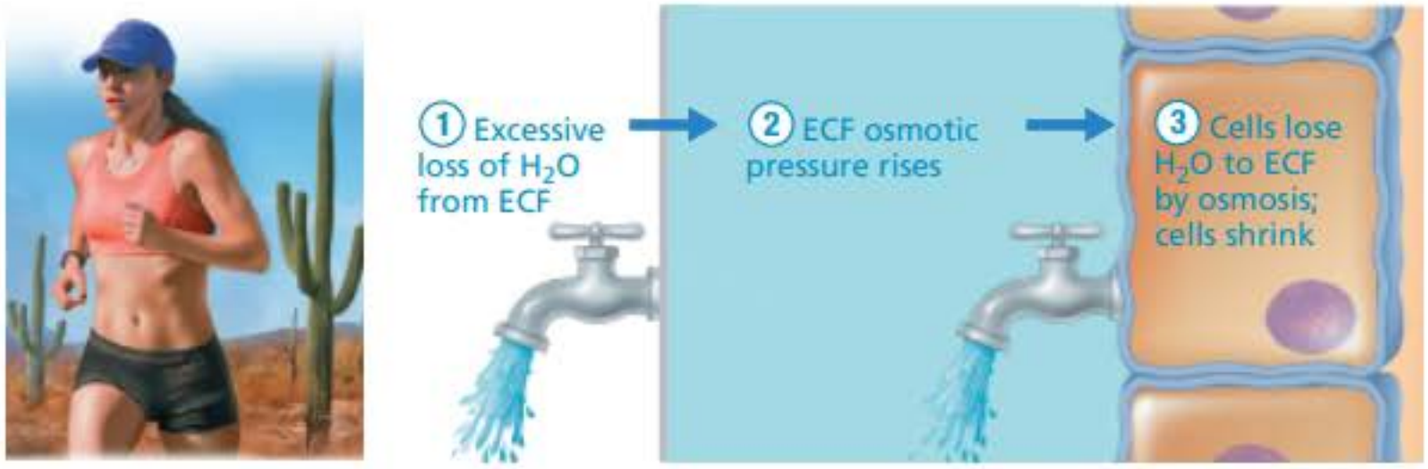
Few people really appreciate the importance of water in keeping the body's "machinery" working at peak efficiency. The principal abnormalities of water balance are dehydration, hypotonic hydration, and edema—each presenting a special set of problems.

Dehydration

Clinically, **dehydration** is defined as fluid loss, either the loss of water or the loss of water and solutes together. Dehydration is a common sequel to hemorrhage, severe burns, prolonged vomiting or diarrhea, profuse sweating, water deprivation, and diuretic abuse. Dehydration may also be caused by endocrine disturbances, such as diabetes mellitus (◀ p. 632) or diabetes insipidus (◀ p. 614).

Early signs and symptoms of dehydration include a "cottony" or sticky oral mucosa, thirst, dry flushed skin, and decreased urine output (*oliguria*). Prolonged dehydration may lead to weight loss, fever, and mental confusion. Another serious consequence of water loss from plasma is inadequate blood volume to maintain normal circulation and ensuing *hypovolemic shock*.

Water and solutes can be lost together (as in hemorrhage), or more water than solutes can be lost (as in profuse sweating). If the body loses more water than solutes, water moves osmotically from the cells into the ECF (**Figure 26.7a**). This water movement equalizes the osmolality of the extracellular and intracellular fluids even though the total fluid volume has been reduced.



(a) Consequences of dehydration. If more water than solutes is lost, cells shrink.

(b) Consequences of hypotonic hydration (water gain). If more water than solutes is gained, cells swell.

Figure 26.7 Disturbances in water balance.

Hypotonic Hydration

Declining ECF osmolality sets several compensatory mechanisms into motion. ADH release is inhibited, and as a result, less water is reabsorbed and excess water is quickly flushed from the body in urine. But, when there is renal insufficiency or we drink an extraordinary amount of water very quickly, a type of cellular *overhydration* called **hypotonic hydration** may occur. In either case, the ECF is diluted—its sodium *content* is normal, but excess water is present so the sodium *concentration* is low. For this reason, the hallmark of hypotonic hydration is **hyponatremia** (low ECF Na^+ concentration), which promotes net osmosis into tissue cells, causing them to swell as they become abnormally hydrated (Figure 26.7b).

Hypotonic hydration leads to severe metabolic disturbances evidenced by nausea, vomiting, muscular cramping, and cerebral edema. It is particularly damaging to neurons. Uncorrected cerebral edema quickly leads to disorientation, convulsions, coma, and death. Indeed, several marathon runners have died of overhydration after drinking too much water. Sudden and severe hyponatremia is treated by administering intravenous hypertonic saline to reverse the osmotic gradient and "pull" water out of the cells.

Edema

Edema (ĕ-de′mah; "a swelling") is an atypical accumulation of fluid in the interstitial space, leading to tissue (but not cell) swelling. Unlike hypotonic hydration, which increases the amount of fluid in all compartments due to an imbalance between water intake and output, edema is an increase in volume of *only* the IF. The extra fluid in the interstitial space can impair tissue function by increasing the distance across which oxygen and nutrients must diffuse between the blood and the cells. Edema may be caused by any event that steps up the flow of fluid out of the blood or hinders its return (see *Focus on Bulk Flow across Capillary Walls*, ◀ Focus Figure 19.1, pp. 732–733). Edema and its various causes are discussed in Chapter 19 (◀ p. 734).

Check Your Understanding

4. What change in plasma is most important for triggering thirst? Where is that change sensed?
5. ADH, by itself, cannot reduce an increase in osmolality in body fluids. Why not? What other mechanism is required?
6. MAKE CONNECTIONS For each of the following, state whether it might result in dehydration, hypotonic hydration, or edema (discussed in Chapter 19): (a) decreased synthesis of plasma proteins due to liver failure; (b) copious sweating; (c) using ecstasy (MDMA), which promotes ADH secretion.

For answers, see Answers Appendix.

26.3 Sodium, potassium, calcium, and phosphate levels are tightly regulated

Learning Outcomes

- **Indicate routes of electrolyte entry and loss from the body.**
- **Describe the importance of sodium in the body's fluid and electrolyte balance.**
- **Describe mechanisms involved in regulating sodium balance, blood volume, and blood pressure.**
- **Explain how potassium, calcium, and anion balances in plasma are regulated.**

Electrolytes include salts, acids, bases, and some proteins, but the term **electrolyte balance** usually refers to salt balance in the body. Salts are important in controlling fluid movements and provide minerals essential for excitability, secretory activity, and membrane permeability. Although many electrolytes are crucial for cellular activity, here we will specifically examine the regulation of sodium, potassium, calcium, and phosphate.

Salts enter the body in foods and fluids, and small amounts are generated during metabolic activity. For example, phosphates are liberated during catabolism of nucleic acids and bone matrix. Obtaining enough electrolytes is usually not a problem. Indeed, most of us have a far greater taste than need for salt. We shake table salt (NaCl) on our food even though natural foods contain ample amounts and processed foods contain exorbitant quantities. The

Table 26.1 Causes and Consequences of Electrolyte Imbalances

ION	ABNORMALITY (SERUM VALUE)	POSSIBLE CAUSES	CONSEQUENCES
Sodium	**Hypernatremia** (Na^+ excess: >145 mEq/L)	Dehydration; uncommon in healthy individuals; may occur in infants, the elderly, or any individual unable to indicate thirst; or may result from excessive intravenous NaCl administration	Thirst. CNS dehydration leads to confusion and lethargy progressing to coma; increased neuromuscular irritability evidenced by twitching and convulsions.
	Hyponatremia (Na^+ deficit: <135 mEq/L)	Solute loss, water retention, or both (e.g., excessive Na^+ loss through vomiting, diarrhea, burned skin, gastric suction, or excessive use of diuretics); deficiency of aldosterone (Addison's disease, ◀ pp. 625–626); renal disease; excess ADH release; excess H_2O ingestion	Most common signs are those of neurologic dysfunction due to brain swelling. If body sodium content is normal but water is excessive, the symptoms are the same as those of water excess: mental confusion; giddiness; coma if development occurs slowly; muscular twitching, irritability, and convulsions if the condition develops rapidly. In hyponatremia accompanied by water loss, the main signs are decreased blood volume and blood pressure (circulatory shock).
Potassium	**Hyperkalemia** (K^+ excess: >5.5 mEq/L)	Renal failure; deficit of aldosterone; rapid intravenous infusion of KCl; burns or severe tissue injuries that cause K^+ to leave cells	Nausea, vomiting, diarrhea; bradycardia; cardiac arrhythmias and arrest; skeletal muscle weakness; flaccid paralysis.
	Hypokalemia (K^+ deficit: <3.5 mEq/L)	Gastrointestinal tract disturbances (vomiting, diarrhea), gastric suction; Cushing's syndrome; inadequate dietary intake (starvation); hyperaldosteronism; diuretic therapy	Cardiac arrhythmias, flattened T wave on ECG; muscular weakness; metabolic alkalosis; mental confusion; nausea; vomiting.
Phosphate	**Hyperphosphatemia** (HPO_4^{2-} excess: >2.9 mEq/L)	Decreased urinary loss due to renal failure; hypoparathyroidism; major tissue trauma; increased intestinal absorption	Clinical symptoms arise because of reciprocal changes in Ca^{2+} levels rather than directly from changes in plasma phosphate concentrations.
	Hypophosphatemia (HPO_4^{2-} deficit: <1.6 mEq/L)	Decreased intestinal absorption; increased urinary output; hyperparathyroidism	
Chloride	**Hyperchloremia** (Cl^- excess: >105 mEq/L)	Dehydration; increased retention or intake; metabolic acidosis; hyperparathyroidism	No direct clinical symptoms; symptoms generally associated with the underlying cause, which is often related to pH abnormalities.
	Hypochloremia (Cl^- deficit: <95 mEq/L)	Metabolic alkalosis (e.g., due to vomiting or excessive ingestion of alkaline substances); aldosterone deficiency	
Calcium	**Hypercalcemia** (Ca^{2+} excess: >5.2 mEq/L or 10.5 mg%)*	Hyperparathyroidism; excessive vitamin D; prolonged immobilization; renal disease (decreased excretion); malignancy	Decreased neuromuscular excitability leading to cardiac arrhythmias and arrest, skeletal muscle weakness, confusion, stupor, and coma; kidney stones; nausea and vomiting.
	Hypocalcemia (Ca^{2+} deficit: <4.5 mEq/L or 9 mg%)*	Burns (calcium trapped in damaged tissues); hypoparathyroidism; vitamin D deficiency; renal tubular disease; renal failure; hyperphosphatemia; diarrhea; alkalosis	Increased neuromuscular excitability leading to tingling fingers, tremors, skeletal muscle cramps, tetany, convulsions; depressed excitability of the heart; osteomalacia; fractures.
Magnesium	**Hypermagnesemia** (Mg^{2+} excess: >2.2 mEq/L)	Rare; occurs in renal failure when Mg^{2+} is not excreted normally; excessive ingestion of Mg^{2+}-containing antacids	Lethargy; impaired CNS functioning, coma, respiratory depression; cardiac arrest.
	Hypomagnesemia (Mg^{2+} deficit: <1.4 mEq/L)	Alcoholism; chronic diarrhea, severe malnutrition; diuretic therapy	Tremors, increased neuromuscular excitability, tetany, convulsions.

*1 mg% = 1 mg/100 ml

taste for very salty foods is learned, but some liking for salt may be innate to ensure adequate intake of these two vital ions.

We lose salts from the body in sweat, feces, urine, and vomit. Even though sweat is normally hypotonic, large amounts of salt can be lost on a hot day simply because more sweat is produced. Gastrointestinal disorders can also lead to large salt losses in feces or vomitus. Consequently, the flexibility of renal mechanisms that regulate the electrolyte balance of the blood is a critical asset. **Table 26.1** summarizes several causes and consequences of electrolyte imbalance.

HOMEOSTATIC IMBALANCE 26.1 CLINICAL

Severe electrolyte deficiencies may cause unusual cravings. For example, in *Addison's disease* (◀ pp. 625–626), the adrenal cortex produces too little aldosterone, and so Na^+ is lost. People with this disorder often crave salty foods.

When minerals such as iron are deficient, a person may even eat substances not usually considered foods, like chalk, clay, starch, and burnt match tips. This appetite for abnormal substances is called *pica*.

The Central Role of Sodium in Fluid and Electrolyte Balance

Sodium holds a central position in fluid and electrolyte balance and overall body homeostasis. Indeed, regulating the balance between sodium input and output is one of the most important renal functions. The salts $NaHCO_3$ and NaCl account for 90–95% of all solutes in the ECF, and they contribute about 280 mOsm of the total ECF solute concentration (300 mOsm).

At its normal plasma concentration of about 142 mEq/L, Na^+ is the single most abundant cation in the ECF and the only one exerting *significant* osmotic pressure. Additionally, cellular plasma membranes are relatively impermeable to Na^+ (some does manage to diffuse in and must be pumped out against its electrochemical gradient). These two qualities give sodium the primary role in controlling ECF volume and water distribution in the body.

Remember: *Water follows salt*. Because all body fluids are in osmotic equilibrium, a change in plasma Na^+ levels affects not only plasma volume and blood pressure, but also ICF and IF volumes. In addition, sodium ions continuously move back and forth between the ECF and body secretions. For example, about 8 L of Na^+-containing secretions (gastric, intestinal, and pancreatic juice, saliva, bile) are spewed into the digestive tract daily, only to be almost completely reabsorbed. Finally, renal acid-base control mechanisms (which we will discuss shortly) are coupled to Na^+ transport.

Sodium Concentration versus Sodium Content

For ions other than Na^+, their concentration in body fluids is the only important variable. For Na^+, however, both the concentration and the total body content (the total amount contained in the body) are important.

- **Concentration of Na^+.** The concentration of Na^+ in the ECF largely determines the osmolality of ECF fluids and influences electrical excitability of neurons and muscles. The concentration of Na^+ normally remains relatively stable because water immediately moves by osmosis into or out of the ICF, counteracting the change in Na^+ concentration. In the long term, the ADH and thirst mechanisms control the ECF Na^+ concentration by controlling water loss or gain.
- **Content of Na^+.** The total amount of Na^+ in the body determines the ECF volume and therefore blood pressure. Na^+ content is regulated by the renin-angiotensin-aldosterone and atrial natriuretic peptide (ANP) hormone mechanisms that control Na^+ reabsorption and excretion (Na^+ balance). We will review these mechanisms in the next section.

It helps to think about these aspects of Na^+ balance as separate and distinct because they have different roles in homeostasis (**Table 26.2**). Nevertheless, there is some overlap between them and their mechanisms are intertwined. For example, as ECF Na^+ content increases, ECF osmolality rises as well, which triggers the ADH and thirst mechanisms. This increases water retention and intake, simultaneously reducing the Na^+ concentration and increasing the ECF volume.

Regulation of Sodium Balance

Despite the crucial importance of sodium, receptors that specifically monitor the concentration or content of Na^+ in body fluids have yet to be found.

- Total body Na^+ content is indirectly monitored by baroreceptors because Na^+ content determines fluid volume and fluid volume determines blood pressure.
- ECF Na^+ concentration, in contrast, is primarily monitored by hypothalamic osmoreceptors.

Changes in these two variables trigger a variety of hormonal and neural controls that regulate Na^+ balance.

Influence of Aldosterone and Angiotensin II

The hormone **aldosterone** "has the most to say" about renal regulation of sodium ions. It is an integral part of the

26

Table 26.2 Sodium Concentration and Sodium Content

	ECF Na^+ CONCENTRATION	BODY Na^+ CONTENT
Homeostatic Importance	ECF osmolality	Blood volume and blood pressure
Sensors	Osmoreceptors	Baroreceptors
Primary Regulators	ADH and thirst mechanisms	Renin-angiotensin-aldosterone and ANP hormone mechanisms*

*ADH and thirst are also required to maintain blood volume and for long-term control of blood pressure.

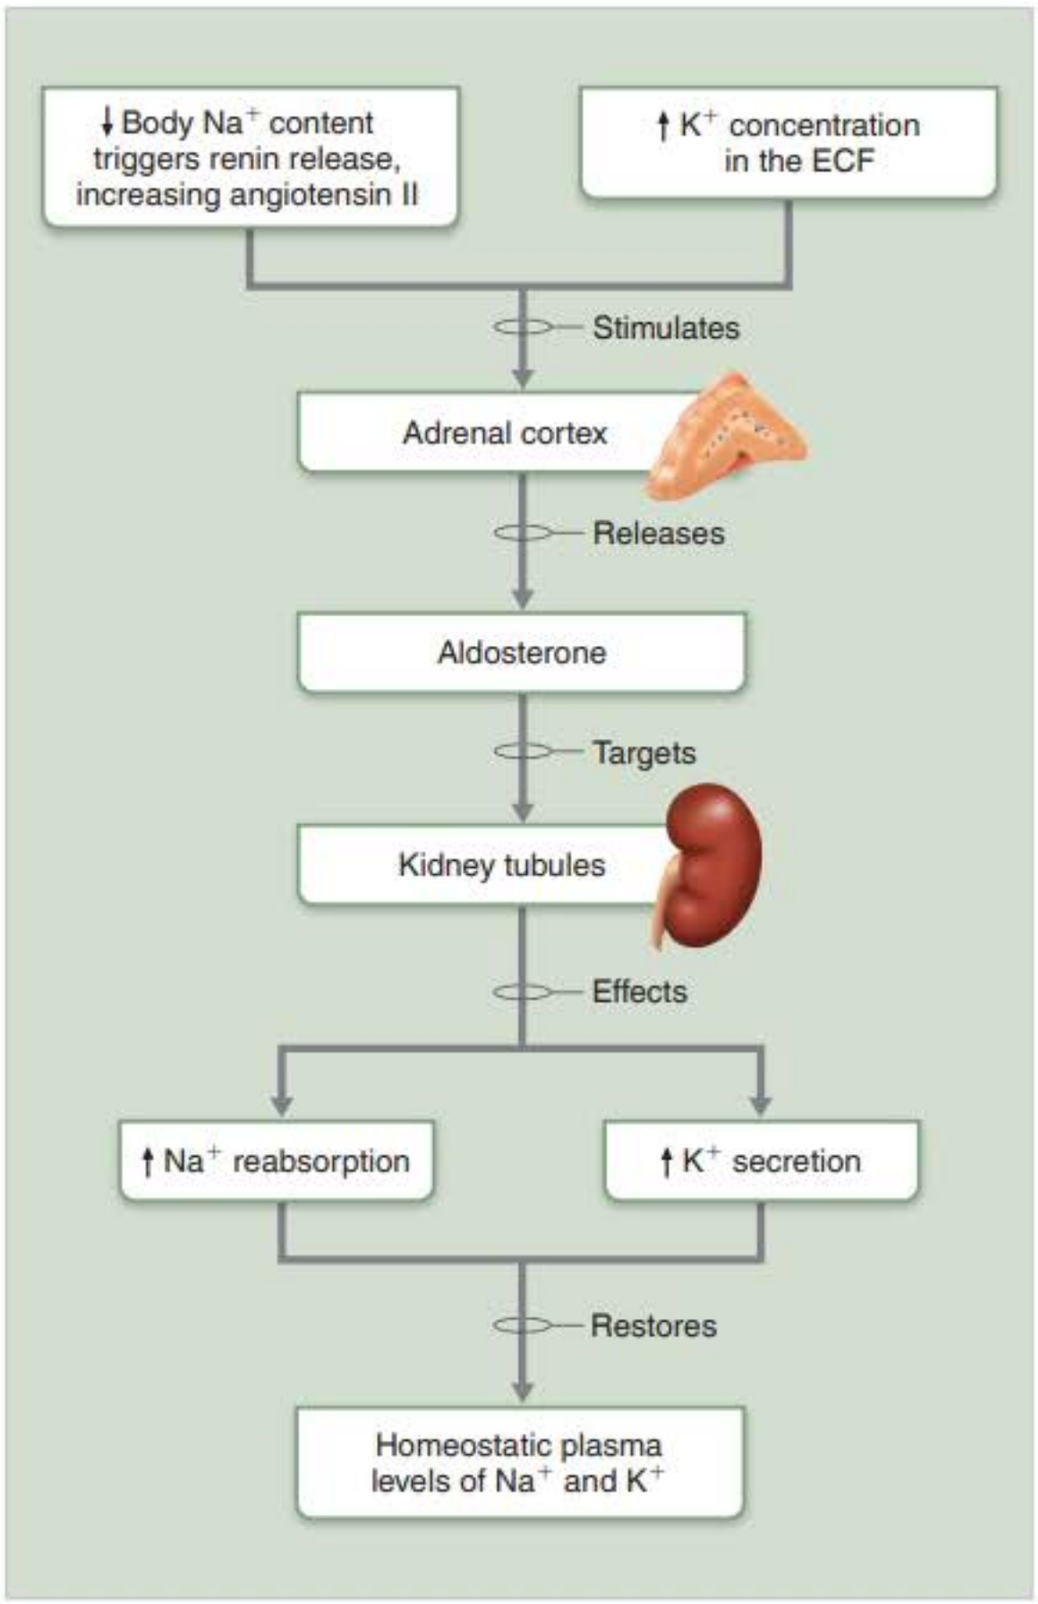


Figure 26.8 Mechanisms and consequences of aldosterone release.

renin-angiotensin-aldosterone mechanism—the body's main mechanism for increasing blood volume and blood pressure (◀ pp. 722–723).

Whether aldosterone is present or not, some 65% of the Na^+ in the renal filtrate is reabsorbed in the proximal tubules of the kidneys and another 25% is reclaimed in the nephron loops (◀ p. 992).

- **When aldosterone concentrations are high.** Essentially *all* the remaining filtered Na^+ is actively reabsorbed in the distal convoluted tubules and collecting ducts. Water always follows Na^+. In this case, the water that follows Na^+ comes from either the intracellular fluid or, if ADH is present, from the filtrate in the collecting ducts. One way or another, aldosterone increases ECF volume.
- **When aldosterone concentrations are low.** Virtually no Na^+ reabsorption occurs beyond the distal convoluted tubule.

Urinary excretion of large amounts of Na^+ *always* results in the excretion of large amounts of water as well, but the reverse is *not* true. Substantial amounts of nearly sodium-free urine can be eliminated as needed to achieve water balance.

The most important trigger for aldosterone release from the adrenal cortex is the renin-angiotensin-aldosterone mechanism mediated by the juxtaglomerular complex (JGC) of nephrons (◀ p. 989). In addition, elevated K^+ concentration in the ECF can directly stimulate adrenal cortical cells to release aldosterone (**Figure 26.8**). The result of aldosterone release is increased reabsorption of Na^+ and increased secretion of K^+. Aldosterone brings about its effects slowly, over a period of hours.

Low blood volume and blood pressure (reflecting decreased body Na^+ content) trigger *renin* release from the granular cells of the JGC in three ways shown in Figure 26.10:

- Sympathetic stimulation
- Decreased filtrate NaCl concentration
- Decreased stretch of the granular cells of the afferent arterioles

Renin catalyzes the initial step in the reactions that produce angiotensin II. Angiotensin II prods the adrenal cortex to release aldosterone, and also directly increases Na^+ reabsorption by kidney tubules. In addition, it has a number of other actions described in Chapter 19 (◀ pp. 722–723) that are all aimed at raising blood volume and blood pressure.

HOMEOSTATIC IMBALANCE 26.2 CLINICAL

A deficiency of aldosterone (as in *Addison's disease*; ◀ pp. 625–626) causes enormous losses of water and NaCl in the urine. People with this condition require careful monitoring to avoid critically low blood volume (hypovolemia), especially during illness or other stresses.

Influence of Atrial Natriuretic Peptide (ANP)

We can summarize the influence of **atrial natriuretic peptide (ANP)** in one sentence: It reduces blood pressure and blood volume by inhibiting nearly all events that promote vasoconstriction and Na^+ and water retention (◀ p. 624) (**Figure 26.9**). A hormone that is released by certain cells of the heart atria when they are stretched by the effects of elevated blood pressure, ANP has diuretic and natriuretic (salt-excreting) effects. It promotes excretion of Na^+ and water by the kidneys by inhibiting the ability of the collecting ducts to reabsorb Na^+ and by suppressing the release of ADH, renin, and aldosterone. Additionally, ANP acts both directly and indirectly (by inhibiting renin-induced generation of angiotensin II) to relax vascular smooth muscle, and in this way it causes vasodilation. Collectively, these effects reduce body Na^+ content and blood pressure.

Influence of Other Hormones

Female Sex Hormones The **estrogens** are chemically similar to aldosterone and, like aldosterone, enhance NaCl reabsorption by the renal tubules. Because water follows, many women retain fluid as their estrogen levels rise during the menstrual cycle. Estrogens are also largely responsible for the edema experienced by many pregnant women. **Progesterone**, in contrast, has a mild

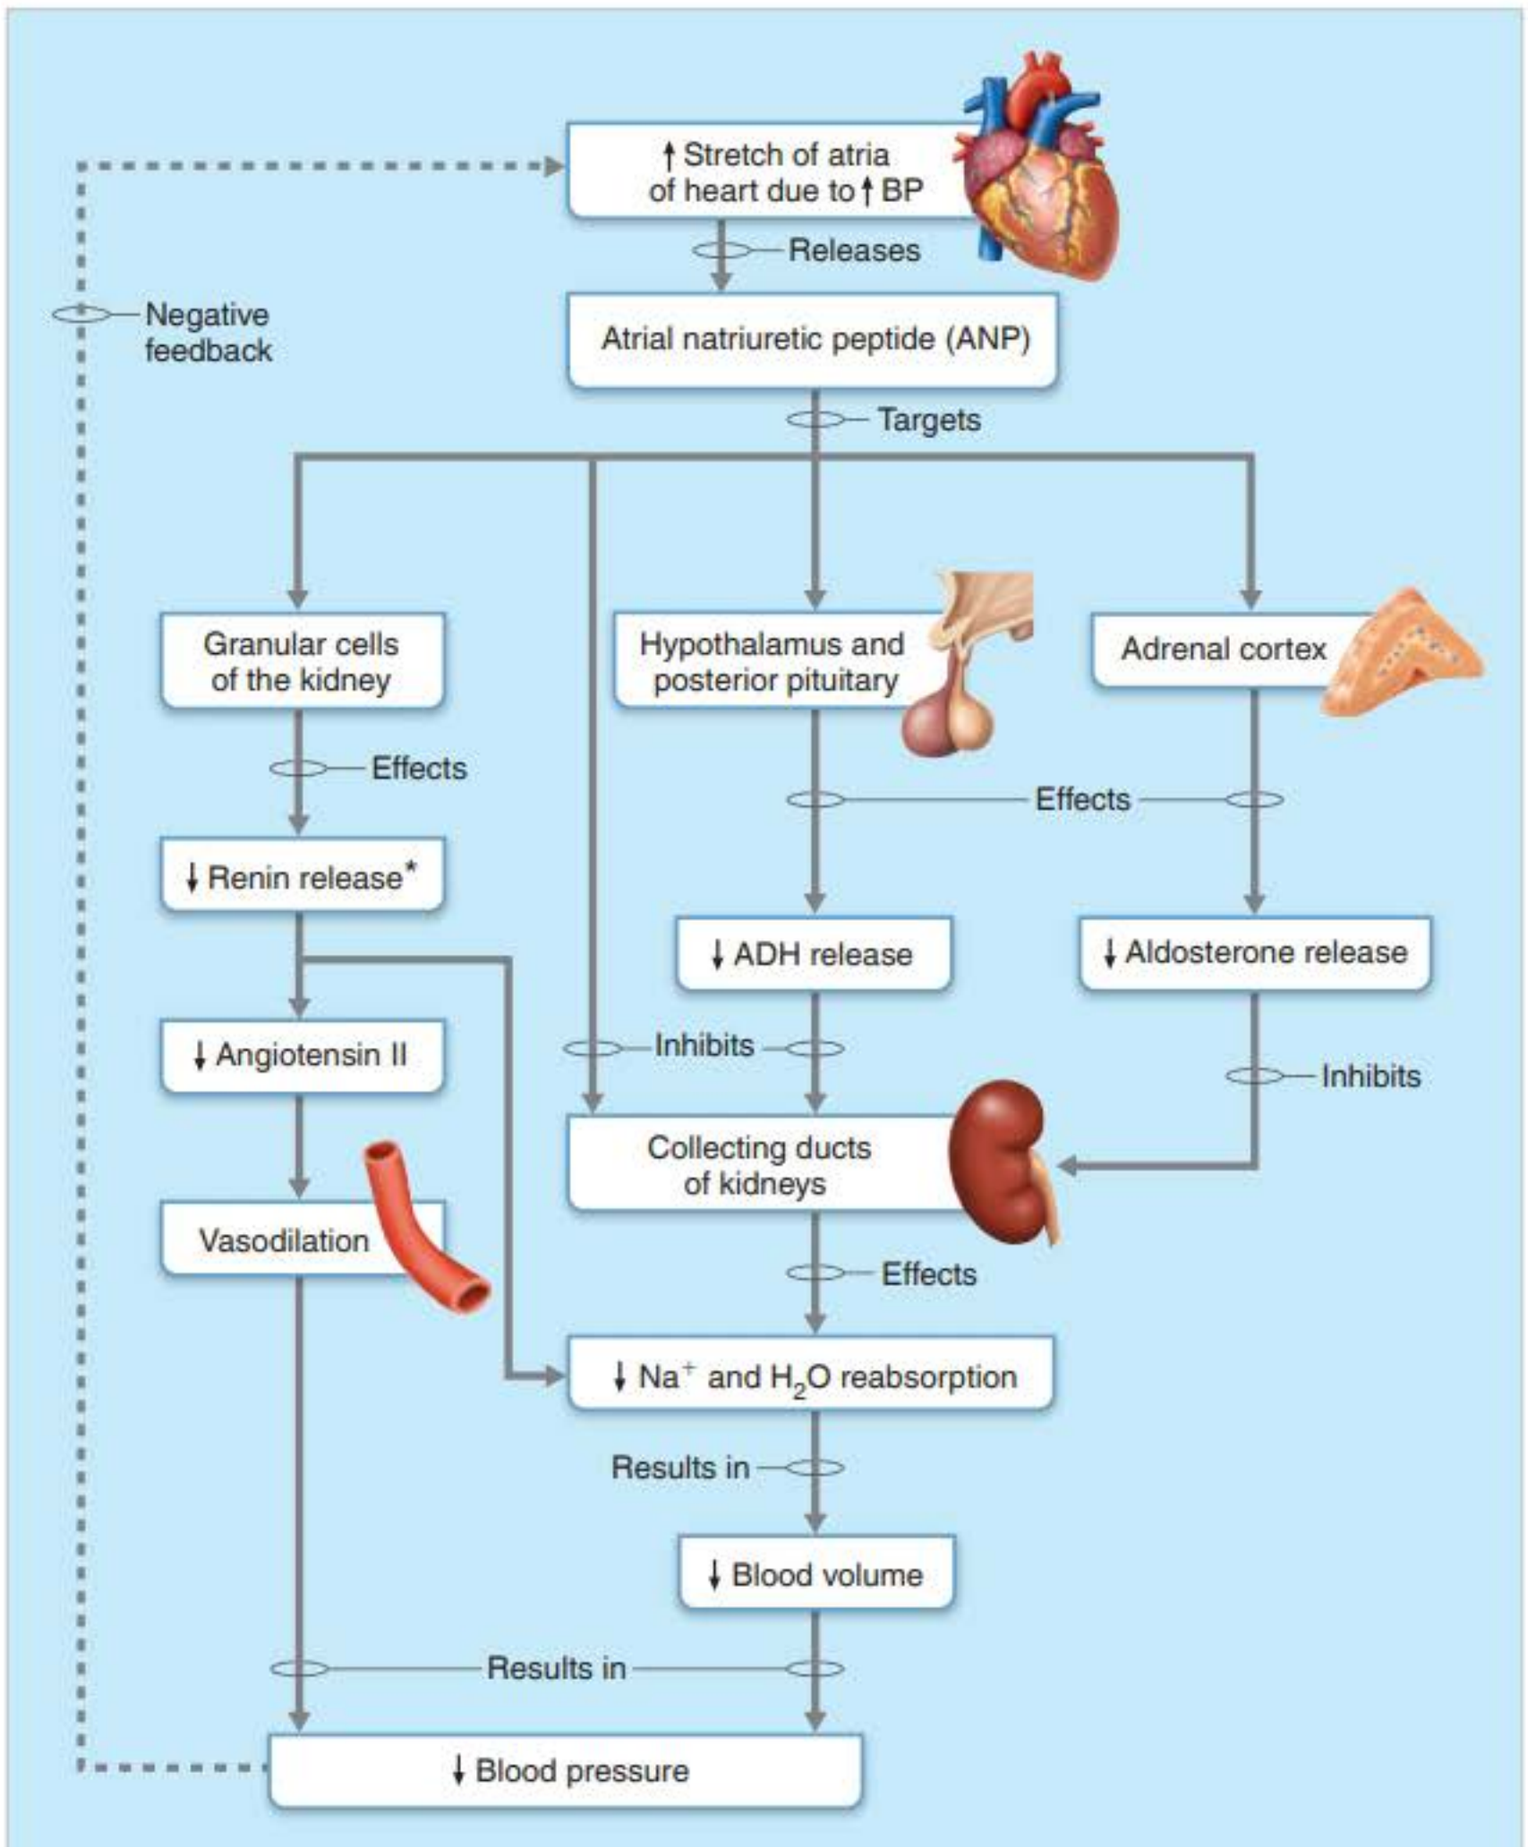

Figure 26.9 Mechanisms and consequences of ANP release.
*↓ Renin release also inhibits ADH and aldosterone release and hence the effects of those hormones.

diuretic effect which is thought to be due to its blocking aldosterone receptors.

Glucocorticoids **Glucocorticoids**, such as cortisol and hydrocortisol, enhance tubular reabsorption of Na^+, but they also promote an increased glomerular filtration rate that may mask their effects on the tubules. However, when their plasma levels are high, the glucocorticoids exhibit potent aldosterone-like effects and promote edema.

Cardiovascular Baroreceptors

Blood volume (and indirectly body Na^+ content) is carefully monitored and regulated to maintain blood pressure and cardiovascular function. As blood volume (and with it, pressure) rises, baroreceptors in the heart and the large vessels of the neck and thorax (carotid arteries and aorta) alert the cardiovascular center in the brain stem. Shortly after, sympathetic nervous system impulses to the kidneys decline, allowing the afferent arterioles to dilate. As the glomerular filtration rate rises, Na^+ output and water output increase. This phenomenon, part of the baroreceptor reflex described in Chapter 19 (◀ pp. 719–720), reduces blood volume and blood pressure.

Drops in systemic blood pressure lead to reflex constriction of systemic arterioles including the afferent arterioles, which reduces filtrate formation and urinary output and increases

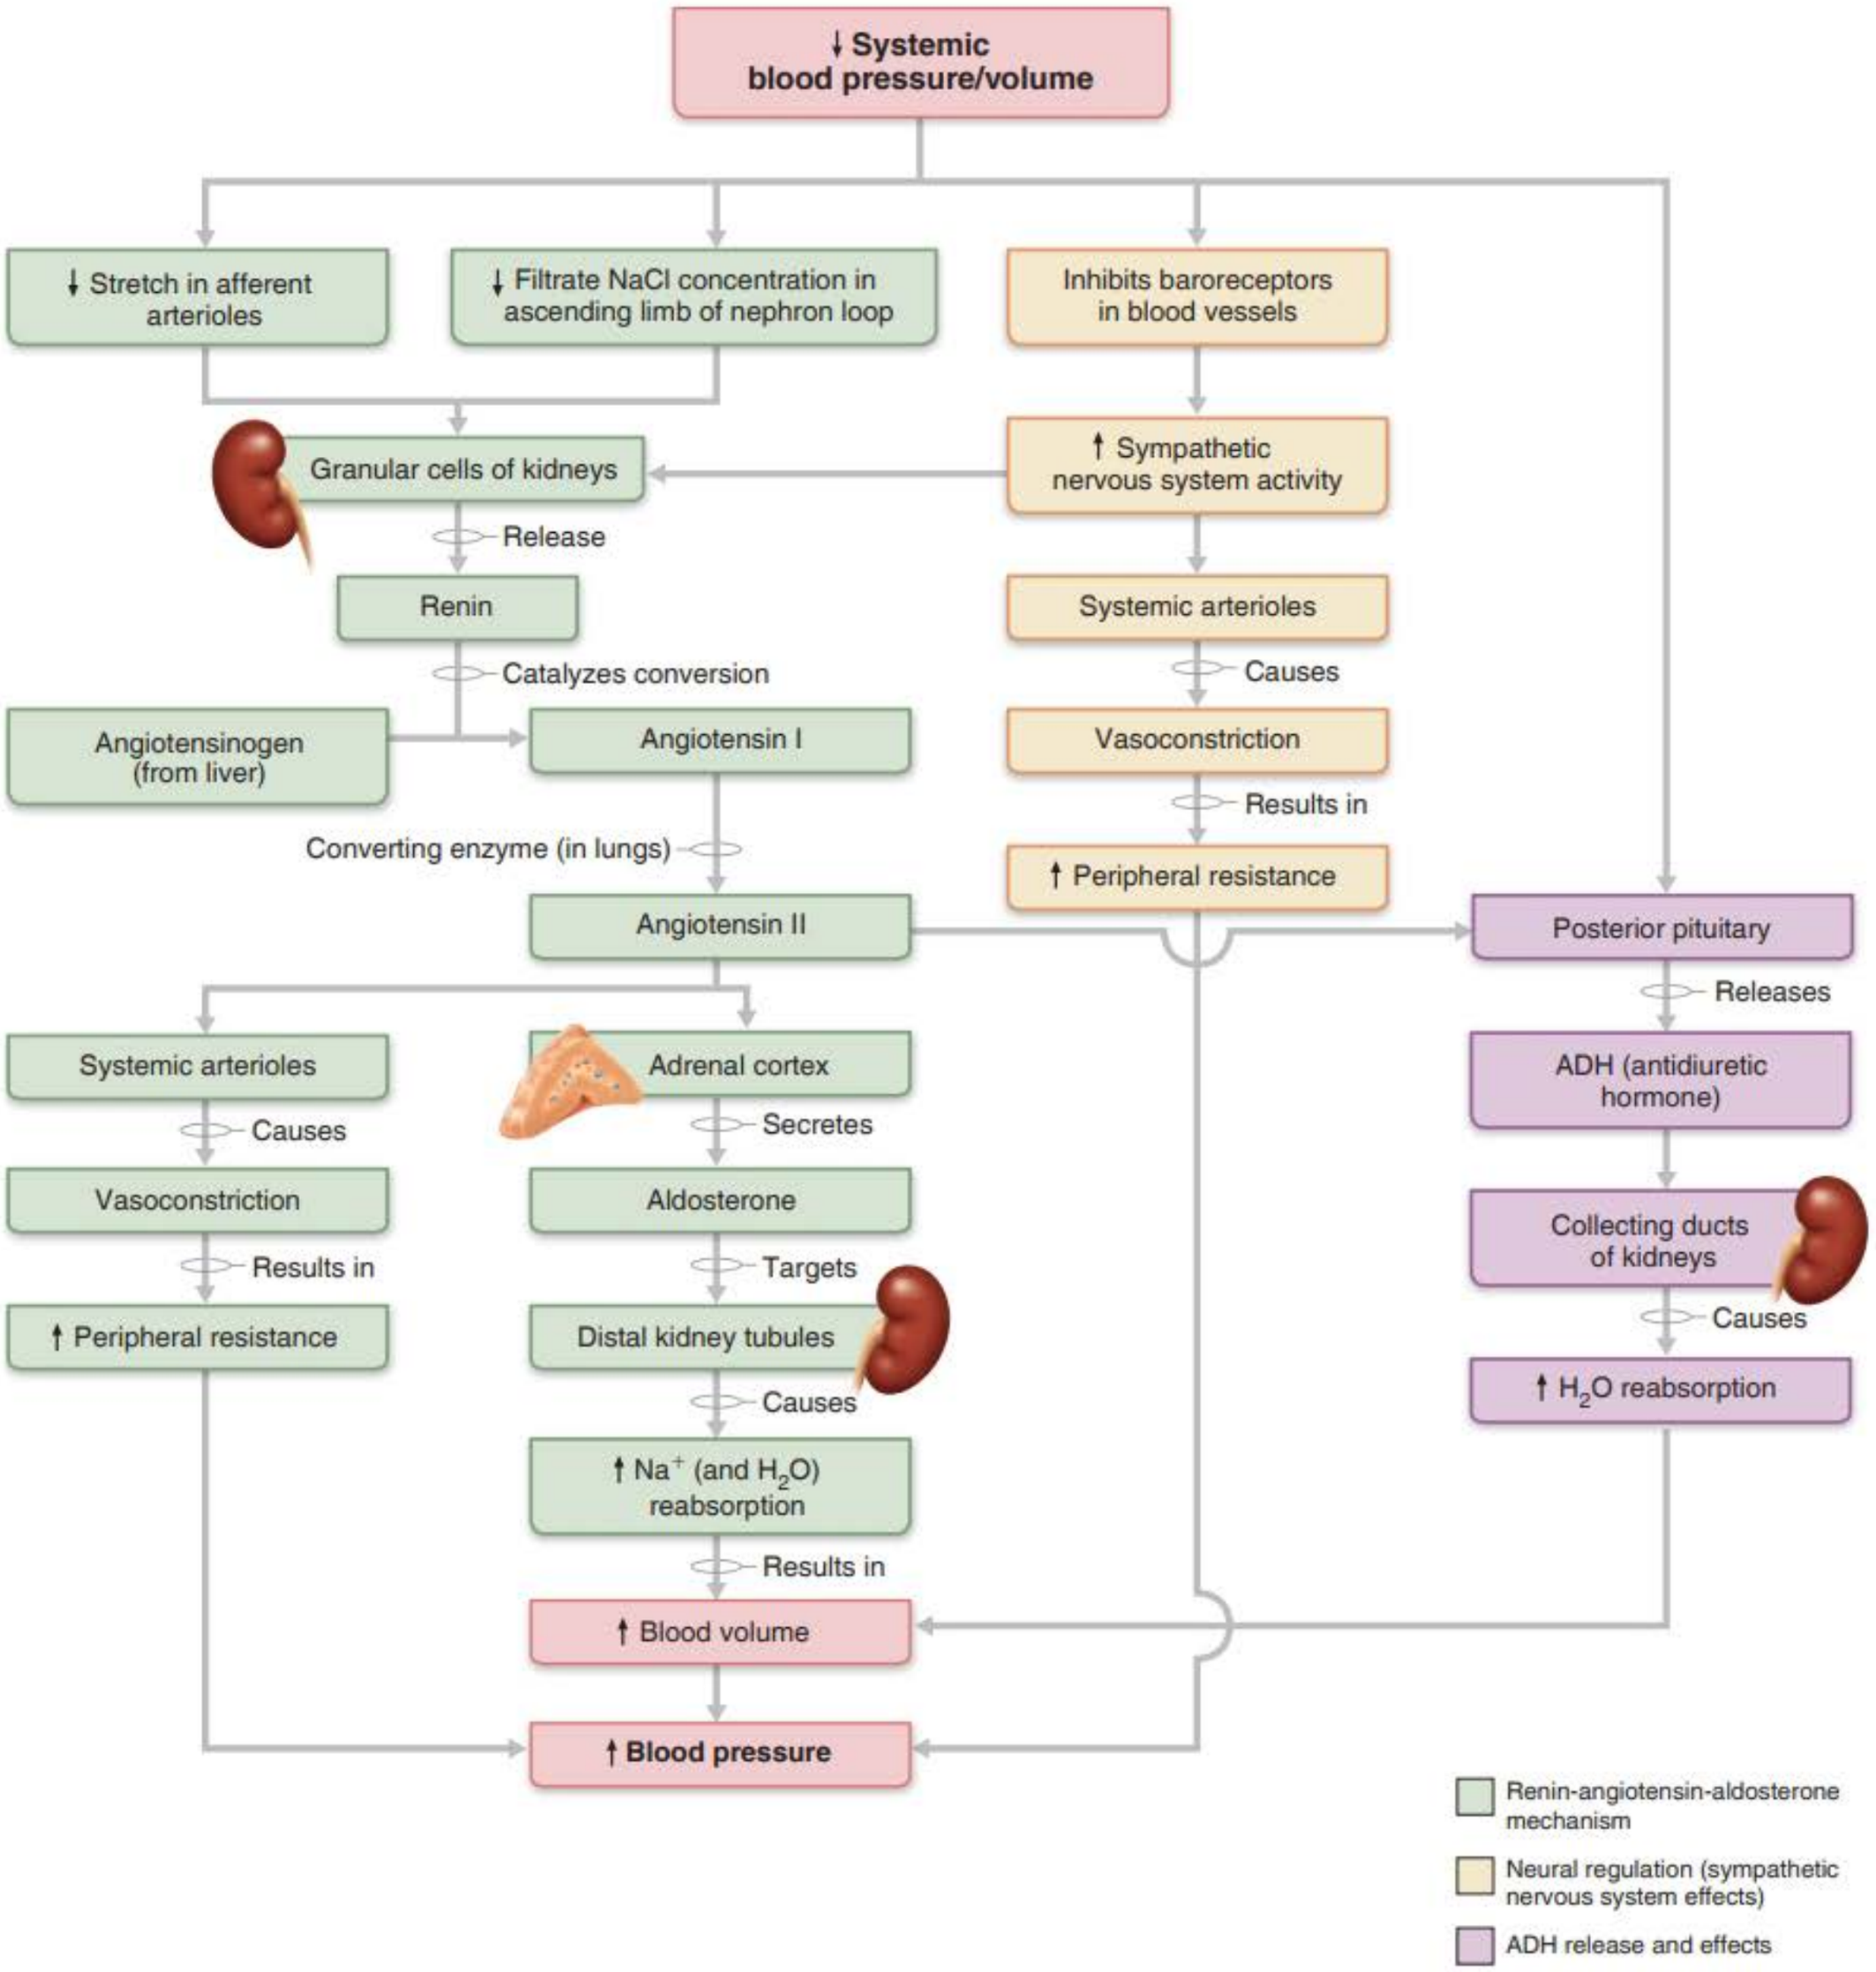

Figure 26.10 Mechanisms regulating sodium and water balance help maintain blood pressure homeostasis. The thirst mechanism, activated by angiotensin II and other factors, is not shown (see Figure 26.5).

systemic blood pressure (**Figure 26.10**). The baroreceptors provide information on the "fullness" or volume of the circulation that is critical for maintaining cardiovascular homeostasis.

Regulation of Potassium Balance

Potassium, the chief intracellular cation, is required for normal neuromuscular functioning as well as for several essential metabolic activities. Even slight changes in K^+ concentration in

the ECF have profound and potentially life-threatening effects on neurons and muscle fibers because the relative ICF-ECF potassium concentration directly affects the resting membrane potential of these cells (◀ pp. 401–403). K^+ excess in the ECF decreases their membrane potential, causing depolarization, often followed by reduced excitability. Too little K^+ in the ECF causes hyperpolarization and nonresponsiveness.

The heart is particularly sensitive to K^+ levels. Both too much and too little K^+ (hyperkalemia and hypokalemia, respectively) can disrupt electrical conduction in the heart, leading to sudden death (Table 26.1).

Potassium is also part of the body's buffer system, which resists changes in the pH of body fluids. Shifts of hydrogen ions (H^+) into and out of cells induce corresponding shifts of K^+ in the opposite direction to maintain cation balance. Consequently, ECF potassium levels rise with acidosis, as K^+ leaves and H^+ enters the cells, and fall with alkalosis, as K^+ enters the cells and H^+ leaves them to enter the ECF. Although these pH-driven shifts do not change the total amount of K^+ in the body, they can seriously interfere with the activity of excitable cells.

Regulatory Site: The DCT and Collecting Duct

Like Na^+ balance, K^+ balance is maintained chiefly by renal mechanisms. However, there are important differences in the way this balance is achieved.

- *K^+ handling.* The proximal tubules reabsorb about 65% of the filtered K^+, and the thick ascending limb of the nephron loop absorbs another 25% or so regardless of need, leaving about 10% at the end of the nephron loop. The responsibility for K^+ balance falls chiefly on the distal convoluted tubule (DCT) and collecting ducts. They achieve this balance mainly by changing the amount of K^+ *secreted* into the filtrate. Notice that nephrons first reabsorb more K^+ than the body needs, and then use secretion of K^+ to fine-tune its balance.
- *Na^+ handling.* In contrast, recall that the amount of Na^+ reabsorbed in the tubules is precisely tailored to need, and Na^+ is *never* secreted into the filtrate.

As a rule, K^+ levels in the ECF are sufficiently high that K^+ needs to be excreted, and the DCT and cortical collecting ducts secrete K^+ into the filtrate. (At times, the amount of K^+ excreted may actually exceed the amount filtered.) The cells responsible for K^+ secretion are the principal cells we described in Chapter 25 (◀ p. 981). Note that these principal cells are the same cells that mediate aldosterone-induced reabsorption of Na^+ and ADH-stimulated reabsorption of water.

When ECF potassium concentrations are abnormally low, the renal principal cells conserve K^+ by reducing its secretion (and therefore excretion) to a minimum. Additionally, *type A intercalated cells*, a unique population of collecting duct cells, can reabsorb some of the K^+ left in the filtrate (in conjunction with active secretion of H^+), thereby helping to reestablish K^+ (and pH) balance.

However, keep in mind that the main thrust of renal regulation of K^+ is to *excrete* it. Because the kidneys have a limited ability to retain K^+, it may be lost in urine even in the face of a deficiency. Consequently, people who don't eat potassium-rich foods can eventually develop a severe deficiency.

Influence of Plasma Potassium Concentration

The single most important factor influencing K^+ secretion is the K^+ concentration in the ECF. A high-potassium diet increases the K^+ content of the ECF. This favors entry of K^+ into the principal cells and prompts them to secrete K^+ into the filtrate so that more of it is excreted. Conversely, a low-potassium diet or accelerated K^+ loss depresses its secretion (and promotes its limited reabsorption).

Influence of Aldosterone

The second factor influencing K^+ secretion into the filtrate is aldosterone. As it stimulates the principal cells to reabsorb Na^+, aldosterone simultaneously enhances K^+ secretion (see Figure 26.8). Adrenal cortical cells are *directly* sensitive to the K^+ content of the ECF bathing them (◀ p. 624). When it increases even slightly, the adrenal cortex is strongly stimulated to release aldosterone, which increases K^+ secretion. The result is that K^+ controls its own concentrations in the ECF via feedback regulation of aldosterone release.

Aldosterone is also secreted in response to the renin-angiotensin-aldosterone mechanism previously described. Given the opposing effects of aldosterone on plasma Na^+ and K^+, you might expect that Na^+- and volume-driven changes in aldosterone would disrupt K^+ balance. This generally does not occur because other compensatory mechanisms in the kidneys maintain plasma K^+.

HOMEOSTATIC IMBALANCE 26.3 — CLINICAL

To reduce their NaCl intake, many people have turned to salt substitutes, which are high in potassium. However, heavy consumption of these substitutes is safe only when aldosterone release in the body is normal. In the absence of aldosterone, hyperkalemia is swift and lethal regardless of K^+ intake (Table 26.1). Conversely, when a person has an adrenocortical tumor that pumps out tremendous amounts of aldosterone, ECF potassium levels fall so low that neurons all over the body hyperpolarize and paralysis occurs.

Regulation of Calcium and Phosphate Balance

About 99% of the body's calcium is found in bones in the form of calcium phosphate salts, which make the skeleton rigid and strong. The bony skeleton provides a dynamic reservoir from which calcium and phosphate can be withdrawn or deposited to maintain the balance of these electrolytes in the ECF (◀ p. 189).

HOMEOSTATIC IMBALANCE 26.4 — CLINICAL

Ionic calcium in the ECF is important for normal blood clotting, cell membrane permeability, and secretory behavior, but

its most important effect by far is on neuromuscular excitability. *Hypocalcemia* increases excitability and causes muscle tetany. *Hypercalcemia* is equally dangerous because it inhibits neurons and muscle cells and may cause life-threatening cardiac arrhythmias (Table 26.1).

ECF calcium ion levels are closely regulated by **parathyroid hormone (PTH)** and rarely deviate from normal limits. [The hormone calcitonin, produced by the thyroid, is often thought of as a calcium-lowering hormone, but, as we discussed in Chapter 6 (◀ p. 189) its effects on blood calcium levels in humans are negligible.] Parathyroid hormone is released by the tiny parathyroid glands located on the posterior aspect of the thyroid gland in the neck. Declining plasma levels of Ca^{2+} directly stimulate the parathyroid glands to release PTH, which promotes an increase in calcium levels by targeting the following organs (see also Figure 16.12, ◀ p. 622):

- **Bones.** PTH activates bone-digesting osteoclasts, which break down the bone matrix, releasing Ca^{2+} and HPO_4^{2-} to the blood.
- **Kidneys.** PTH increases Ca^{2+} reabsorption by the renal tubules while decreasing phosphate ion reabsorption. In this way, calcium conservation and phosphate excretion go hand in hand. The *mathematical product* of Ca^{2+} and HPO_4^{2-} concentrations ($[Ca^{2+}] \times [HPO_4^{2-}]$) in the ECF remains constant, preventing calcium-salt deposits in bones or soft body tissues.
- **Small intestine.** PTH enhances intestinal absorption of Ca^{2+} indirectly by stimulating the kidneys to transform vitamin D to its active form, which is necessary for the small intestine to absorb Ca^{2+}.

Most Ca^{2+} is reabsorbed passively in the proximal convoluted tubule (PCT) via diffusion through the paracellular route (◀ p. 990) (a process driven by its electrochemical gradient). However, as with other ions, Ca^{2+} reabsorption is fine-tuned in the distal nephron. PTH-regulated Ca^{2+} channels control Ca^{2+} entry into DCT cells at the apical membrane, while Ca^{2+} pumps and antiporters export it at the basolateral membrane. Under normal circumstances about 98% of the filtered Ca^{2+} is reabsorbed owing to the action of PTH.

As a rule, 75% of the filtered phosphate ions (including $H_2PO_4^-$, HPO_4^{2-}, and PO_4^{3-}) are reabsorbed in the PCT by secondary active transport. Phosphate reabsorption is set by its transport maximum. Amounts over that maximum simply flow out in urine. PTH inhibits active transport of phosphate by decreasing its transport maximum.

When ECF calcium levels are within normal limits (9–11 mg/100 ml of blood) or higher, PTH secretion is inhibited. Consequently, release of Ca^{2+} from bone is inhibited, more Ca^{2+} is lost in feces and urine, and more phosphate is retained.

Regulation of Anions

Chloride is the major anion accompanying Na^+ in the ECF and, like sodium, Cl^- helps maintain the osmotic pressure of the blood. When blood pH is within normal limits or slightly alkaline, about 99% of filtered Cl^- is reabsorbed. In the PCT, it moves passively and simply follows sodium ions out of the filtrate and into the peritubular capillary blood. In most other tubule segments, Na^+ and Cl^- transport are coupled.

When acidosis occurs, less Cl^- accompanies Na^+ because HCO_3^- reabsorption is stepped up to restore blood pH to its normal range. Thus, the choice between Cl^- and HCO_3^- serves acid-base regulation.

Most other anions, such as sulfates and nitrates, have transport maximums, and when their concentrations in the filtrate exceed the amount that can be reabsorbed, the excess spills into urine.

26.4 Chemical buffers and respiratory regulation rapidly minimize pH changes

Learning Outcomes

- **List important sources of acids in the body.**
- **List the three major chemical buffer systems of the body and describe how they resist pH changes.**
- **Describe the influence of the respiratory system on acid-base balance.**

Because of their abundant hydrogen bonds, all proteins are influenced by H^+ concentration, and because many proteins are enzymes, nearly all biochemical reactions are influenced by the pH of their fluid environment. Consequently, the **acid-base balance** of body fluids is closely regulated (see ◀ pp. 39–41 for a review of the basic principles).

Optimal pH varies from one body fluid to another, but not by much. The normal pH of arterial blood is 7.4, that of venous

blood and IF is 7.35, and that of ICF averages 7.0. The lower pH in cells and venous blood reflects their greater amounts of acidic metabolites and of carbon dioxide, which combines with water to form carbonic acid, H_2CO_3.

Whenever the pH of arterial blood rises above 7.45, a person is said to have **alkalosis** (al″kah-lo′sis) or **alkalemia**. A drop in arterial pH below 7.35 results in **acidosis** (as″ĭ-do′sis) or **acidemia**. Because pH 7.0 is neutral, chemically speaking 7.35 is not acidic. However, it is a higher-than-optimal H^+ concentration for most cells, so any arterial pH between 7.0 and 7.35 is called *physiological acidosis*.

Although small amounts of acidic substances enter the body via ingested foods, most hydrogen ions originate as metabolic by-products or end products. For example:

- Breakdown of phosphorus-containing proteins releases *phosphoric acid* into the ECF.
- Anaerobic respiration of glucose produces *lactic acid.*
- Fat metabolism yields other organic acids, such as fatty acids and *ketone bodies.*
- Loading and transport of carbon dioxide in the blood as HCO_3^- liberates hydrogen ions.

The H^+ concentration in blood is regulated sequentially by:

1. *Chemical buffers.* Chemical buffers are the first line of defense and act within a fraction of a second to resist pH changes.
2. *Brain stem respiratory centers.* Changes in respiratory rate and depth occur to compensate for acidosis or alkalosis within 1–3 minutes.
3. *Renal mechanisms.* The kidneys are the body's most potent acid-base regulatory system, but ordinarily require hours to a day or more to alter blood pH.

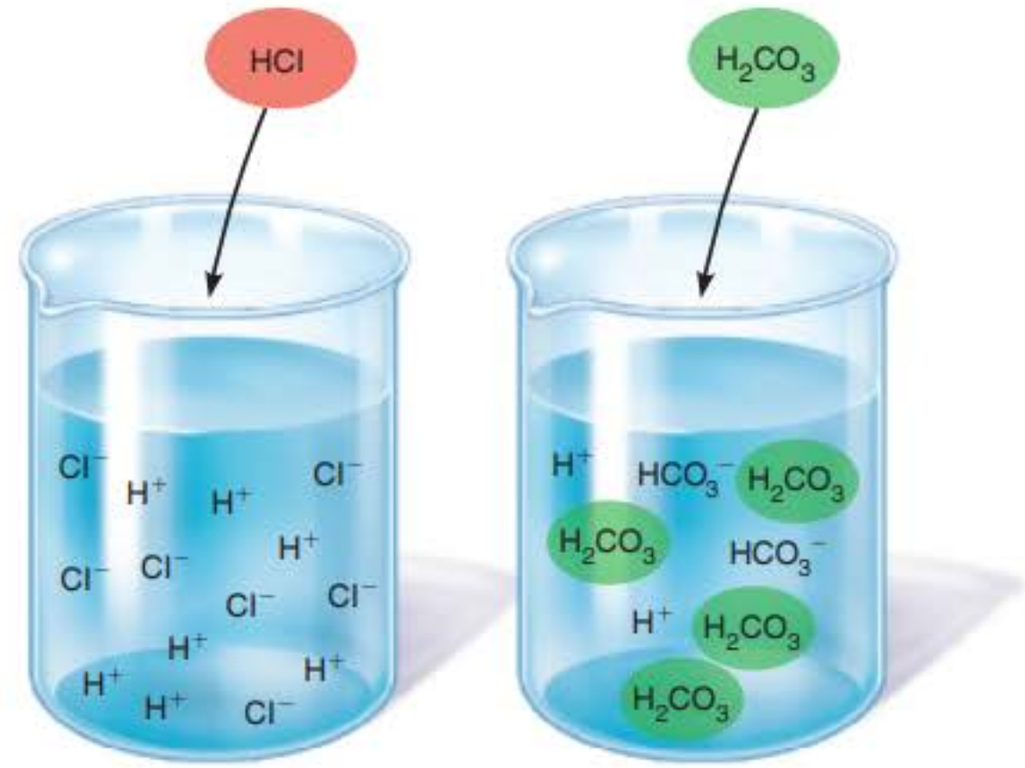
The respiratory and renal systems together form the *physiological buffering systems* that control pH by regulating the amount of acid or base in the body. Although physiological buffer systems act more slowly than chemical buffer systems, they have many times the buffering power of all the body's chemical buffers combined.

Chemical Buffer Systems

Recall that acids are *proton donors*, and that the acidity of a solution reflects only the *free* hydrogen ions, not those bound to anions. *Strong acids* dissociate completely and liberate all their H^+ in water (**Figure 26.11a**). They can dramatically change a solution's pH. By contrast, *weak acids* dissociate only partially (Figure 26.11b). Accordingly, they have a much smaller effect on pH. However, weak acids are efficient at preventing pH changes, and this feature allows them to play important roles in chemical buffer systems.

Bases are *proton acceptors*. Strong bases are those that dissociate easily in water and quickly tie up H^+. Conversely, weak bases are less likely to accept protons.

A **chemical buffer** is a system of one or more compounds that resists changes in pH when a strong acid or base is added. They do this by binding H^+ ions whenever the pH drops and releasing them when pH rises.



(a) A strong acid such as HCl dissociates completely into its ions. **(b) A weak acid such as H_2CO_3 does *not* dissociate completely.**

Figure 26.11 Dissociation of strong and weak acids in water. HCl = hydrochloric acid; H_2CO_3 = carbonic acid.

The three major chemical buffer systems in the body are the *bicarbonate*, *phosphate*, and *protein buffer systems*. Anything that causes a shift in H^+ concentration in one fluid compartment simultaneously causes a change in the others. As a result, the buffer systems actually buffer one another, so the *entire* buffer system resists any drifts in pH.

Bicarbonate Buffer System

The **bicarbonate buffer system** is a mixture of carbonic acid (H_2CO_3) and its salt, sodium bicarbonate ($NaHCO_3$, a weak base), in the same solution. Although it also buffers the ICF, it is the *only* important ECF buffer.

Carbonic acid, a weak acid, does not dissociate to any great extent in neutral or acidic solutions. When a strong acid such as HCl is added to this buffer system, the existing carbonic acid remains intact. However, the bicarbonate ions of the salt act as weak bases to tie up the H^+ released by the stronger acid (HCl), forming *more* carbonic acid:

$$\underset{\text{strong acid}}{HCl} + \underset{\text{weak base}}{NaHCO_3} \rightarrow \underset{\text{weak acid}}{H_2CO_3} + \underset{\text{salt}}{NaCl}$$

Because it is converted to the weak acid H_2CO_3, HCl lowers the pH of the solution only slightly.

When a strong base such as sodium hydroxide (NaOH) is added to the same buffer solution, a weak base such as sodium bicarbonate ($NaHCO_3$) does not dissociate further under the alkaline conditions. However, the added base forces the carbonic acid to dissociate further, donating more H^+ to tie up the OH^- released by the strong base:

$$\underset{\text{strong base}}{NaOH} + \underset{\text{weak acid}}{H_2CO_3} \rightarrow \underset{\text{weak base}}{NaHCO_3} + \underset{\text{water}}{H_2O}$$

The net result is that a weak base ($NaHCO_3$) replaces a strong base (NaOH), so the pH of the solution rises very little.

Although the bicarbonate salt in the example is sodium bicarbonate, other bicarbonate salts function in the same way because HCO_3^- is the important ion, not the cation it is paired with. In cells, where little Na^+ is present, potassium and magnesium bicarbonates are part of the bicarbonate buffer system.

The buffering power of this type of system is directly related to the concentrations of the buffering substances. If enough acid enters the blood so that all the available HCO_3^- ions, often referred to as the **alkaline reserve**, are tied up, the buffer system becomes ineffective and blood pH changes.

The bicarbonate ion concentration in the ECF is normally around 25 mEq/L and is closely regulated by the kidneys. The concentration of H_2CO_3 is just over 1 mEq/L but the supply of H_2CO_3 (which comes from the CO_2 released during cellular respiration) is almost limitless, so obtaining that member of the buffer pair is usually not a problem. The H_2CO_3 content of the blood is subject to respiratory controls.

Phosphate Buffer System

The operation of the **phosphate buffer system** is nearly identical to that of the bicarbonate buffer. The components of the phosphate system are the salts of dihydrogen phosphate ($H_2PO_4^-$) and monohydrogen phosphate (HPO_4^{2-}). For example NaH_2PO_4 acts as a weak acid. Na_2HPO_4, with one less hydrogen atom, acts as a weak base.

Again, H^+ released by strong acids is tied up in weak acids:

$$\underset{\text{strong acid}}{HCl} + \underset{\text{weak base}}{Na_2HPO_4} \rightarrow \underset{\text{weak acid}}{NaH_2PO_4} + \underset{\text{salt}}{NaCl}$$

and strong bases are converted to weak bases:

$$\underset{\text{strong base}}{NaOH} + \underset{\text{weak acid}}{NaH_2PO_4} \rightarrow \underset{\text{weak base}}{Na_2HPO_4} + \underset{\text{water}}{H_2O}$$

Because the phosphate buffer system is present in low concentrations in the ECF (approximately one-sixth that of the bicarbonate buffer system), it is relatively unimportant for buffering blood plasma. However, it is a very effective buffer in urine and in ICF, where phosphate concentrations are usually higher.

Protein Buffer System

Proteins in plasma and in cells are the body's **protein buffer system**. In fact, at least three-quarters of all the buffering power of body fluids resides in cells, and most of this reflects the powerful buffering activity of intracellular proteins.

As described in Chapter 2, proteins are polymers of amino acids. Some of the linked amino acids have exposed side chains of atoms called *carboxyl groups* (—COOH), organic acid groups that release H^+ when the pH begins to rise:

$$R—COOH \rightarrow R—COO^- + H^+$$

(Note that R indicates the rest of the organic molecule, which contains many atoms.)

Other amino acids have exposed groups that can act as bases and accept H^+. For example, an exposed $—NH_2$ group can bind with a hydrogen ion, becoming $—NH_3^+$:

$$R—NH_2 + H^+ \rightarrow R—NH_3^+$$

Bicarbonate Buffer System
- Mixture of H_2CO_3 (weak acid) and salts of HCO_3^- (weak base)
- Main ECF buffer; also operates in ICF

Phosphate Buffer System
- Salts of $H_2PO_4^-$ (weak acid) and HPO_4^{2-} (weak base)
- Important buffer in urine and ICF

Protein Buffer System
- Some amino acid side chains can act as weak acids (—COOH) or weak bases (e.g., $—NH_2$)
- Most important buffer in ICF; also in blood plasma

Figure 26.12 Quick summary of chemical buffer systems.

Because this binding removes free hydrogen ions from the solution, it prevents the solution from becoming too acidic. Consequently, a single protein molecule can function reversibly as either an acid or a base depending on the pH of its environment. Molecules with this ability are called **amphoteric molecules** (am″fo-ter′ik).

Hemoglobin in red blood cells is an excellent example of an intracellular protein buffer. As we explained in Chapter 22 (◀ pp. 850–851), CO_2 released from the tissues combines with water to form carbonic acid (H_2CO_3), which dissociates to liberate H^+ and HCO_3^- in the blood. Meanwhile, hemoglobin is unloading oxygen, becoming reduced hemoglobin, which carries a negative charge. Because H^+ rapidly binds to the hemoglobin anions, pH changes are minimized. In this case, carbonic acid, a weak acid, is buffered by an even weaker acid, hemoglobin.

The three main chemical buffers are summarized in **Figure 26.12**.

Respiratory Regulation of H^+

As we described in Chapter 22, the respiratory system eliminates CO_2, an acid, from the blood while replenishing its supply of O_2. Carbon dioxide generated by cellular respiration enters erythrocytes in the circulation and is converted to bicarbonate ions for transport in the plasma (◀ p. 850):

$$CO_2 + H_2O \underset{\text{carbonic acid}}{\overset{\text{carbonic anhydrase}}{\rightleftharpoons}} H_2CO_3 \rightleftharpoons H^+ + \underset{\text{bicarbonate ion}}{HCO_3^-}$$

The first set of double arrows indicates a reversible equilibrium between dissolved carbon dioxide and water on the left and carbonic acid on the right. The second set indicates a reversible equilibrium between carbonic acid on the left and hydrogen and bicarbonate ions on the right. Because of these equilibria, an increase in any of these chemical species pushes the reaction in the opposite direction. Notice also that the right side of the equation is equivalent to the bicarbonate buffer system.

Healthy individuals expel CO_2 from the lungs at the same rate it is formed in the tissues. During carbon dioxide unloading, the reaction shifts to the left, and H^+ generated from carbonic acid is reincorporated into water. Because of the protein

buffer system, H^+ produced by CO_2 transport is not allowed to accumulate and has little or no effect on blood pH.

If P_{CO_2} (the partial pressure, or level, of CO_2 in the blood) rises, it activates medullary chemoreceptors (via cerebral acidosis promoted by excessive accumulation of CO_2). As a result, respiratory rate and depth increase (◀ Figure 22.28, p. 855). Additionally, a rising plasma H^+ concentration resulting from any metabolic process excites the respiratory centers indirectly (via peripheral chemoreceptors) to stimulate deeper, more rapid respiration. As ventilation increases, more CO_2 is removed from the blood, pushing the reaction to the left and reducing the H^+ concentration.

When blood pH rises, the respiratory centers are depressed. As respiratory rate drops and respiration becomes shallower, CO_2 accumulates, pushing the equilibrium to the right and causing the H^+ concentration to increase. Again blood pH is restored to the normal range. These respiratory system–mediated corrections of blood pH are accomplished within a minute or so.

Changes in alveolar ventilation can produce dramatic changes in blood pH—far more than is needed. For example, doubling alveolar ventilation can raise blood pH by about 0.2 pH unit. Likewise, cutting alveolar ventilation in half can lower blood pH by the same amount. Because normal arterial pH is 7.4, a change of 0.2 pH unit yields a blood pH of 7.6 or 7.2—both well beyond the normal limits. Respiratory controls of blood pH have a tremendous reserve capacity because alveolar ventilation can rise about 15-fold or fall (briefly) to zero.

Anything that impairs respiratory system functioning causes acid-base imbalances. For example, net carbon dioxide retention (hypoventilation) leads to acidosis. On the other hand, hyperventilation, which causes net elimination of CO_2, causes alkalosis. When respiratory system problems cause the pH imbalance, the resulting condition is either *respiratory acidosis* or *respiratory alkalosis* (see Table 26.3 on p. 1033).

10. Define acidemia and alkalemia.

11. What are the body's three major chemical buffer systems? What is the most important buffer inside cells?

12. APPLY Joanne, a diabetic patient, is at the emergency department with acidosis due to the production of ketone bodies (◀ p. 632). Would you expect her ventilation to be increased or decreased? Why?

For answers, see Answers Appendix.

26.5 Renal regulation is a long-term mechanism for controlling acid-base balance

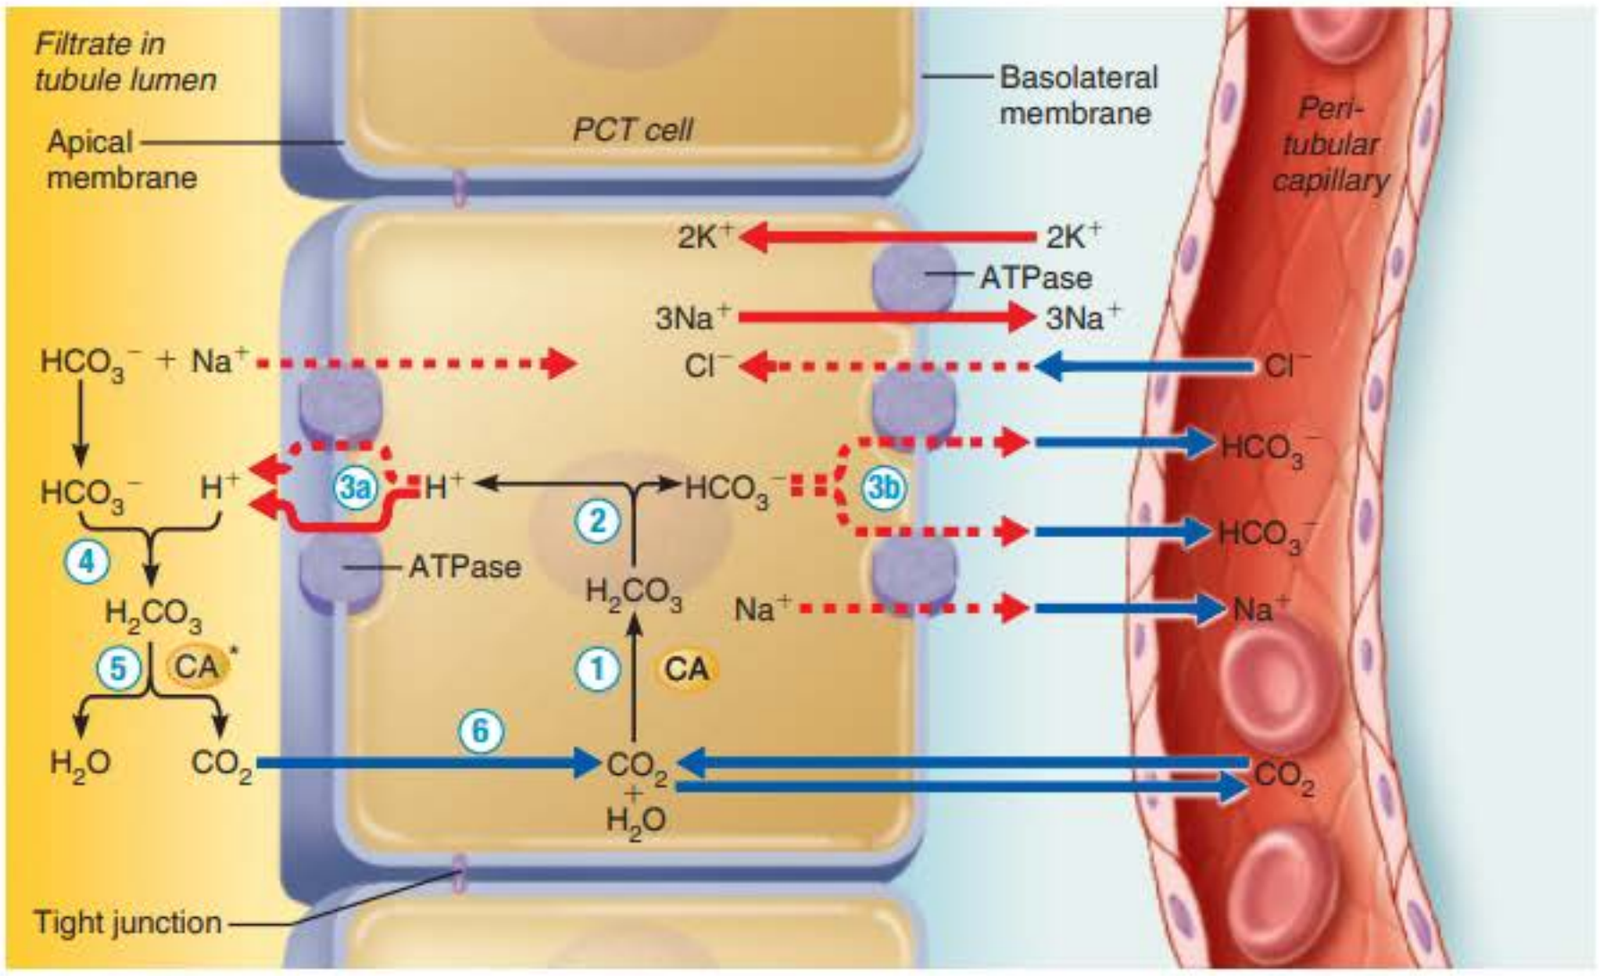
Learning Outcome

▶ **Describe how the kidneys regulate hydrogen and bicarbonate ion concentrations in the blood.**

The ultimate acid-base regulatory organs are the kidneys, which act slowly but surely to compensate for acid-base imbalances resulting from variations in diet or metabolism, or disease. Chemical buffers can tie up excess acids or bases temporarily, but they cannot eliminate them from the body. And while the lungs can dispose of the **volatile acid** carbonic acid by eliminating CO_2, only the kidneys can rid the body of other acids generated by cellular metabolism: phosphoric, uric, and lactic acids, and ketone bodies. These acids are referred to as **nonvolatile (fixed) acids**. Additionally, only the kidneys can regulate blood levels of alkaline substances and renew chemical buffers that are used up in regulating H^+ levels in the ECF.

The kidneys regulate acid-base balance by adjusting the amount of bicarbonate in the blood. Depending on the blood's pH, the kidneys do one of the following:

- Conserve (reabsorb) or generate new HCO_3^-
- Excrete HCO_3^-



1. CO_2 combines with water within the tubule cell, forming H_2CO_3.
2. H_2CO_3 is quickly split, forming H^+ and bicarbonate ion (HCO_3^-).
3a. H^+ is secreted into the filtrate.
3b. For each H^+ secreted, a HCO_3^- enters the peritubular capillary blood either via symport with Na^+ or via antiport with Cl^-.
4. Secreted H^+ combines with HCO_3^- in the filtrate, forming carbonic acid (H_2CO_3). HCO_3^- disappears from the filtrate at the same rate that HCO_3^- (formed within the tubule cell) enters the peritubular capillary blood.
5. The H_2CO_3 formed in the filtrate dissociates to release CO_2 and H_2O.
6. CO_2 diffuses into the tubule cell, where it triggers further H^+ secretion.

Figure 26.13 Reabsorption of filtered HCO_3^- is coupled to H^+ secretion.

*The breakdown of H_2CO_3 to CO_2 and H_2O in the tubule lumen is catalyzed by carbonic anhydrase only in the proximal convoluted tubule (PCT).

If we look back at the equation on p. 1028 for the CO_2–carbonic acid–bicarbonate buffer system, we can see that losing a HCO_3^- from the body produces the same net effect as gaining a H^+, because it pushes the equation to the right, increasing the H^+ level. By the same token, generating or reabsorbing HCO_3^- is the same as losing H^+ because it pushes the equation to the left, decreasing the H^+ level. For this reason, to reabsorb bicarbonate, the kidney has to secrete H^+, and when it excretes excess HCO_3^-, H^+ is retained (not secreted).

Because the mechanisms for regulating acid-base balance depend on H^+ being secreted into the filtrate, we consider that process first. Secretion of H^+ occurs mainly in the PCT and in type A intercalated cells of the collecting duct. The H^+ secreted comes from the dissociation of carbonic acid, which is created when CO_2 and water combine within the tubule cells in a reaction catalyzed by *carbonic anhydrase* (**Figure 26.13** ①, ②). As H^+ is secreted into the lumen of the PCT, Na^+ is reabsorbed from the filtrate, maintaining the electrical balance (Figure 26.13 3a).

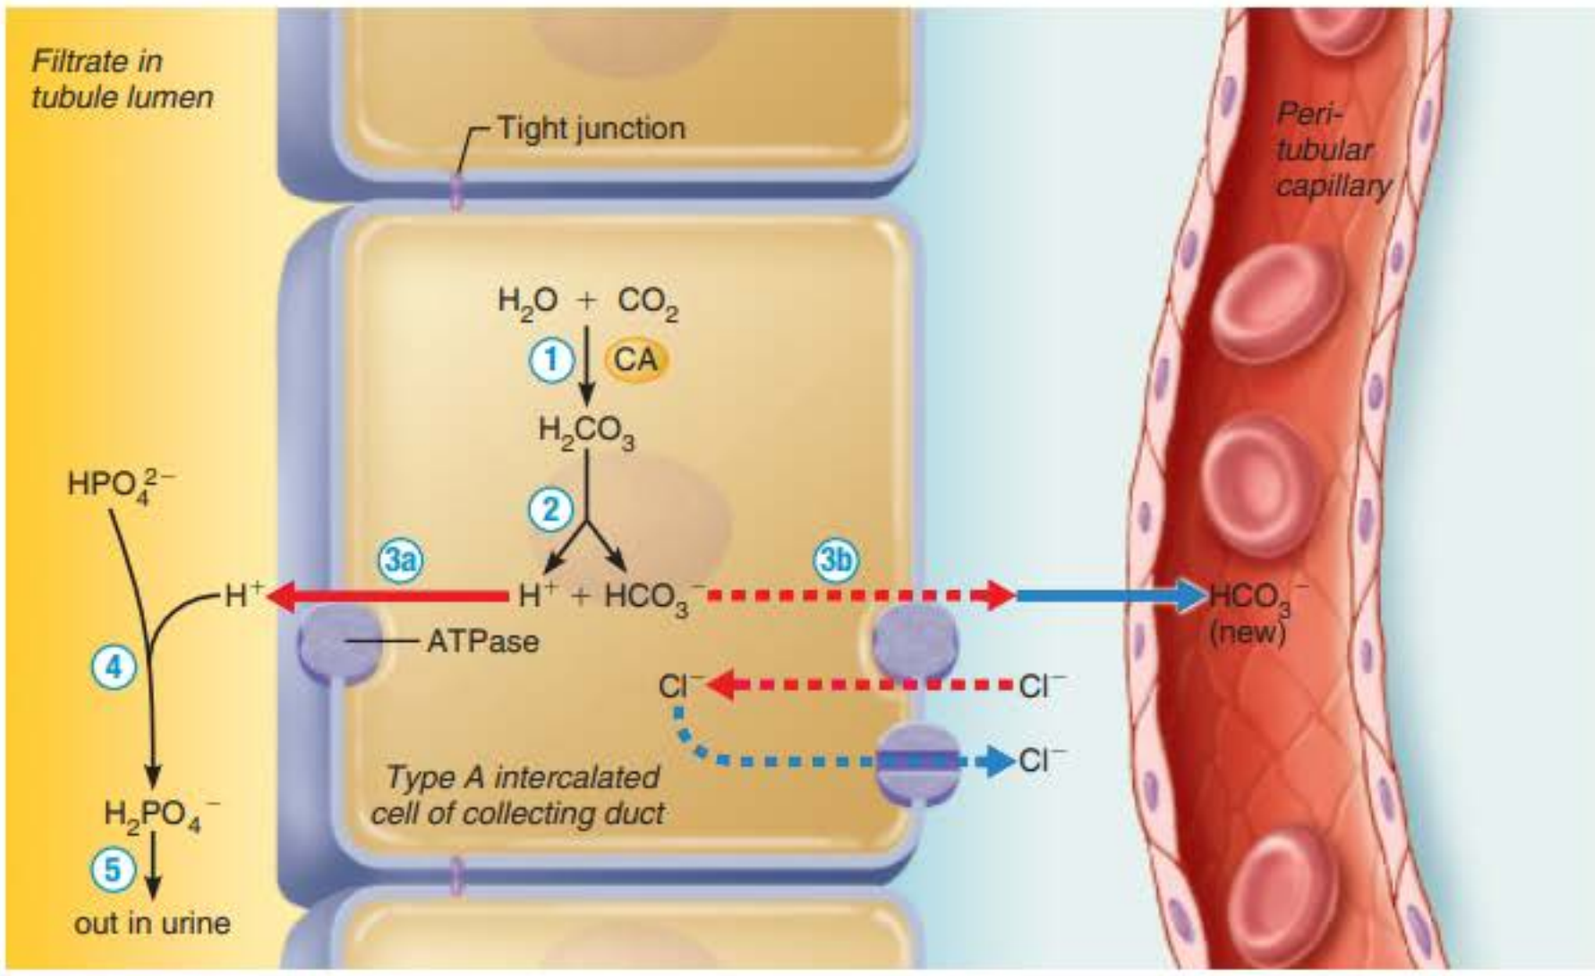
The rate of H^+ secretion rises and falls with CO_2 levels in the ECF. The more CO_2 in the peritubular capillary blood, the faster the rate of H^+ secretion. Because blood CO_2 levels directly relate to blood pH, this system can respond to both rising and falling H^+ concentrations. Notice that secreted H^+ can combine with HCO_3^- in the filtrate, generating CO_2 and water (Figure 26.13 ④, ⑤). In this case, H^+ is bound in water. The rising concentration of CO_2 in the filtrate creates a steep diffusion gradient for its entry into the tubule cell (Figure 26.13 ⑥), where it promotes still more H^+ secretion (Figure 26.13 3a).

Conserving Filtered Bicarbonate Ions: Bicarbonate Reabsorption

Bicarbonate (HCO_3^-; a base) is an important part of the bicarbonate buffer system, a critical blood buffer. If this reservoir of base, the *alkaline reserve*, is to be maintained, the kidneys must do more than just eliminate enough hydrogen ions to counter rising blood H^+ levels. Depleted stores of HCO_3^- have to be replenished. This task is more complex than it seems because the apical membranes of the tubule cells have no transporters for HCO_3^- and so HCO_3^- cannot cross these membranes. As a result, tubule cells cannot reabsorb HCO_3^- directly.

However, the kidneys can conserve filtered HCO_3^- in a rather roundabout way. As you can see, dissociation of carbonic acid liberates HCO_3^- as well as H^+ (Figure 26.13 ②). Although the tubule cells cannot reclaim HCO_3^- directly from the filtrate, they can and do shunt HCO_3^- generated within them (as a result of splitting H_2CO_3) into the peritubular capillary blood. HCO_3^- leaves the tubule cell either accompanied by Na^+ or in exchange for Cl^- (Figure 26.13 3b). H^+ is actively secreted, mostly by a Na^+-H^+ antiporter, but also by a H^+ ATPase (Figure 26.13 3a). In the filtrate, H^+ combines with filtered HCO_3^- (Figure 26.13 ④, ⑤). For this reason, reabsorption of HCO_3^- depends on the active secretion of H^+.

In short, for each filtered HCO_3^- that "disappears" from the filtrate, a HCO_3^- generated within the tubule cells enters the blood—a one-for-one exchange. When large amounts of H^+ are secreted, correspondingly large amounts of HCO_3^- enter the



(1) CO_2 combines with water within the type A intercalated cell, forming H_2CO_3.

(2) H_2CO_3 is quickly split, forming H^+ and bicarbonate ion (HCO_3^-).

(3a) H^+ is secreted into the filtrate by a H^+ ATPase (pump).

(3b) For each H^+ secreted, a HCO_3^- enters the peritubular capillary blood via an antiport carrier in a HCO_3^--Cl^- exchange process.

(4) Secreted H^+ combines with HPO_4^{2-} in the tubular filtrate, forming $H_2PO_4^-$.

(5) The $H_2PO_4^-$ is excreted in the urine.

Figure 26.14 New HCO_3^- is generated via buffering of secreted H^+ by HPO_4^{2-} (monohydrogen phosphate).

peritubular blood. The net effect is to remove HCO_3^- almost completely from the filtrate.

Generating New Bicarbonate Ions

Two renal mechanisms commonly carried out by cells of the PCT and collecting ducts generate *new* (as opposed to filtered) HCO_3^- that can be added to plasma. Both mechanisms involve renal excretion of acid, *via secretion and excretion* of either H^+ or ammonium ions in urine. Let's examine how these mechanisms differ.

As long as *filtered bicarbonate* is reclaimed, as we saw in Figure 26.13, the secreted H^+ is *not excreted or lost* from the body in urine. Instead, the H^+ is buffered by HCO_3^- in the filtrate and ultimately becomes part of water molecules (most of which are reabsorbed) (Figure 26.13 (4), (5)).

However, once the filtered HCO_3^- is "used up" (usually by the time the filtrate reaches the collecting ducts), any additional H^+ secreted is excreted in urine. More often than not, this is the case.

Reclaiming filtered HCO_3^- simply restores the bicarbonate concentration of plasma that exists at the time. However, metabolism of food normally releases new H^+ into the body. This additional H^+ uses up HCO_3^- and so must be balanced by generating *new* HCO_3^- that moves into the blood to counteract acidosis. This process of alkalinizing the blood is the way the kidneys compensate for acidosis.

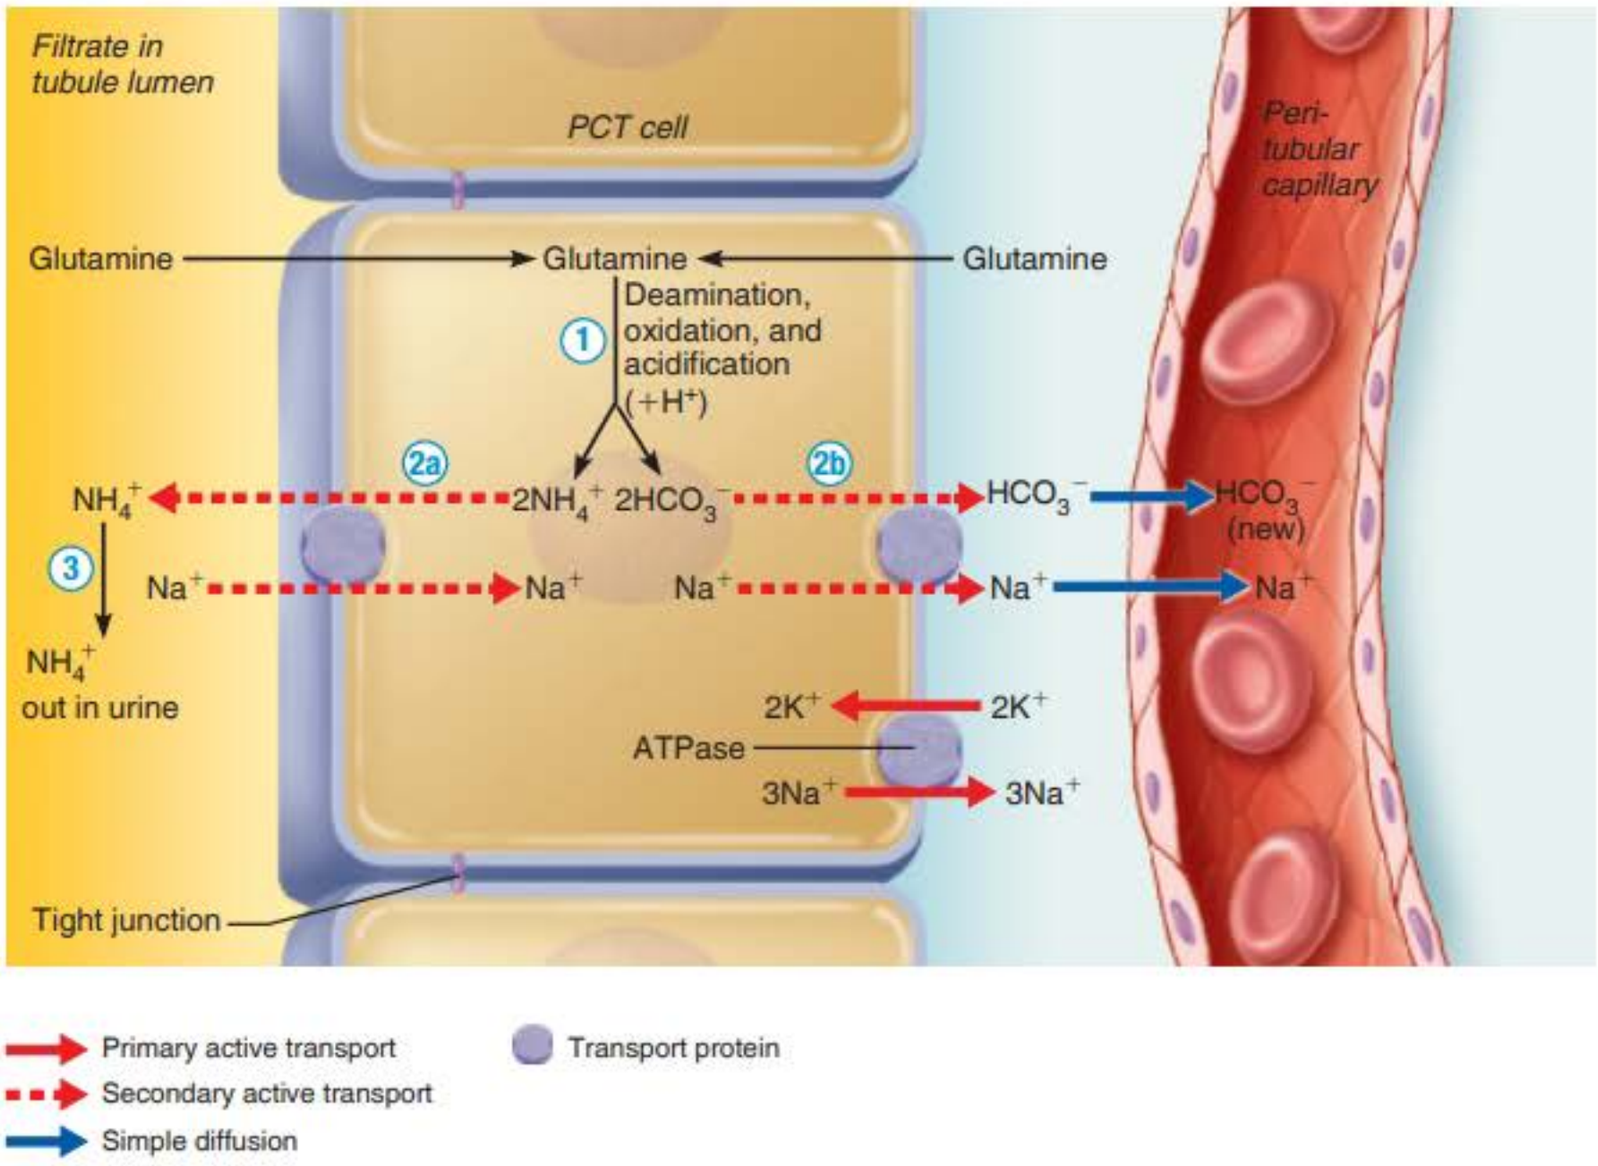
Via Excretion of Buffered H^+

Binding H^+ to buffers in the filtrate minimizes the H^+ concentration gradient, allowing the proton pumps of the type A intercalated cells to secrete the large numbers of H^+ that the body must get rid of to prevent acidosis. (H^+ secretion ceases when urine pH falls to 4.5 because the proton pumps cannot pump against this large gradient.) The most important urine buffer is the *phosphate buffer system*, specifically its weak base *monohydrogen phosphate* (HPO_4^{2-}).

The components of the phosphate buffer system filter freely into the tubules, and about 75% of the filtered phosphate is reabsorbed. However, their reabsorption is inhibited during acidosis. As a result, the buffer pair becomes more and more concentrated as the filtrate moves through the renal tubules.

As shown in **Figure 26.14** (3a), the type A intercalated cells secrete H^+ actively via a H^+ ATPase pump and via a K^+-H^+ antiporter (not illustrated). The secreted H^+ combines with HPO_4^{2-}, forming $H_2PO_4^-$ which then flows out in urine (Figure 26.14 (4) and (5)).

Bicarbonate ions generated in the cells during the same reaction move into the interstitial space via a HCO_3^--Cl^- antiport process and then move passively into the peritubular capillary blood (Figure 26.14 (3b)). Notice again that when H^+ is being excreted, "brand new" bicarbonate ions are added to the blood—over and above those reclaimed from the filtrate. As you can see, in response to acidosis, the kidneys generate new HCO_3^- and add it to the blood (alkalinizing the blood) while adding an equal amount of H^+ to the filtrate (acidifying the urine).



1 PCT cells metabolize glutamine to NH_4^+ and HCO_3^-.

2a This weak acid NH_4^+ (ammonium) is secreted into the filtrate, taking the place of H^+ on a Na^+-H^+ antiport carrier.

2b For each NH_4^+ secreted, a bicarbonate ion (HCO_3^-) enters the peritubular capillary blood via a symport carrier.

3 The NH_4^+ is excreted in the urine.

Figure 26.15 New HCO_3^- is generated via glutamine metabolism and NH_4^+ secretion.

Via NH_4^+ Excretion

The second and more important mechanism for excreting acid uses the ammonium ion (NH_4^+) produced by glutamine metabolism in PCT cells. Ammonium ions are weak acids that donate few H^+ at physiological pH.

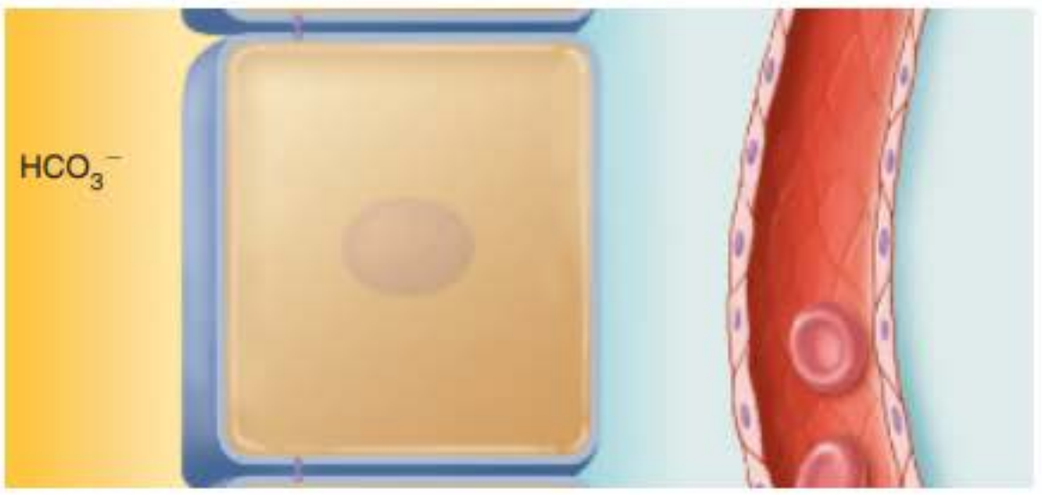
As **Figure 26.15** step (1) shows, for each glutamine metabolized (deaminated, oxidized, and acidified by combining with H^+), two NH_4^+ and two HCO_3^- result. The HCO_3^- moves through the basolateral membrane into the blood (Figure 26.15 (2b)). The NH_4^+, in turn, is excreted and lost in urine (Figure 26.15 (2a), (3)). As with the phosphate buffer system, this buffering mechanism replenishes the alkaline reserve of the blood, because the newly made HCO_3^- enters the blood as NH_4^+ is secreted.

Bicarbonate Ion Secretion

When the body is in alkalosis, another population of intercalated cells (type B) in the collecting ducts exhibit net HCO_3^- *secretion* while reclaiming H^+ to acidify the blood. Overall we can think of the type B cells as "flipped" type A cells, and we can visualize the HCO_3^- secretion process as the exact opposite of the HCO_3^- reabsorption process illustrated in Figure 26.13. However, the predominant process in the nephrons and collecting ducts is HCO_3^- reabsorption, and even during alkalosis, much more HCO_3^- is conserved than excreted.

Check Your Understanding

13. What is the most important urinary buffer of H^+?
14. List the two mechanisms by which tubule and collecting duct cells generate new HCO_3^-.
15. DRAW Using arrows and the appropriate equations, show how bicarbonate is reabsorbed from the tubular lumen. You do not need to include Na^+, K^+, Cl^-, or transport proteins. Remember that there are no transport proteins for moving bicarbonate into the tubule cell.



16. MAKE CONNECTIONS Renal tubule cells acidify the urine and parietal cells acidify the stomach contents (see Chapter 23, ◀ p. 891). In each case (a) which intracellular enzyme is key, and (b) blood concentration of which ion increases?

For answers, see Answers Appendix.

26.6 Abnormalities of acid-base balance are classified as metabolic or respiratory

CLINICAL

Learning Outcomes

- **Distinguish between acidosis and alkalosis resulting from respiratory and metabolic factors.**
- **Describe the importance of respiratory and renal compensations in maintaining acid-base balance.**

All cases of acidosis and alkalosis can be classed according to cause as *respiratory* or *metabolic* (**Table 26.3**). **A Closer Look** on p. 1034 discusses methods for determining the cause of an acid-base disturbance and whether it is being compensated (whether the lungs or kidneys are taking steps to correct the imbalance).

Respiratory Acidosis and Alkalosis

Respiratory pH imbalances result from some failure of the respiratory system to perform its normal pH-balancing role. The partial pressure of carbon dioxide (P_{CO_2}) in the arteries is the single most important indicator of the adequacy of respiratory function. When respiratory function is normal, the P_{CO_2} fluctuates between 35 and 45 mm Hg. Generally speaking, values above 45 mm Hg indicate respiratory acidosis, and values below 35 mm Hg signal respiratory alkalosis.

Respiratory acidosis is a common cause of acid-base imbalance. It most often occurs when a person breathes shallowly or

Table 26.3 Causes and Consequences of Acid-Base Imbalances

CONDITION AND HALLMARK	POSSIBLE CAUSES; COMMENTS
Respiratory Acidosis (Hypoventilation)	
If uncompensated (uncorrected): P_{CO_2} >45 mm Hg; pH <7.35	**Impaired lung function** (e.g., chronic bronchitis, cystic fibrosis, emphysema): impaired gas exchange or alveolar ventilation
	Impaired ventilatory movement: paralyzed respiratory muscles, chest injury, extreme obesity
	Narcotic or barbiturate overdose or injury to brain stem: depression of respiratory centers, resulting in hypoventilation and respiratory arrest
Respiratory Alkalosis (Hyperventilation)	
If uncompensated: P_{CO_2} <35 mm Hg; pH >7.45	**Strong emotions:** pain, anxiety, fear, panic attack
	Hypoxemia: asthma, pneumonia, high altitude; represents effort to raise P_{O_2} at the expense of excessive CO_2 excretion
	Brain tumor or injury: abnormal respiratory controls
Metabolic Acidosis	
If uncompensated: HCO_3^- <22 mEq/L; pH <7.35	**Severe diarrhea:** bicarbonate-rich intestinal (and pancreatic) secretions rushed through digestive tract before their solutes can be reabsorbed
	Renal disease: failure of kidneys to rid body of acids formed by normal metabolic processes
	Untreated diabetes mellitus: lack of insulin or inability of tissue cells to respond to insulin, resulting in inability to use glucose; fats are used as primary energy fuel, and ketoacidosis occurs
	Starvation: lack of dietary nutrients for cellular fuels; body proteins and fat reserves are used for energy—both yield acidic metabolites as they are broken down for energy
	Excess alcohol ingestion: results in excess acids in blood
Metabolic Alkalosis	
If uncompensated: HCO_3^- >26 mEq/L; pH >7.45	**Vomiting or gastric suctioning:** loss of stomach HCl requires that H^+ be withdrawn from blood to replace stomach acid; thus H^+ decreases and HCO_3^- increases proportionately
	Selected diuretics: cause K^+ depletion and H_2O loss. Low K^+ directly stimulates tubule cells to secrete H^+. Reduced blood volume elicits the renin-angiotensin-aldosterone mechanism, which stimulates Na^+ reabsorption and H^+ secretion.
	Ingestion of excessive sodium bicarbonate (antacid): bicarbonate moves easily into ECF, where it enhances natural alkaline reserve
	Excess aldosterone (e.g., adrenal tumors): promotes excessive reabsorption of Na^+, which pulls increased amount of H^+ into urine. Hypovolemia promotes the same relative effect because aldosterone secretion is increased to enhance Na^+ (and H_2O) reabsorption.

Sleuthing: Using Blood Values to Determine the Cause of Acidosis or Alkalosis

Students, particularly nursing students, are often given blood values and asked to determine (1) whether the patient is in acidosis or alkalosis, (2) the cause of the condition (respiratory or metabolic), and (3) whether the condition is being compensated. If you approach these questions systematically, they are not nearly as difficult as they may appear.

To analyze a person's acid-base balance, scrutinize the blood values in the following order:

1. *Note the pH.* This tells you whether the person is in acidosis (pH below 7.35) or alkalosis (pH above 7.45), but it does not tell you the cause.
2. *Check the P_{CO_2}* to see if this is causing the acid-base imbalance. Because the respiratory system is a fast-acting system, an excessively high or low P_{CO_2} may indicate that the respiratory system is either causing the condition or compensating for it. For example, if the pH indicates acidosis and
   a. The P_{CO_2} is over 45 mm Hg, then the respiratory system is the cause of the problem and the condition is respiratory acidosis
   b. The P_{CO_2} is below normal limits (below 35 mm Hg), then the respiratory system is *not the cause but is compensating*
   c. The P_{CO_2} is within normal limits, then the condition is *neither caused nor compensated* by the respiratory system
3. *Check the bicarbonate level.* If step 2 proves that the respiratory system is not responsible for the imbalance, then the condition is metabolic and should be reflected in increased or decreased bicarbonate levels. HCO_3^- values below 22 mEq/L indicate metabolic acidosis, and values over 26 mEq/L indicate metabolic alkalosis. Notice that whereas P_{CO_2} levels vary inversely with blood pH (P_{CO_2} rises as blood pH falls), HCO_3^- levels vary directly with blood pH (increased HCO_3^- results in increased pH).

Beyond this bare-bones approach there is something else to consider when you are assessing acid-base problems. If an imbalance is fully compensated, the pH may be normal even while the patient is in trouble. So, when the pH is normal, carefully scrutinize the P_{CO_2} or HCO_3^- values for clues to what imbalance may be occurring.

Consider the following two examples of the three-step approach.

Problem 1

Blood values: pH 7.6; P_{CO_2} 24 mm Hg; HCO_3^- 23 mEq/L

Analysis:

1. The pH is elevated: alkalosis.
2. The P_{CO_2} is very low: the cause of the alkalosis.
3. The HCO_3^- value is within normal limits.

Conclusion: This is respiratory alkalosis not compensated by renal mechanisms, as might occur during short-term hyperventilation.

Problem 2

Blood values: pH 7.48; P_{CO_2} 46 mm Hg; HCO_3^- 33 mEq/L

Analysis:

1. The pH is elevated: alkalosis.
2. The P_{CO_2} is elevated: the cause of acidosis, not alkalosis. Thus, the respiratory system is compensating and is not the cause.
3. The HCO_3^- is elevated: the cause of the alkalosis.

Conclusion: This is metabolic alkalosis being compensated by respiratory acidosis (retention of CO_2 to restore blood pH to the normal range).

Use the accompanying simple chart to help you in your future sleuthing.

	Normal Range in Plasma		
Acid-Base Disturbance	**pH 7.35–7.45**	**P_{CO_2} 35–45 mm Hg**	**HCO_3^- 22–26 mEq/L**
Respiratory acidosis	↓	↑	↑ if compensating
Respiratory alkalosis	↑	↓	↓ if compensating
Metabolic acidosis	↓	↓ if compensating	↓
Metabolic alkalosis	↑	↑ if compensating	↑

when gas exchange is hampered by diseases such as pneumonia, cystic fibrosis, or emphysema. Under such conditions, CO_2 accumulates in the blood. Thus, respiratory acidosis is characterized by falling blood pH and rising P_{CO_2}.

Respiratory alkalosis results when carbon dioxide is eliminated from the body faster than it is produced. This is called **hyperventilation** (deeper and faster breathing than needed to remove CO_2; ◀ p. 855), and results in the blood becoming more alkaline. While respiratory acidosis is frequently associated with respiratory system pathology, respiratory alkalosis is often due to stress or pain.

Metabolic Acidosis and Alkalosis

Metabolic pH imbalances include all abnormalities of acid-base imbalance *except* those caused by too much or too little carbon dioxide in the blood. Bicarbonate ion levels below or above the normal range of 22–26 mEq/L indicate a metabolic acid-base imbalance.

Another common cause of acid-base imbalance, **metabolic acidosis**, is recognized by low blood pH and HCO_3^- levels. Typical causes are ingesting too much alcohol (which is metabolized to acetic acid) and excessive loss of HCO_3^-, as might result from persistent diarrhea. Other causes are accumulation of lactic acid during exercise or shock, the ketosis that occurs in diabetic crisis or starvation, and, infrequently, kidney failure.

Metabolic alkalosis, indicated by rising blood pH and HCO_3^- levels, is much less common than metabolic acidosis. Typical causes are vomiting the acidic contents of the stomach (or loss of those secretions through gastric suctioning) and intake of excess base (too many antacids, for example).

Effects of Acidosis and Alkalosis

The absolute blood pH limits for life are a low of 6.8 and a high of 7.8. When blood pH falls below 6.8, the central nervous system is so depressed that the person goes into coma and death soon follows. When blood pH rises above 7.8, the nervous system is overexcited, leading to muscle tetany, extreme nervousness, and convulsions. Death often results from respiratory arrest.

Respiratory and Renal Compensations

If one of the physiological buffer systems (lungs or kidneys) malfunctions and disrupts acid-base balance, the other system tries to compensate. The respiratory system attempts to compensate for metabolic acid-base imbalances, and the kidneys (although much slower) work to correct imbalances caused by respiratory disease. We can recognize these **respiratory** and **renal compensations** by the resulting changes in plasma P_{CO_2} and bicarbonate ion concentrations (see *A Closer Look*). Because the compensations act to restore normal blood pH, a patient may have a normal pH despite a significant medical problem.

Respiratory Compensations

As a rule, changes in respiratory rate and depth are evident when the respiratory system is attempting to compensate for metabolic acid-base imbalances. In metabolic acidosis, respiratory rate and depth are usually elevated—an indication that high H^+ levels are stimulating the respiratory centers. Blood pH is low (below 7.35) and the HCO_3^- level is below 22 mEq/L. As the respiratory system "blows off" CO_2 to rid the blood of excess acid, the P_{CO_2} falls below 35 mm Hg. In contrast, in respiratory acidosis, the respiratory rate is often depressed and *is the immediate cause of the acidosis* (with some exceptions such as pneumonia or emphysema where gas exchange is impaired).

Respiratory compensation for metabolic alkalosis involves slow, shallow breathing, which allows CO_2 to accumulate in the blood. Evidence of metabolic alkalosis being compensated by respiratory mechanisms includes a pH over 7.45 (at least initially), elevated bicarbonate levels (over 26 mEq/L), and a P_{CO_2} above 45 mm Hg.

Renal Compensations

When an acid-base imbalance is of respiratory origin, renal mechanisms are stepped up to compensate for the imbalance. For example, a hypoventilating individual will exhibit acidosis. When renal compensation is occurring, both the P_{CO_2} and the HCO_3^- levels are high. The high P_{CO_2} causes the acidosis, and the rising HCO_3^- level indicates that the kidneys are retaining bicarbonate to offset the acidosis.

Conversely, a person with renal-compensated respiratory alkalosis will have a high blood pH and a low P_{CO_2}. Bicarbonate ion levels begin to fall as the kidneys eliminate more HCO_3^- from the body by failing to reclaim it or by actively secreting it. Note that the kidneys cannot compensate for alkalosis or acidosis if that condition reflects a *renal* problem.

Check Your Understanding

17. Which two abnormalities in plasma are key features of an uncompensated metabolic alkalosis? An uncompensated respiratory acidosis?
18. How do the kidneys compensate for respiratory acidosis?

For answers, see Answers Appendix.

Developmental Aspects of Fluid, Electrolyte, and Acid-Base Balance

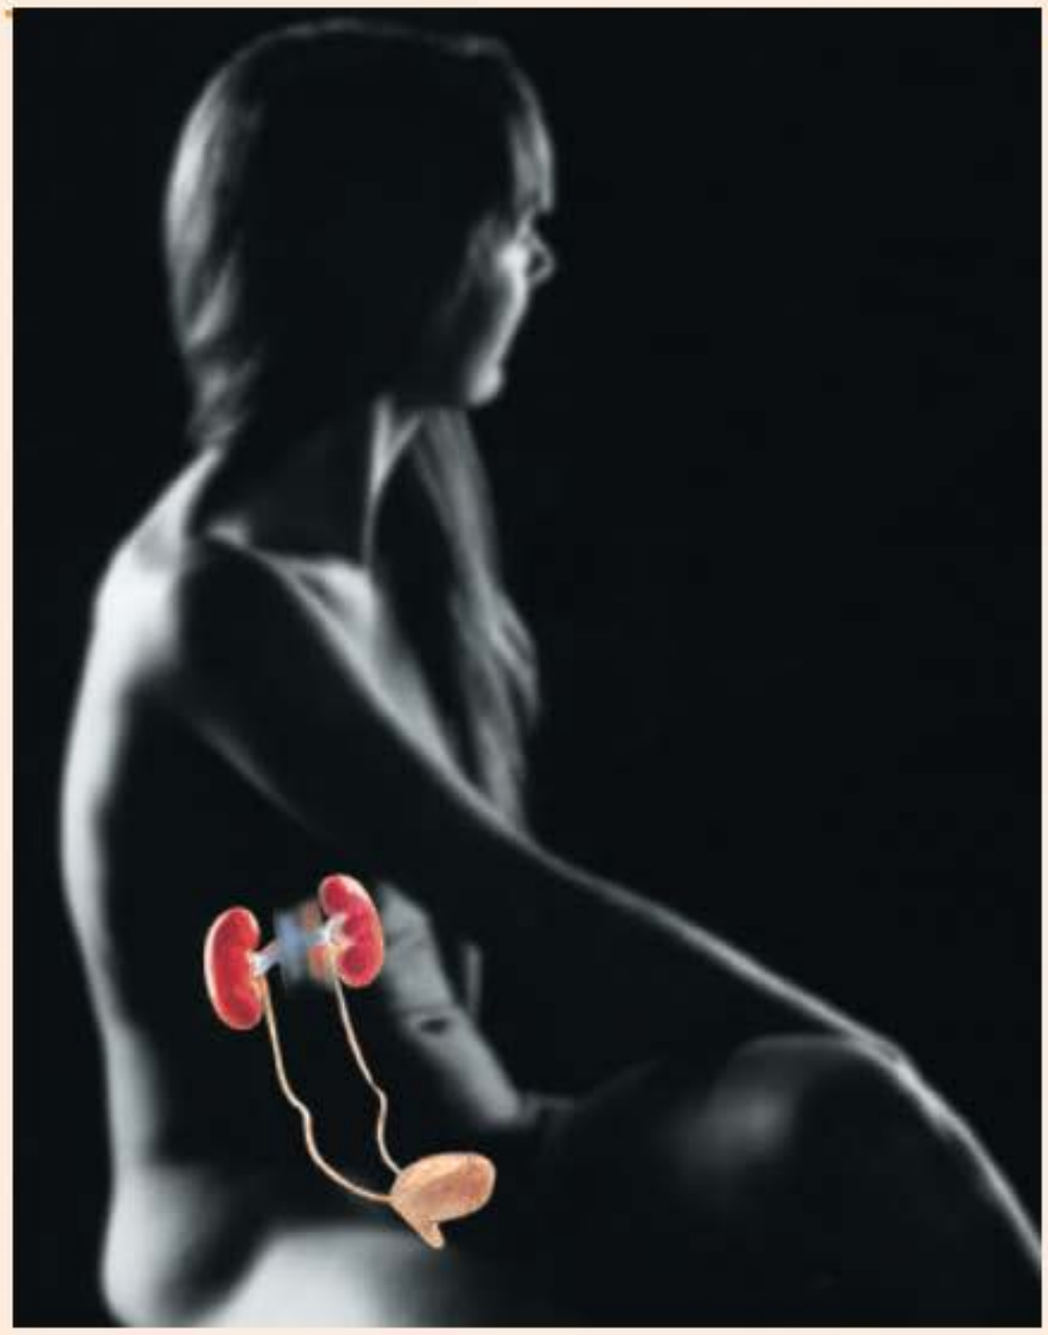
An embryo and a very young fetus are more than 90% water, but solids accumulate as fetal development continues, and at birth an infant is "only" 70–80% water. (The average value for adults is 50–60%.) Infants have proportionately more ECF than adults and, consequently, a much higher NaCl content in relation to K^+, Mg^{2+}, and PO_4^{3-} salts.

Distribution of body water begins to change about two months after birth and achieves the adult pattern by age 2. Plasma electrolyte concentrations are similar in infants and adults, but K^+ and Ca^{2+} values are higher and Mg^{2+}, HCO_3^-, and total protein levels are lower in the first few days of life than at any other time. At puberty, sex differences in body water content become obvious as males develop relatively greater amounts of skeletal muscle.

Problems with fluid, electrolyte, and particularly acid-base balance are most common in infancy, reflecting the following conditions:

- *The very low residual volume of infant lungs* (approximately half that of adults relative to body weight). When respiration is altered, P_{CO_2} can shift rapidly and dramatically.
- *The high rate of fluid intake and output in infants* (about seven times higher than in adults). Infants may exchange fully half their ECF daily. Though infants have proportionately much more body water than adults, this does not protect them from excessive fluid shifts. Even slight alterations in fluid balance can cause serious problems. Further, although adults can live without water for about ten days, infants can survive for only three to four days.
- *The relatively high infant metabolic rate* (about twice that of adults). The higher metabolic rate yields much larger amounts of metabolic wastes and acids that the kidneys must excrete. This, along with buffer systems that are not yet fully effective, results in a tendency toward acidosis.

Homeostatic Interrelationships between the Urinary System and Other Body Systems



Integumentary System Chapter 5

- Kidneys maintain fluid, electrolyte, and acid-base balance of blood; dispose of nitrogenous wastes
- Skin provides external protective barrier; site of water loss (via perspiration); vitamin D synthesis site

Skeletal System Chapters 6–8

- Kidneys maintain fluid, electrolyte, and acid-base balance of blood; dispose of nitrogenous wastes
- Bones of rib cage provide some protection to kidneys; form major store of calcium and phosphate ions

Muscular System Chapters 9–10

- Kidneys maintain fluid, electrolyte, and acid-base balance of blood; dispose of nitrogenous wastes; renal regulation of K^+, Ca^{2+}, and Na^+ content in ECF crucial for muscle excitability and contractility
- Muscles of pelvic diaphragm and external urethral sphincter function in voluntary control of micturition; creatinine is a nitrogenous waste product of muscle metabolism that must be excreted by the kidneys

Nervous System Chapters 11–15

- Kidneys maintain fluid, electrolyte, and acid-base balance of blood; dispose of nitrogenous wastes; renal control of K^+, Ca^{2+}, and Na^+ in ECF essential for normal neural function
- Neural controls involved in micturition; sympathetic nervous system activity triggers the renin-angiotensin-aldosterone mechanism

Endocrine System Chapter 16

- Kidneys maintain fluid, electrolyte, and acid-base balance of blood; dispose of nitrogenous wastes; produce erythropoietin; renal regulation of Na^+ and water balance essential for blood pressure homeostasis and hormone transport in blood
- ADH, aldosterone, ANP, and other hormones help regulate renal reabsorption of water and electrolytes

Cardiovascular System Chapters 17–19

- Kidneys maintain fluid, electrolyte, and acid-base balance of blood; dispose of nitrogenous wastes; renal regulation of Na^+ and water balance essential for blood pressure homeostasis. K^+, Ca^{2+}, and Na^+ regulation maintains cardiac excitability
- Systemic arterial blood pressure is the driving force for glomerular filtration; heart secretes atrial natriuretic peptide; blood transports nutrients, oxygen, etc. to urinary organs

Lymphatic System/Immunity Chapters 20–21

- Kidneys maintain fluid, electrolyte, and acid-base balance of blood; dispose of nitrogenous wastes
- By returning leaked plasma fluid to cardiovascular system, lymphatic vessels help ensure normal systemic arterial pressure required for kidney function; immune cells protect urinary organs from infection and cancer

Respiratory System Chapter 22

- Kidneys maintain fluid, electrolyte, and long-term acid-base balance of blood; dispose of nitrogenous wastes
- Respiratory system provides oxygen required by kidney cells for their high metabolic activity; disposes of carbon dioxide; rapid acid-base balance of blood; lung capillary endothelial cells convert angiotensin I to angiotensin II

Digestive System Chapter 23

- Kidneys maintain fluid, electrolyte, and acid-base balance of blood; dispose of nitrogenous wastes; metabolize vitamin D to the active form needed for calcium absorption
- Digestive organs provide nutrients needed for kidney cell health; liver synthesizes urea and glutamine to transport waste nitrogen to the kidneys for excretion

Reproductive System Chapter 27

- Kidneys maintain fluid, electrolyte, and acid-base balance of blood; dispose of nitrogenous wastes

- *The high rate of insensible water loss in infants because of their larger surface area relative to body volume* (about three times that of adults). Infants lose substantial amounts of water through their skin.
- *The inefficiency of infant kidneys.* At birth, the kidneys are immature, only about half as proficient as adult kidneys at concentrating urine, and notably inefficient at ridding the body of acids.

All these factors put newborns at risk for dehydration and acidosis, at least until the end of the first month when the kidneys achieve reasonable efficiency. Bouts of vomiting or diarrhea greatly amplify the risk.

In old age, total body water often decreases (the loss is largely from the intracellular compartment) because muscle mass progressively declines and body fat rises. Few changes occur in the solute concentrations of body fluids, but the speed with which homeostasis is restored after being disrupted declines with age.

Elders may be unresponsive to thirst cues and thus are at risk for dehydration. Additionally, they are the most frequent prey of diseases that lead to severe fluid, electrolyte, or acid-base problems, such as congestive heart failure (and its attendant edema) and diabetes mellitus. Because most fluid, electrolyte, and acid-base imbalances occur when body water content is highest or lowest, the very young and the very old are most frequently affected.

RELATED CLINICAL TERMS

Antacid An agent that counteracts acidity, such as sodium bicarbonate, aluminum hydroxide gel, and magnesium trisilicate. Commonly used to manage heartburn.

Hyperaldosteronism (Conn's disease) A condition of hypersecretion of aldosterone by adrenal cortical cells accompanied by excessive loss of potassium and generalized muscular weakness, hypernatremia, and hypertension. Usual cause is adrenal tumor; usual treatment is adrenal-suppressing drugs prior to tumor removal.

Renal tubular acidosis A metabolic acidosis resulting from impaired renal reabsorption of bicarbonate; the urine is alkaline.

Syndrome of inappropriate ADH secretion (SIADH) A group of disorders associated with excessive ADH secretion in the absence of appropriate (osmotic or nonosmotic) stimuli. Characterized by hypotonic hydration (hyponatremia, fluid retention, and weight gain) and concentrated urine. Usual causes are ectopic secretion of ADH by cancer cells (e.g., small cell lung cancers) and brain disorders or trauma affecting the ADH-secreting hypothalamic neurons. Temporary management involves restricting water intake.

CHAPTER SUMMARY

26.1 Body fluids consist of water and solutes in three main compartments (pp. 1013–1015)

Body Water Content (p. 1013)

1. Water accounts for 45–75% of body weight, depending on age, sex, and amount of body fat.

Fluid Compartments (p. 1013)

2. About two-thirds (25 L) of body water is found within cells in the intracellular fluid (ICF) compartment; the balance (15 L) is in the extracellular fluid (ECF) compartment. The ECF includes plasma and interstitial fluid.

Composition of Body Fluids (pp. 1013–1015)

3. Solutes dissolved in body fluids include electrolytes and nonelectrolytes. Electrolyte concentration is expressed in mEq/L.
4. Plasma contains more proteins than does interstitial fluid; otherwise, extracellular fluids are similar. The most abundant ECF electrolytes are sodium, chloride, and bicarbonate ions.
5. Intracellular fluids contain large amounts of protein anions and potassium, phosphate, and magnesium ions.

Fluid Movement among Compartments (p. 1015)

6. Substances usually pass through the plasma and interstitial fluid to reach the intracellular fluid.
7. Osmotic and hydrostatic pressure regulate fluid exchanges between plasma and interstitial fluid compartments: (a) Hydrostatic pressure forces filtrate out of the capillaries and colloid osmotic pressure pulls filtrate back in. (b) Water moves freely between the ECF and the ICF by osmosis, but solute movements are restricted by size, charge, and dependence on transport proteins. (c) Water flows always follow changes in ECF osmolality.

26.2 Both intake and output of water are regulated (pp. 1016–1019)

1. Sources of body water are ingested foods and fluids and metabolic water.
2. Water leaves the body primarily via the lungs, skin, gastrointestinal tract, and kidneys.

Regulation of Water Intake (pp. 1016–1017)

3. Increased plasma osmolality triggers the thirst mechanism, mediated by hypothalamic osmoreceptors. Thirst, inhibited by distension of the gastrointestinal tract by ingested water and then by reduced osmolality, may be damped before body needs for water are met.

Regulation of Water Output (p. 1017)

4. Obligatory water loss is unavoidable and includes insensible water losses from the lungs, the skin, and in feces, and about 500 ml of urine output daily.
5. Beyond obligatory water loss, the volume of urinary output depends on water intake and loss via other routes and reflects the influence of antidiuretic hormone on the renal collecting ducts.

Influence of Antidiuretic Hormone (ADH) (pp. 1017–1018)

6. Antidiuretic hormone causes aquaporins (water channels) to be inserted in the cell membranes of the collecting ducts, so that most filtered water is reabsorbed. ADH release is triggered if ECF osmolality is high, or if a large drop in blood volume or pressure occurs.

Disorders of Water Balance (pp. 1018–1019)

7. Dehydration occurs when water loss exceeds water intake over time. It is evidenced by thirst, dry skin, and decreased urine output. A serious consequence is hypovolemic shock.
8. Hypotonic hydration occurs when body fluids are excessively diluted and entering water makes cells swell. The most serious consequence is cerebral edema.
9. Edema is an abnormal accumulation of fluid in the interstitial space (increased IF), which may impair blood circulation.

26.3 Sodium, potassium, calcium, and phosphate levels are tightly regulated (pp. 1019–1026)

1. Most electrolytes are obtained from ingested foods and fluids. Salts, particularly NaCl, are often ingested in excess of need.
2. Electrolytes are lost in sweat, feces, and urine (and sometimes in vomit). The kidneys are most important in regulating electrolyte balance.

The Central Role of Sodium in Fluid and Electrolyte Balance (p. 1021)

3. Sodium salts are the most abundant solutes in ECF. They exert the bulk of ECF osmotic pressure and control water volume and distribution in the body.

Regulation of Sodium Balance (pp. 1021–1024)

4. Total body sodium ion content is linked to ECF volume and blood pressure regulation. Blood volume and blood pressure are monitored by baroreceptors and regulated by both neural and hormonal controls.
5. Na^+ concentration in ECF is monitored by osmoreceptors and regulated primarily by thirst and ADH mechanisms.
6. Aldosterone promotes Na^+ reabsorption to maintain blood volume and blood pressure.
7. Declining blood pressure and falling filtrate NaCl concentration stimulate the granular cells to release renin. Renin, via angiotensin II, enhances systemic blood pressure, Na^+ reabsorption, and aldosterone release.
8. Atrial natriuretic peptide, released by certain atrial cells in response to rising blood pressure (or blood volume), causes systemic vasodilation and inhibits renin, aldosterone, and ADH release. As a result, it enhances Na^+ and water excretion, reducing blood volume and blood pressure.
9. Estrogens and glucocorticoids increase renal retention of sodium. Progesterone promotes enhanced sodium and water excretion in urine.
10. Cardiovascular system baroreceptors sense changing arterial blood pressure, prompting changes in sympathetic vasomotor activity. Rising arterial pressure leads to vasodilation and enhanced Na^+ and water loss in urine. Falling arterial pressure promotes vasoconstriction and conserves Na^+ and water.

Regulation of Potassium Balance (pp. 1024–1025)

11. The more proximal regions of the nephrons reabsorb about 90% of filtered potassium.
12. The main thrust of renal regulation of K^+ is to excrete it. Aldosterone and increased plasma K^+ content enhance potassium ion secretion distal to the nephron loop. In the collecting duct, principal cells secrete K^+ whereas type A intercalated cells reabsorb small amounts of K^+ during K^+ deficit.

Regulation of Calcium and Phosphate Balance (pp. 1025–1026)

13. Calcium balance is regulated primarily by parathyroid hormone (PTH), which enhances blood Ca^{2+} levels by targeting the bones, kidneys, and intestine. PTH-regulated reabsorption occurs primarily in the distal convoluted tubule.
14. PTH decreases renal reabsorption of phosphate ions.

Regulation of Anions (p. 1026)

15. When blood pH is normal or slightly high, chloride is the major anion accompanying sodium reabsorption. In acidosis, bicarbonate replaces chloride.
16. Reabsorption of most other anions is regulated by their transport maximums (T_m).

26.4 Chemical buffers and respiratory regulation rapidly minimize pH changes (pp. 1026–1029)

1. The homeostatic pH range of arterial blood is 7.35 to 7.45. A higher pH represents alkalosis; a lower pH reflects acidosis.
2. Some acids enter the body in foods, but most are generated by breakdown of phosphorus-containing proteins, incomplete oxidation of fats or glucose, and the loading and transport of carbon dioxide in the blood.
3. Acid-base balance is achieved by chemical buffers, respiratory regulation, and in the long term by renal regulation of bicarbonate ion (and therefore, hydrogen ion) concentration of body fluids.

Chemical Buffer Systems (pp. 1027–1028)

4. Acids are proton (H^+) donors; bases are proton acceptors. Acids that dissociate completely in solution are strong acids; those that dissociate incompletely are weak acids. Strong bases are more effective proton acceptors than are weak bases.
5. Chemical buffers are single or paired sets (a weak acid and its salt) of molecules that act rapidly to resist excessive shifts in pH by releasing or binding H^+.
6. Chemical buffers of the body include the bicarbonate, phosphate, and protein buffer systems.

Respiratory Regulation of H^+ (pp. 1028–1029)

7. Respiratory regulation of acid-base balance of the blood utilizes the bicarbonate buffer system and the fact that CO_2 and H_2O are in reversible equilibrium with H_2CO_3.
8. Acidosis activates the respiratory centers to increase respiratory rate and depth, which eliminates more CO_2 and causes blood pH to rise. Alkalosis depresses the respiratory centers, resulting in CO_2 retention and a fall in blood pH.

26.5 Renal regulation is a long-term mechanism for controlling acid-base balance (pp. 1029–1032)

1. The kidneys provide the major long-term mechanism for controlling acid-base balance by maintaining stable HCO_3^- levels in the ECF. Nonvolatile acids (organic acids other than carbonic acid) can be eliminated from the body only by the kidneys.
2. Secreted hydrogen ions come from the dissociation of carbonic acid generated within the tubule cells.

3. Tubule cells are impermeable to bicarbonate in the filtrate, but they can conserve filtered bicarbonate ions indirectly by absorbing HCO_3^- generated within them (by dissociation of carbonic acid to HCO_3^- and H^+). For each HCO_3^- reabsorbed, one H^+ is secreted into the filtrate, where it combines with HCO_3^-.
4. To generate and add new HCO_3^- to plasma to counteract acidosis, either of two mechanisms may be used:
   - Secreted H^+, buffered by bases other than HCO_3^-, is excreted from the body in urine (the major urine buffer is the phosphate buffer system).
   - NH_4^+ (derived from glutamine catabolism) is excreted in urine.
5. To counteract alkalosis, bicarbonate ion is secreted into the filtrate and H^+ is reabsorbed.

26.6 Abnormalities of acid-base balance are classified as metabolic or respiratory (pp. 1033–1035)

1. Respiratory acidosis results from carbon dioxide retention. Respiratory alkalosis occurs when carbon dioxide is eliminated faster than it is produced.
2. Metabolic acidosis occurs when nonvolatile acids (lactic acid, ketone bodies, and others) accumulate in the blood or when bicarbonate is lost from the body. Metabolic alkalosis occurs when bicarbonate levels are excessive.
3. Extremes of pH for life are 6.8 and 7.8.
4. Compensations occur when the respiratory system or kidneys counteract acid-base imbalances resulting from abnormal or inadequate functioning of the alternate system. Respiratory compensations involve changes in respiratory rate and depth. Renal compensations modify blood levels of HCO_3^-.

Developmental Aspects of Fluid, Electrolyte, and Acid-Base Balance (pp. 1035–1037)

1. Infants have a higher risk of dehydration and acidosis because of their low lung residual volume, high rate of fluid intake and output, high metabolic rate, relatively large body surface area, and functionally immature kidneys at birth.
2. The elderly are at risk for dehydration because of their low percentage of body water and insensitivity to thirst cues. Diseases that promote fluid and acid-base imbalances (cardiovascular disease, diabetes mellitus, and others) are most common in the aged.

REVIEW QUESTIONS

To access additional practice questions using your smartphone, tablet, or computer: MasteringA&P® > Study Area > Practice Tests & Quizzes

Level 1 Remember/Understand

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Body water content is greatest in **(a)** infants, **(b)** young adults, **(c)** elderly adults.
2. Potassium, magnesium, and phosphate ions are the predominant electrolytes in **(a)** plasma, **(b)** interstitial fluid, **(c)** intracellular fluid.
3. Sodium balance is regulated primarily by control of amount(s) **(a)** ingested, **(b)** excreted in urine, **(c)** lost in perspiration, **(d)** lost in feces.
4. Water balance is regulated by control of amount(s) (use choices in question 3).

Answer questions 5 through 10 by choosing responses from the following:

(a) ammonium ions
(b) bicarbonate
(c) calcium
(d) chloride
(e) hydrogen ions
(f) magnesium
(g) phosphate
(h) potassium
(i) sodium
(j) water

5. Two main substances regulated by the influence of aldosterone on the kidney tubules.
6. Two substances regulated by parathyroid hormone.
7. Two substances secreted into the proximal convoluted tubules in exchange for sodium ions.
8. Part of an important chemical buffer system in plasma.
9. Two ions produced during catabolism of glutamine.
10. Substance regulated by ADH's effects on the renal tubules.
11. Which of the following factors will enhance ADH release? **(a)** increase in ECF volume, **(b)** decrease in ECF volume, **(c)** decrease in ECF osmolality, **(d)** increase in ECF osmolality.
12. In an individual with metabolic acidosis, a clue that the respiratory system is compensating is provided by **(a)** high blood bicarbonate levels, **(b)** low blood bicarbonate levels, **(c)** rapid, deep breathing, **(d)** slow, shallow breathing.
13. Name the body fluid compartments, noting their locations and the approximate fluid volume in each.

Level 2 Apply/Analyze

14. Describe the thirst mechanism, indicating how it is triggered and terminated.
15. Explain why and how ECF osmolality is maintained.
16. Explain why and how total body sodium content, ECF volume, and blood pressure are jointly regulated.
17. Describe the role of the respiratory system in controlling acid-base balance.
18. Explain how the chemical buffer systems resist changes in pH.
19. Explain the relationship of the following to renal secretion and excretion of hydrogen ions: **(a)** plasma carbon dioxide levels, **(b)** phosphate, and **(c)** sodium bicarbonate reabsorption.

Level 3 Evaluate/Synthesize

20. Mr. Jessup, a 55-year-old man, is operated on for a cerebral tumor. About a month later, he appears at his physician's office complaining of excessive thirst. He claims to have been drinking about 20 liters of water daily for the past week and says he has been voiding nearly continuously. A urine sample is collected and its specific gravity is reported as 1.001. What is your diagnosis of Mr. Jessup's problem? What connection might exist between his previous surgery and his present problem?
21. For each of the following sets of blood values, name the acid-base imbalance (acidosis or alkalosis), determine its cause (metabolic or respiratory), decide whether the condition is being compensated, and cite at least one possible cause of the imbalance.
    Problem 1: pH 7.63; P_{CO_2} 19 mm Hg; HCO_3^- 19.5 mEq/L
    Problem 2: pH 7.22; P_{CO_2} 30 mm Hg; HCO_3^- 12.0 mEq/L
22. Explain how emphysema and congestive heart failure can lead to acid-base imbalance.
23. Mrs. Bush, a 70-year-old woman, is admitted to the hospital. Her history states that she has been suffering from diarrhea for three weeks. On admission, she complains of severe fatigue and

muscle weakness. A blood chemistry study yields the following information: Na^+ 142 mEq/L; K^+ 1.5 mEq/L; Cl^- 92 mEq/L; P_{CO_2} 32 mm Hg. Which electrolytes are within normal limits? Which are so abnormal that the patient has a medical emergency? Which of the following represents the greatest danger to Mrs. Bush? **(a)** a fall due to her muscular weakness, **(b)** edema, **(c)** cardiac arrhythmia and cardiac arrest.

24. During a routine medical checkup, Shelby, a 26-year-old physiotherapy student, is surprised to hear that her blood pressure is 180/110. She also has a rumbling systolic and diastolic abdominal bruit (murmur) that is loudest at the mid-epigastric area. Her physician suspects renal artery stenosis (narrowing). She orders an abdominal ultrasound and renal artery arteriography, which confirm that Shelby has a small right kidney and the distal part of her right renal artery is narrowed by more than 70%. Her physician prescribes diuretics and calcium channel blockers as temporary measures, and refers Shelby to a cardiovascular surgeon. Explain the connection between Shelby's renal artery stenosis and her hypertension. Why is her right kidney smaller than her left? What would you expect Shelby's blood levels of K^+, Na^+, aldosterone, angiotensin II, and renin to be?

CLINICAL CASE STUDY

72-Year-Old Male with Abdominopelvic Trauma

Mr. Heyden, 72, is brought to the emergency room after an accident at his farm. The paramedics report that his left side was pinned beneath his tractor, and that when he was freed, his left lower quadrant appeared to be compressed. His blood pressure is 90/50 mm Hg and falling, and his heart rate is 116 beats/min. His pulse is thready. Mr. Heyden complains of pain in his left side and then loses consciousness.

1. Given the values above, what would you conclude is Mr. Heyden's immediate problem?

2. + NCLEX-STYLE Mr. Heyden's low blood pressure will trigger certain compensatory mechanisms. Which statement below best reflects the changes in hormone levels that will occur?

- **a.** Mr. Heyden's ADH, aldosterone, and renin will increase.
- **b.** Mr. Heyden's ADH will decrease, his aldosterone will increase, and his renin will be unchanged.
- **c.** Mr. Heyden's ADH will increase, and his aldosterone and renin will decrease.
- **d.** Mr. Heyden's ADH and renin will decrease, and his aldosterone will increase.

A CT scan reveals a ruptured spleen and a large hematoma in the upper left abdominal quadrant. Splenic repair surgery is scheduled but unsuccessful; the spleen is removed. Post-surgery urinalysis reveals some granular casts (particulate cell debris) and that the urine is brownish-red in color; other values are normal, but urine output is very low. An order is given to rapidly infuse intravenous saline solution.

3. **(a)** What might account for the low volume of urine output? (Name at least two possibilities.) **(b)** What might explain the casts and abnormal color of his urine? Can you see any possible relationship between his crush injury and these findings?

The next day, Mr. Heyden is awake and alert. His urine output is still low and his blood work indicates the beginnings of acute renal failure.

4. + NCLEX-STYLE Mr. Heyden's blood K^+ levels are high. Which of the following best explains his high K^+ levels?

- **a.** Mr. Heyden's increased secretion of aldosterone will cause his K^+ levels to increase.
- **b.** Mr. Heyden's damaged kidneys can no longer adequately remove K^+ from his blood.
- **c.** Mr. Heyden's increased secretion of ADH will cause his K^+ levels to increase.
- **d.** The loss of Mr. Heyden's spleen means that his aged and fragile erythrocytes are not being removed, and so are rupturing in his blood vessels and releasing K^+.

5. Mr. Heyden's blood pH is 7.33, P_{CO_2} is 34 mm Hg, and his HCO_3^- is 20 mEq/L. Explain these findings.

27 The Reproductive System

In this chapter, you will learn that

The reproductive organs complement each other's function in reproducing the body

by comparing

27.1 Common features of...

Male

and exploring

Most organ systems function almost continuously to maintain the well-being of the individual. The **reproductive system**, however, appears to "slumber" until puberty, after which it plays an important role in our adult lives. Although male and female reproductive organs are quite different, their common purpose is to produce offspring. To do this successfully, the reproductive system must carry out four tasks:

1. Form specialized cells for sexual reproduction called *gametes*—*sperm* in males and *ova* (eggs) in females.
2. Bring the gametes from the male and female together. The process of *sexual intercourse* (*copulation*) delivers male gametes to the female.
3. Combine the genetic information contained within the male and female gametes. This process is called *fertilization*. When a sperm and egg fuse, they form a fertilized egg, or **zygote**. The zygote is the first cell of a new individual and all body cells arise from it.
4. Support the development of the fetus (*gestation*) and birth of the baby (*parturition*).

We will consider the first two tasks in this chapter. Note that the male and female reproductive systems are equal partners in the events leading up to fertilization. The last two tasks, fertilization and pregnancy, occur entirely within the female and will be described in Chapter 28. Once fertilization has occurred, the female's uterus provides the protective environment where the embryo develops until birth.

27.1 The male and female reproductive systems share common features

Learning Outcomes

- **Give examples of homologous reproductive structures in males and females.**
- **Describe the HPG axis and its activation at puberty.**
- **Define meiosis. Compare and contrast it to mitosis.**

Although most of this chapter will explore male and female reproductive anatomy and physiology separately, let's begin by considering some of the things the male and female reproductive systems have in common.

Gonads and Accessory Reproductive Organs

Many of the reproductive structures in males and females are *homologues*—that is, they share a common origin during development. **Homologous structures** (ho-mol′ŏ-gus) often have functions in common. Some examples of homologues are the male testes and female ovaries (described next), and the male penis and female clitoris. We will point out additional examples (and their overlapping functions) as we encounter them in the chapter.

Although many people think of sex organs as being the external reproductive structures (external genitalia), the **primary sex organs** are actually the **gonads** (go′nadz; "seeds")—the *testes* in males and the *ovaries* in females. The type of gonad present during embryonic development determines the fate (male or female pattern of development) of all of the other developing reproductive structures. The gonads of both sexes produce two essential products:

- **Gametes** (gam′ēts; "spouses"). Males produce *sperm* and females produce *ova* (*eggs*). Gamete formation depends on a special type of cell division called *meiosis* (described below).
- **Sex hormones.** These steroid hormones—mainly testosterone in males, estrogens and progesterone in females—play vital roles both in the development and function of the reproductive organs and in sexual behavior and drives. These hormones also influence the growth and development of many other organs and tissues of the body (◀ p. 634).

In both males and females, the remaining reproductive structures—ducts, glands, and external genitalia (jen-ĭ-ta′le-ah)—are called **accessory reproductive organs**.

Reproductive Hormone Secretion

In both males and females, hormonal interactions between the hypothalamus, anterior pituitary, and gonads regulate the production of gametes and sex hormones. The relationship between these components is called the **hypothalamic-pituitary-gonadal (HPG) axis**.

The HPG Axis

Between each level of the HPG axis, hormones regulate the secretion of other hormones (◀ Figure 16.4c, p. 607). In both sexes, the basic pattern is the same (**Figure 27.1**) and resembles patterns you are already familiar with (◀ Figure 16.7, p. 616). The hormones involved are:

- **Gonadotropin-releasing hormone (GnRH)**, released from the hypothalamus (◀ p. 616), indirectly stimulates the testes

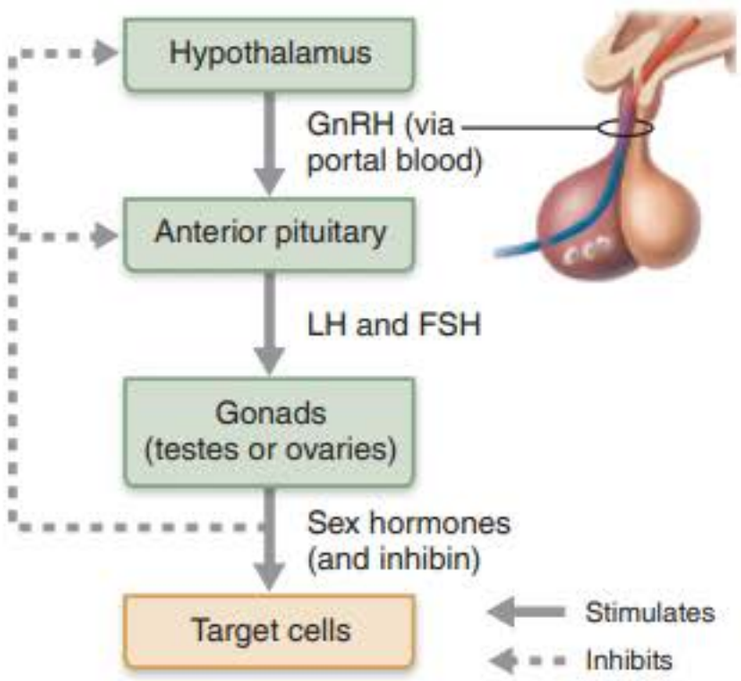

Figure 27.1 Basic pattern of interactions along the hypothalamic-pituitary-gonadal (HPG) axis. Note that inhibin only inhibits FSH release.

or ovaries via its effect on FSH and LH release. GnRH reaches the anterior pituitary cells via the hypophyseal portal system.

- **Follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)** are gonadotropins released from the anterior pituitary (◀ p. 616). Notice that these hormones are named for their actions in the female, but act in both sexes. FSH and LH act on specific cells in the gonads where they stimulate gamete production and sex hormone secretion.
- *Sex hormones* (primarily testosterone in males and estrogens and progesterone in females) act at target tissues in the body. They also exert negative feedback on the hypothalamus and anterior pituitary.

An additional hormone, called **inhibin**, is released from the gonads of both males and females. As its name implies, this peptide hormone also exerts negative feedback, but in this case, only on FSH release from the anterior pituitary.

Understanding the basic pattern of interactions along the HPG axis will help you when you encounter variations in this pattern later in the chapter (particularly in the female).

Activation of the HPG Axis at Puberty

Puberty is the period of life when the reproductive organs grow to adult size and become functional. It represents the earliest time that reproduction is possible.

Before puberty, the circulating levels of all steroidal sex hormones (testosterone, estrogens, and progesterone) are low. Even these very low levels are sufficient to suppress secretion of GnRH by the hypothalamus. As puberty approaches, the hypothalamus becomes less sensitive to inhibition by these sex hormones. As a result, it begins to release GnRH in a rhythmic, pulselike manner. In response to the elevated GnRH levels, the anterior pituitary releases FSH and LH. These gonadotropins, in turn, stimulate the release of more sex hormones from the gonads. As the threshold for inhibition of GnRH release continues to rise, more and more sex hormones are released until the adult pattern of hormone interaction is achieved. These high levels of sex hormones bring about the bodywide changes of puberty that we describe later in this chapter.

Meiosis

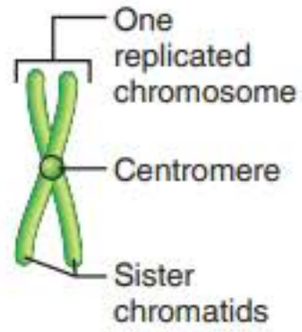
Gamete formation in both sexes involves **meiosis** (mi-o′sis; "a lessening"), a unique kind of nuclear division that occurs only in the gonads. Although the type and number of gametes produced by males and females differ, the underlying process—meiosis—is the same in both sexes.

Without meiosis, sexual reproduction cannot take place. This is because reproduction normally involves fusing together one cell from each parent. If those cells were somatic cells (normal body cells), the resulting zygote would then have twice as many chromosomes as the parental cells. One main function of meiosis is to prevent this from happening by reducing the number of chromosomes in gametes by half. As we will see, its second function is to greatly increase the genetic variability of gametes.

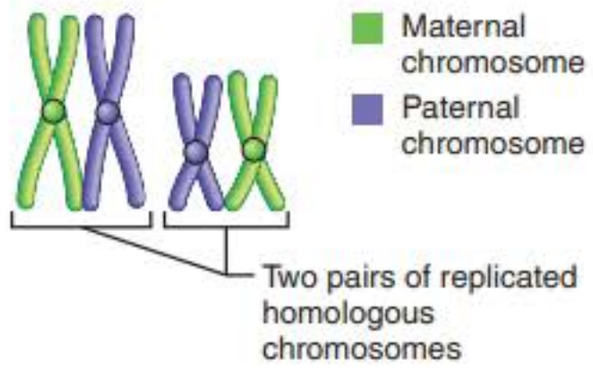
Terminology of Meiosis

Before we describe meiosis, let's define some terms.

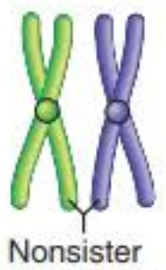
- **Sister chromatids.** As in mitosis, the cell's DNA is replicated during interphase (◀ pp. 96–97) before meiosis begins. As a result, each chromosome has two **sister chromatids**. These sister chromatids are identical, and joined together by a centromere (◀ p. 100). The DNA then coils and condenses, which makes the chromosome visible (as shown at right) when viewed through a light microscope.



- **Homologous pairs of chromosomes.** In humans, chromosomes come in pairs called **homologous chromosomes** (shown at right). One member of each pair is from the male parent (the *paternal chromosome*), and the other is from the female parent (the *maternal chromosome*). Generally speaking, the two homologues of each chromosome pair look alike and carry genes that code for the same traits, though not necessarily for identical expression of those traits. In Chapter 29, we will consider how our mom's and dad's genes interact to produce our visible traits.



- **Nonsister chromatids.** Within a homologous pair of chromosomes, the chromatids of one chromosome are **nonsister chromatids** to the chromatids of the other chromosome in the pair (shown at right). Nonsister chromatids are not identical to each other because one is paternal and the other is maternal. One of the special features of meiosis is that nonsister chromatids exchange DNA with each other in a process called *crossing over*. This process greatly increases genetic variability because it combines maternal and paternal genes on the same chromatid. We will discuss this in more detail on the next page.



- **Diploid.** The **diploid chromosomal number** (dip′loid) is the normal number of chromosomes in most body cells. It consists of two sets of chromosomes, one from each parent, and is symbolized as $2n$. In humans, the diploid chromosomal number is 46, and *diploid* cells contain 23 pairs of homologous chromosomes.
- **Haploid.** The **haploid chromosomal number** (hap′loid), or n, is the number of chromosomes in a gamete. In humans, the haploid chromosomal number is 23. Gametes are *haploid* and contain only one member of each homologous pair, either maternal or paternal. When sperm and egg fuse, they form a zygote that reestablishes the typical diploid chromosomal number of human cells ($2n$).

Sequence of Events in Meiosis

Meiosis consists of two consecutive nuclear divisions (*meiosis I* and *meiosis II*) that follow a single round of DNA replication. Its product is four haploid daughter cells. Each of these nuclear divisions consists of four steps, each having the same name as a corresponding step of mitosis: prophase, metaphase, anaphase, and telophase. Before we examine the details, let's step back and look at the big picture of what happens before and then during meiosis I and meiosis II (**Figure 27.2**).

- During the interphase preceding meiosis, all of the chromosomes are replicated.

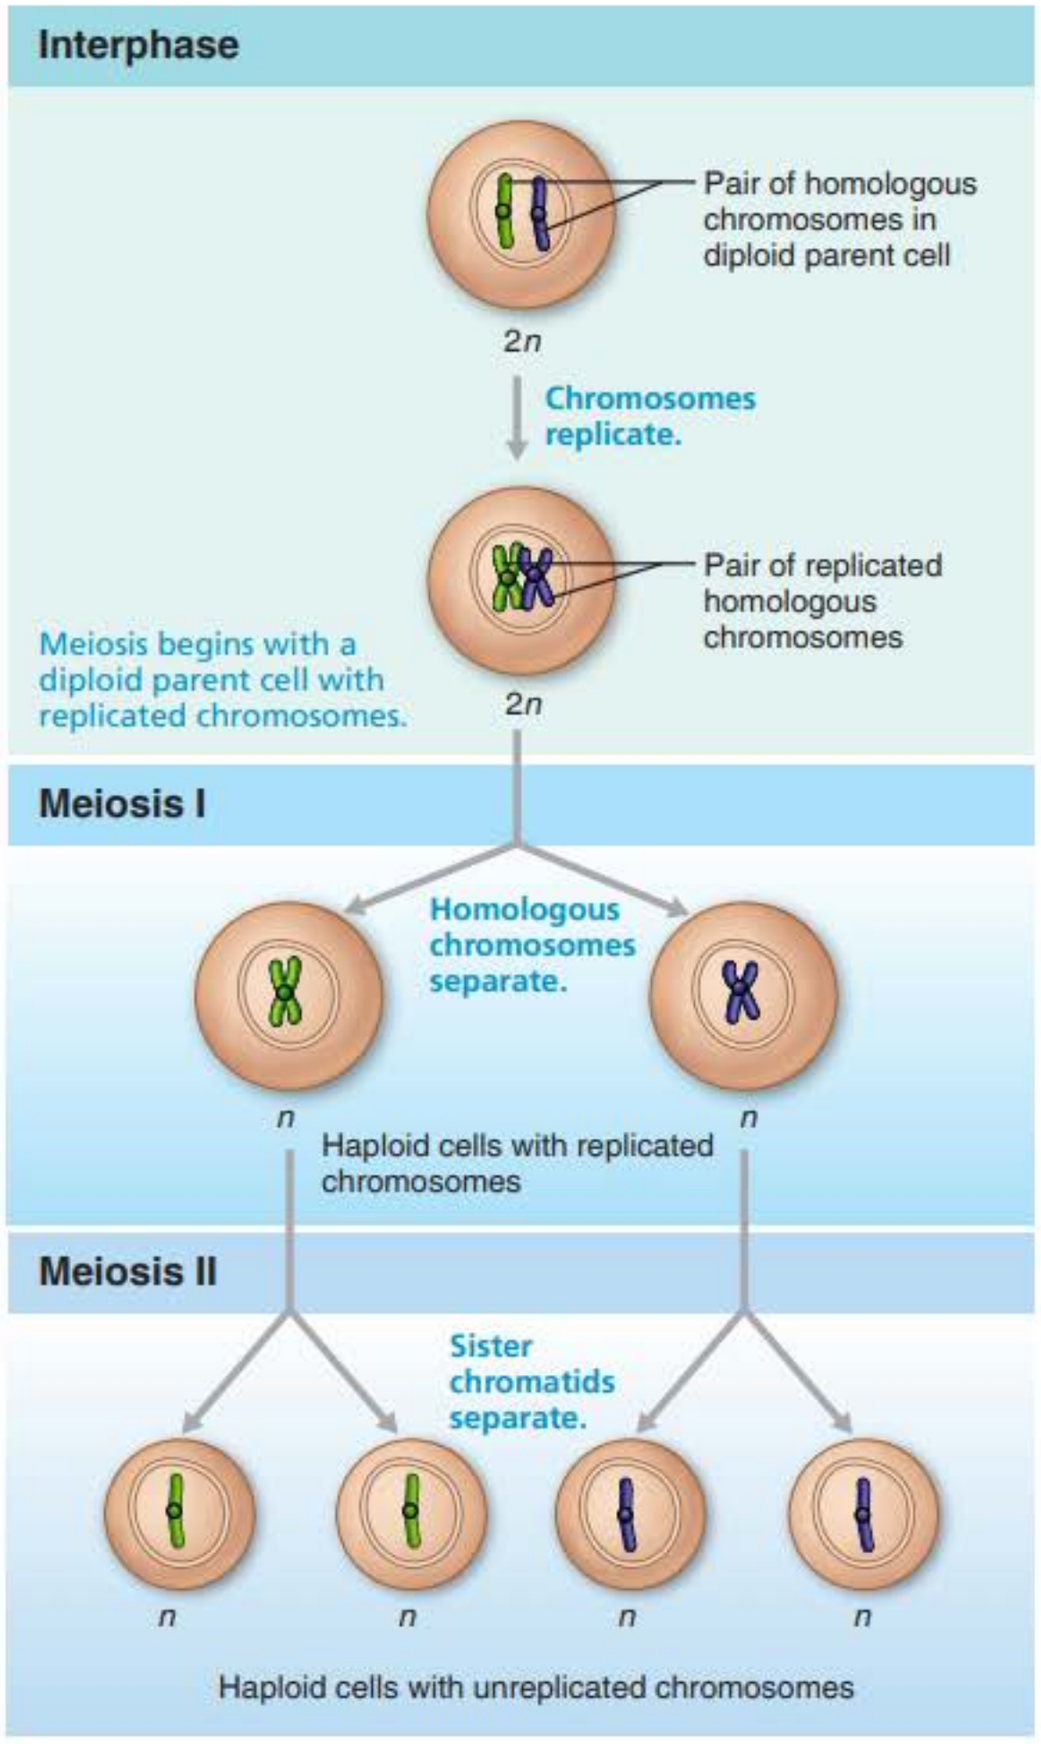


Figure 27.2 Overview of meiosis. For simplicity, all chromosomes are shown as condensed.

- During meiosis I, homologous pairs of chromosomes separate from each other, reducing the number of chromosomes from $2n$ to n. For this reason, it is sometimes called the **reduction division of meiosis**.
- During meiosis II, the sister chromatids of each chromosome separate. Each daughter cell gets an equal share of chromosomes, so this is sometimes called the **equational division of meiosis**.

Now you are ready to study **Figure 27.3**, which describes each of the steps of meiosis in detail. Meiosis is complicated, so take some time to work your way through this figure while reading the text below.

Meiosis I As we have seen, meiosis I reduces the chromosome number from $2n$ to n. As in mitosis, during prophase I of meiosis the chromosomes coil and condense, the nuclear envelope and nucleolus break down and disappear, and a spindle forms.

In addition, prophase I of meiosis includes an event never seen in mitosis (nor in meiosis II for that matter): The replicated chromosomes pair up with their homologous partners. (In the complicated dance of the chromosomes that is meiosis, finding your partner is the first step.) The alignment between homologous pairs of chromosomes takes place at discrete spots along their entire length—more like buttoning together than zipping. This process, called **synapsis**, forms little groups of four chromatids called **tetrads** (Figure 27.3).

During synapsis, a second unique event, called **crossing over**, occurs. These *crossovers* are called **chiasmata** (singular: chiasma), and form within each tetrad as the free ends of nonsister chromatids wrap around each other at one or more points. Crossing over allows the paired maternal and paternal chromosomes to exchange genetic material (see Figure 29.3, p. 1127). By the end of prophase I, the tetrads are attached to the spindle and are moving toward the spindle equator.

During metaphase I, the pairs of homologous chromosomes line up *randomly* at the spindle equator, so that either the paternal or maternal homologous chromosome can be on a given side of the equator (see Figure 29.2, p. 1126). (In our dance of the chromosomes, this is like partners lining up at the start of the dance with males and females randomly placed on either side of the line.)

During anaphase I, the sister chromatids representing each homologue behave as a unit—almost as if replication had not occurred. The homologous chromosomes, each still composed of two joined sister chromatids (a dyad), are distributed to opposite ends of the cell.

As a result, when meiosis I ends, each daughter cell has:

- *Two* copies of one member of each homologous pair (either the paternal or maternal) and none of the other
- A *haploid* chromosomal number (because the still-united sister chromatids are considered a single chromosome), but twice the amount of DNA in each chromosome

Meiosis II The second meiotic division, meiosis II, mirrors mitosis in every way (◀ pp. 100–101), except that:

- The chromosomes are *not* replicated before it begins.
- The cells that undergo meiosis II are haploid, not diploid.

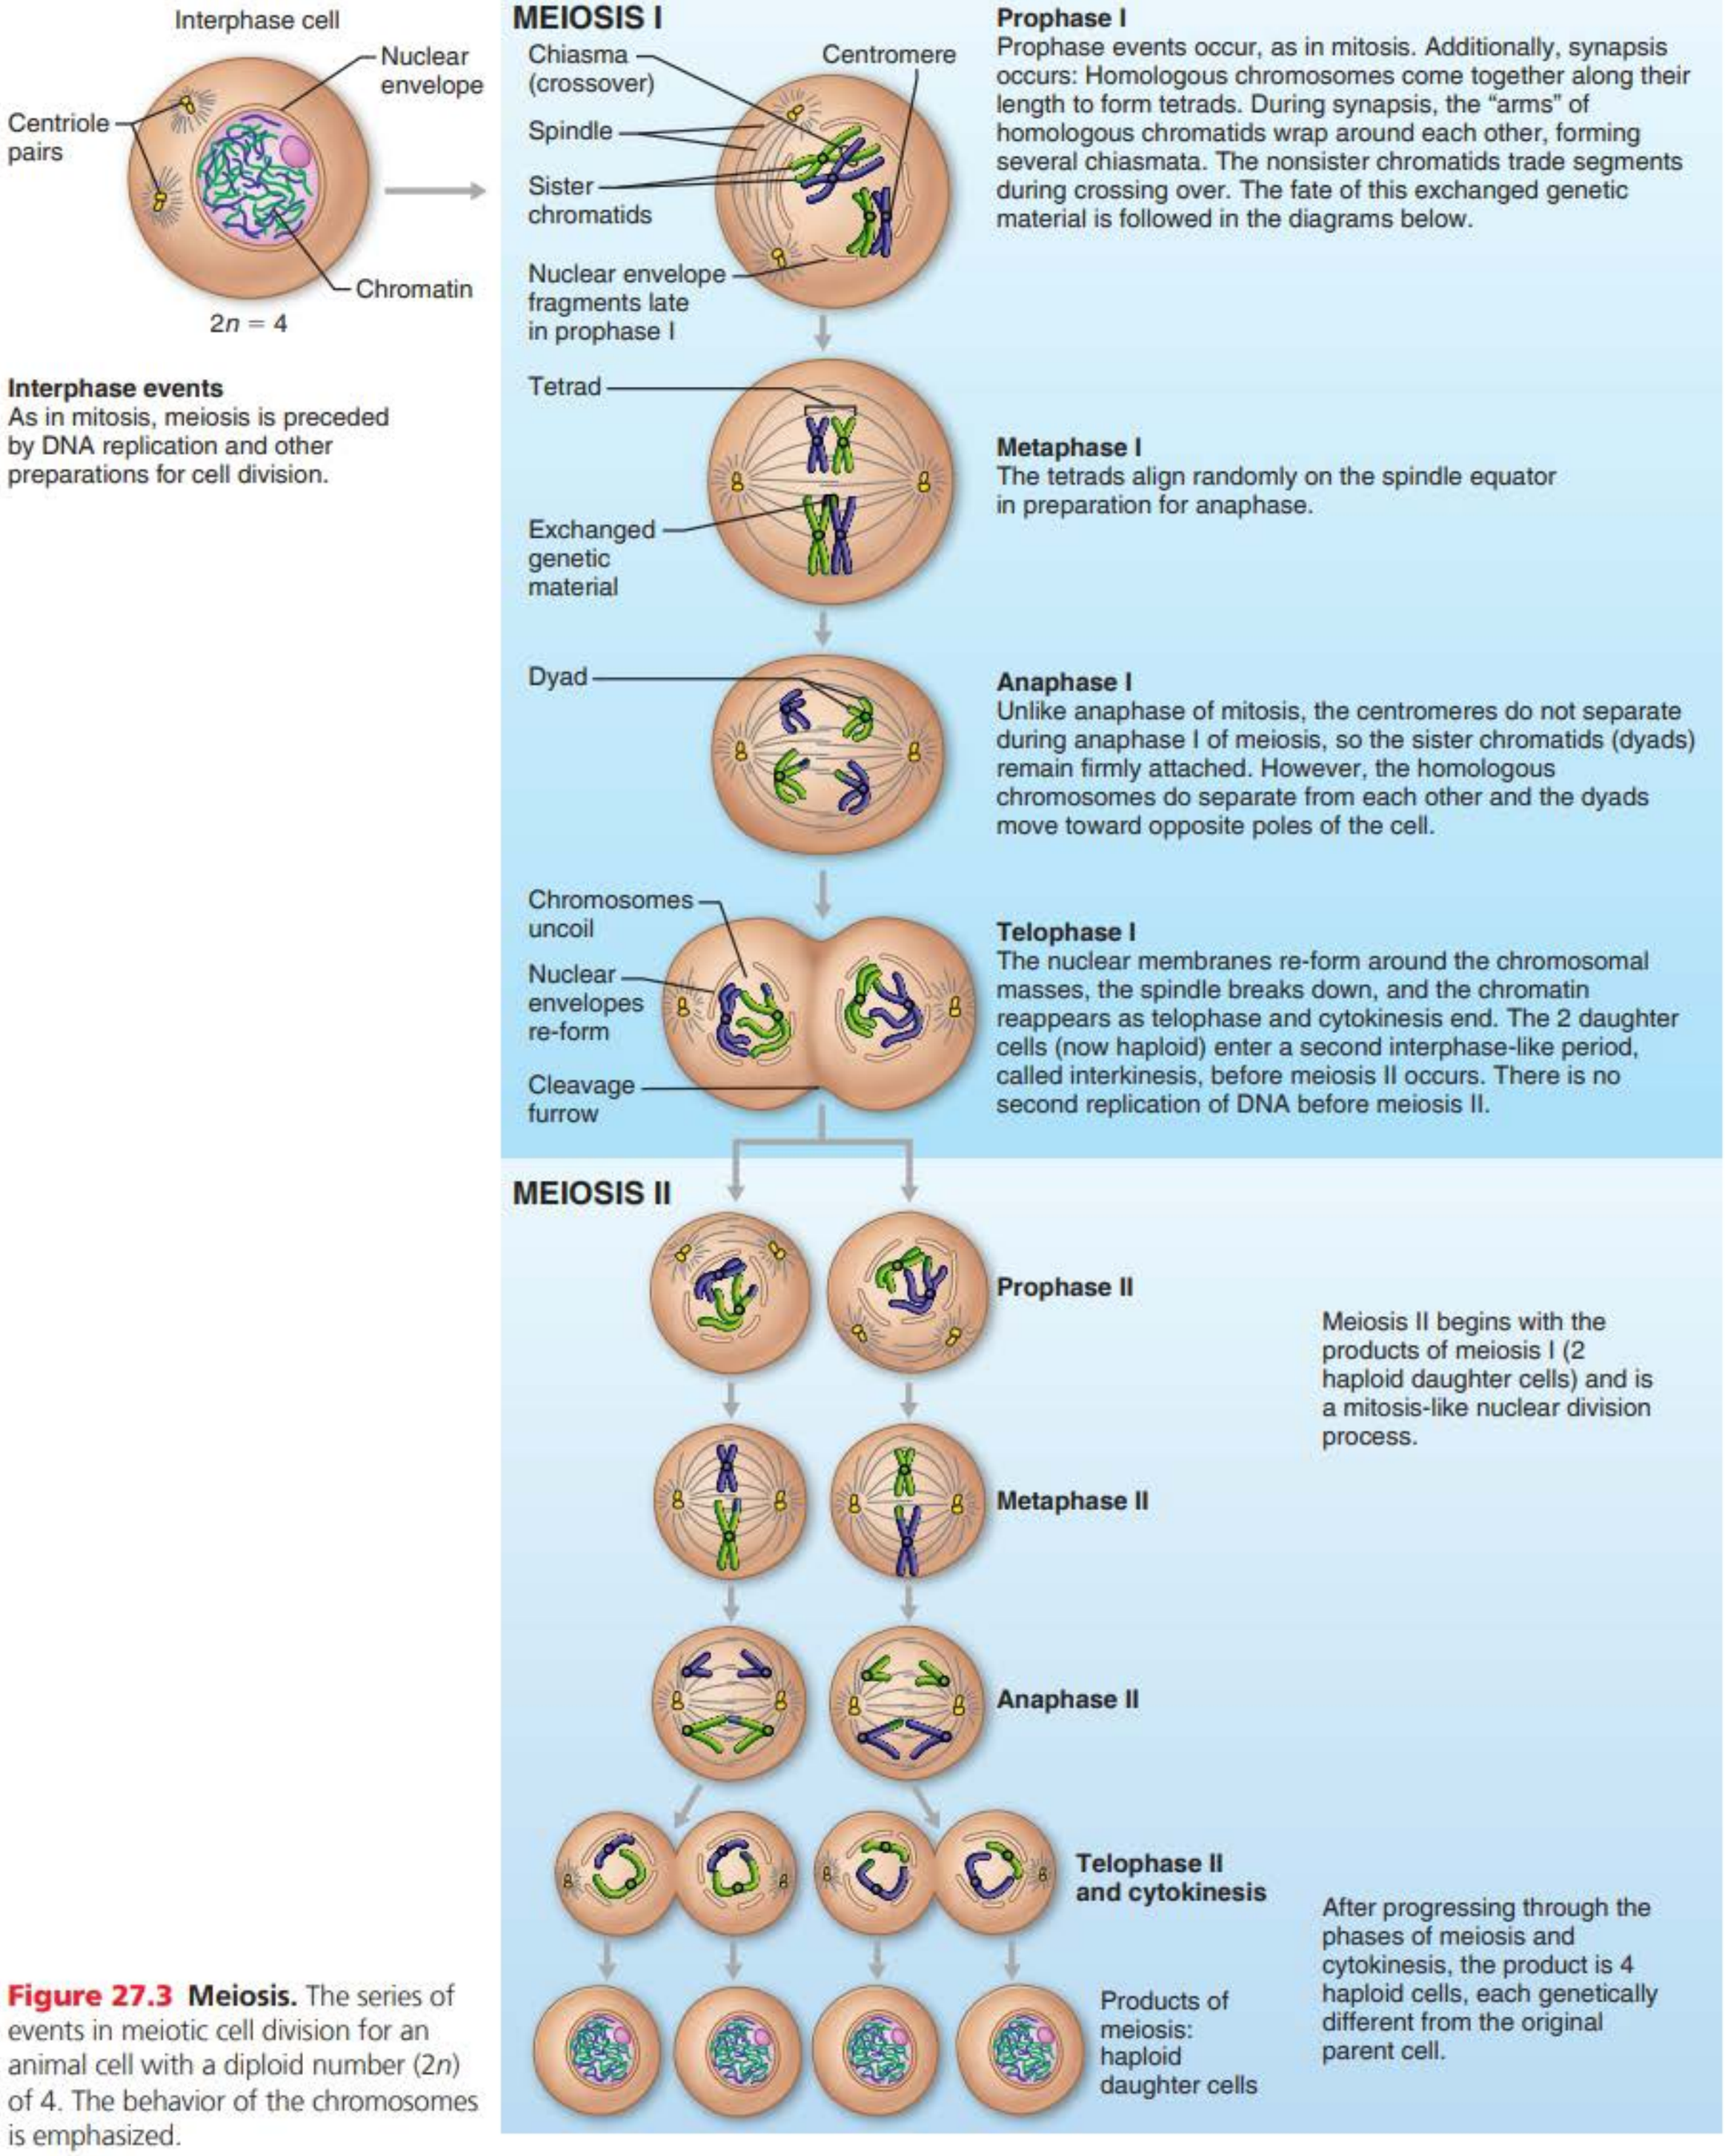

Figure 27.3 Meiosis. The series of events in meiotic cell division for an animal cell with a diploid number ($2n$) of 4. The behavior of the chromosomes is emphasized.

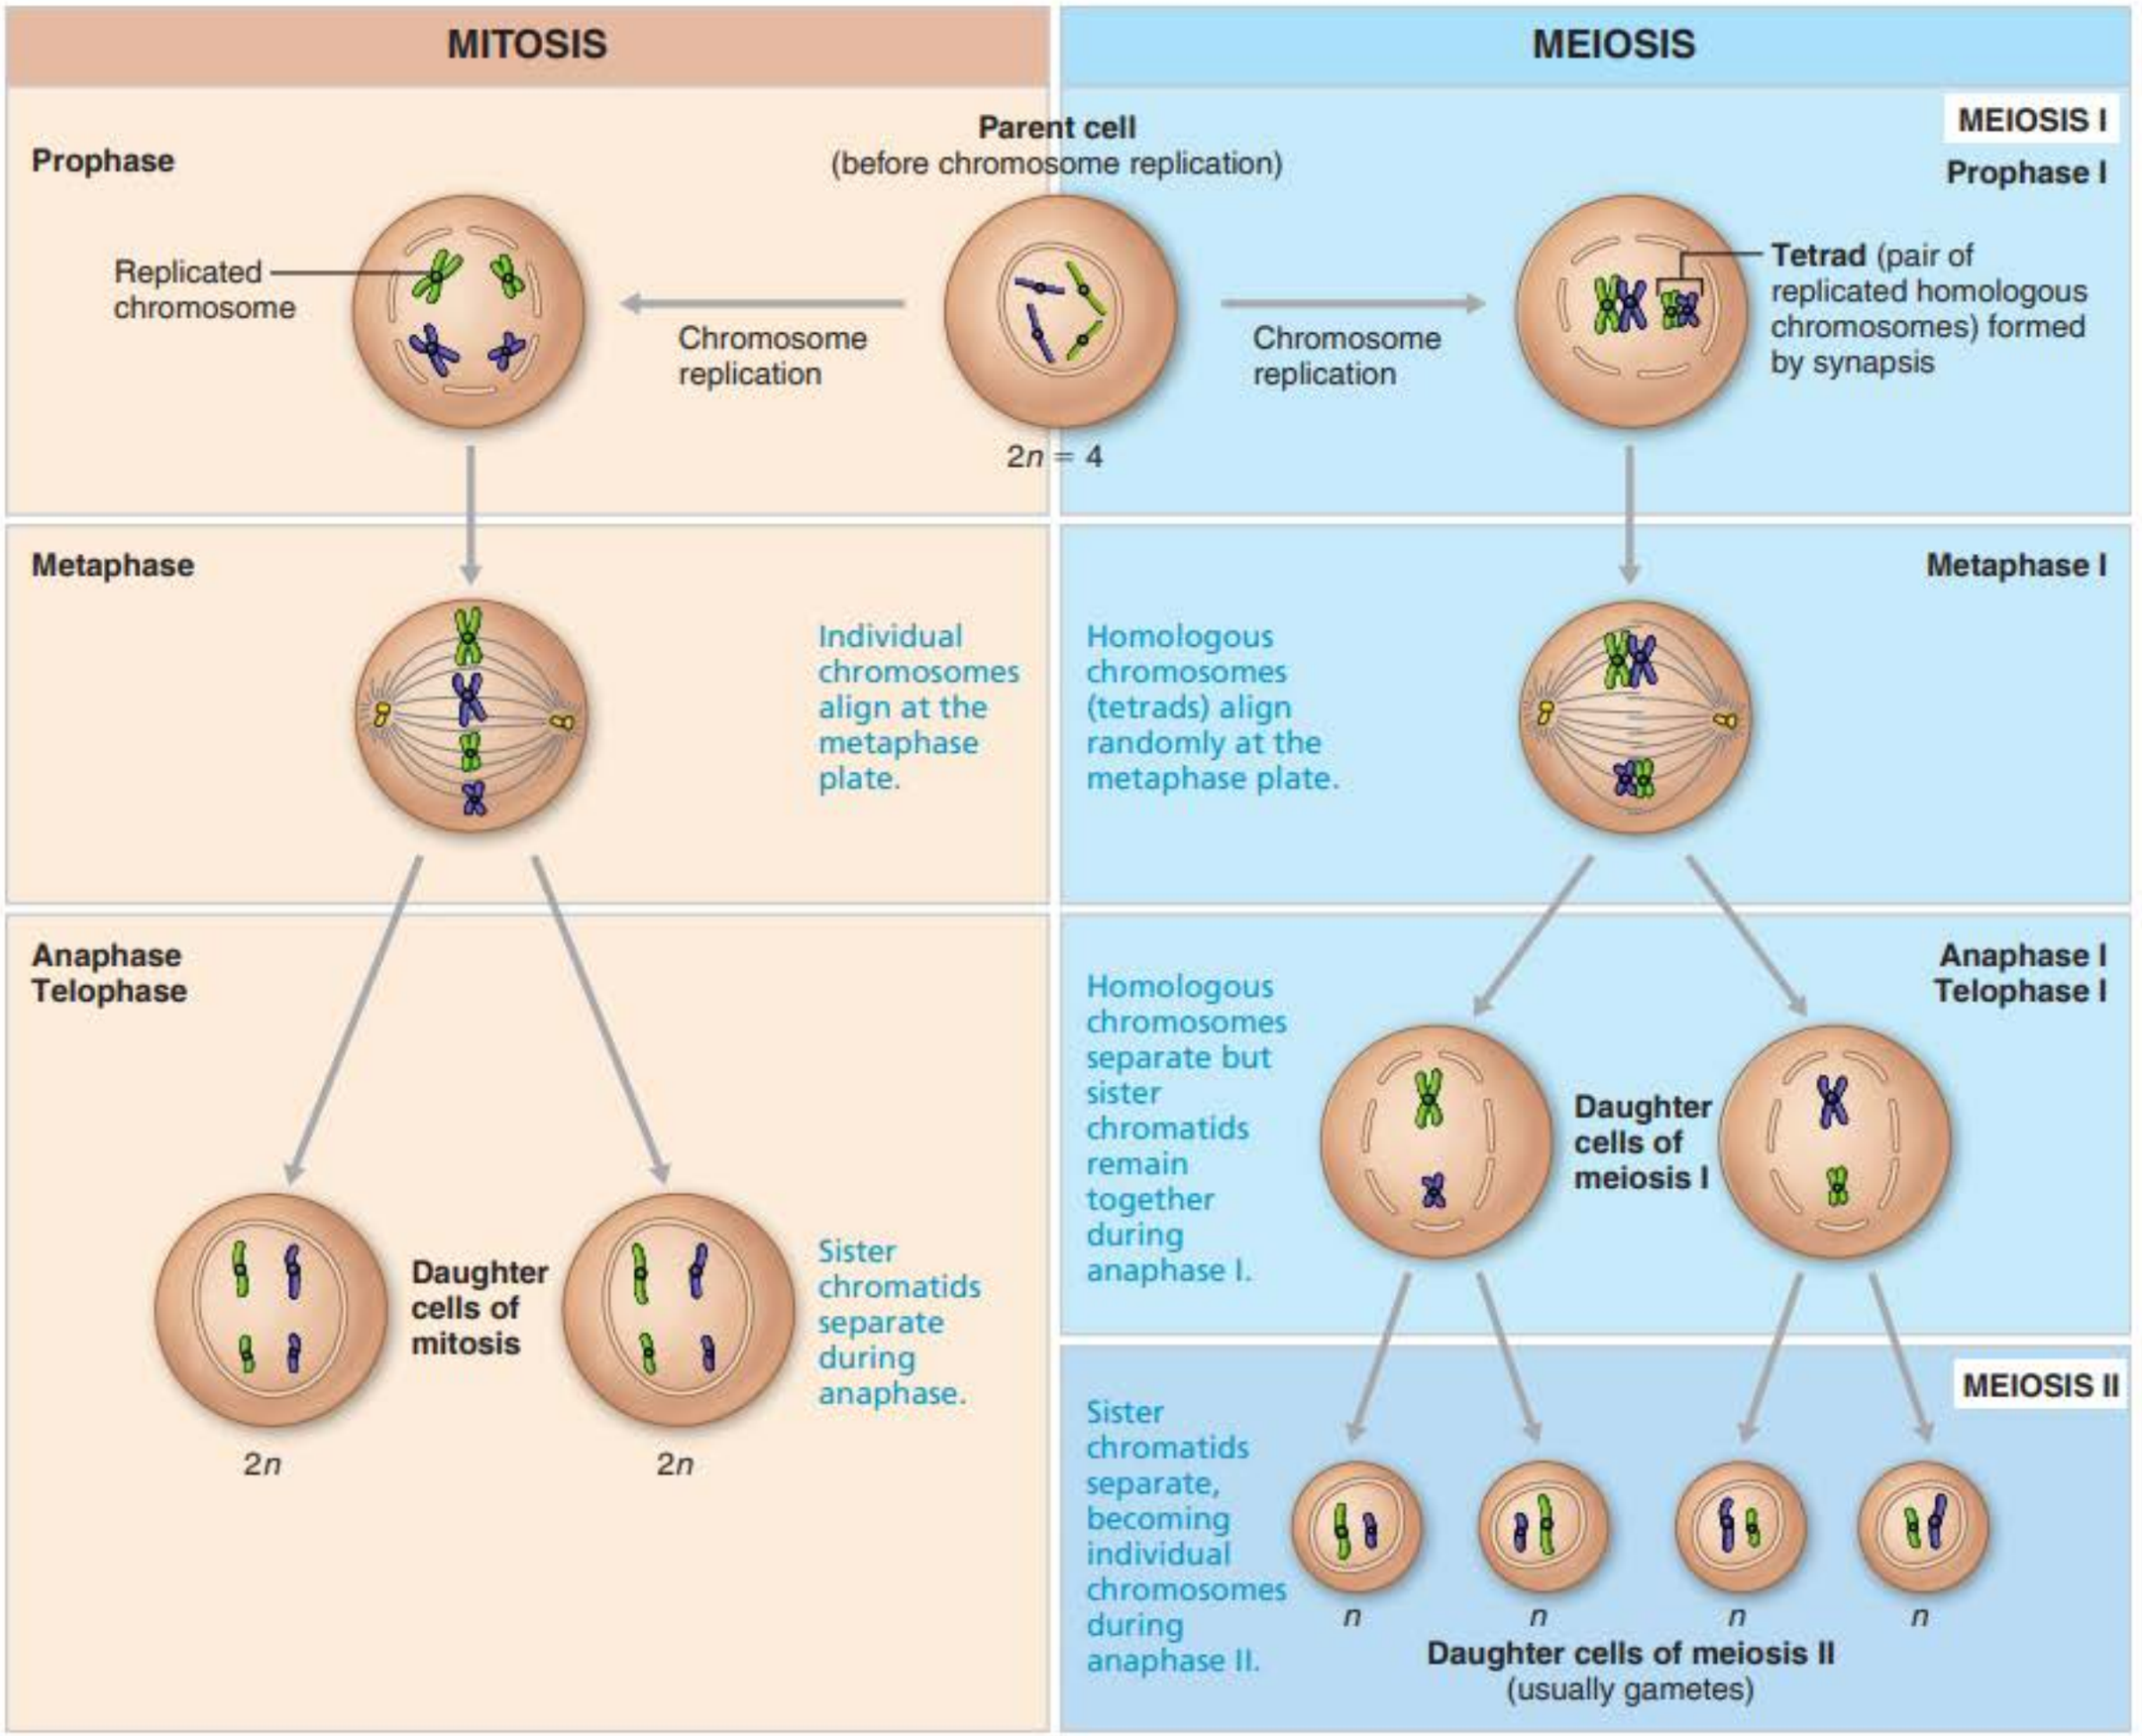

PROPERTY	MITOSIS	MEIOSIS
DNA replication	Occurs during interphase, before mitosis begins.	Occurs during interphase before meiosis I but not meiosis II.
Number of divisions	One, consisting of prophase, metaphase, anaphase, and telophase.	Two, each consisting of prophase, metaphase, anaphase, and telophase.
Synapsis of homologous chromosomes	Does not occur.	Occurs during prophase I; tetrads form, allowing crossing over to occur.
Number of daughter cells and genetic composition	Two. Each diploid ($2n$) cell is identical to the parent cell.	Four. Each haploid (n) cell contains half as many chromosomes as the parent cell and is genetically different from the parent cell.
Roles in the body	• Development of multicellular adult from zygote • Tissue repair and renewal • Ensures constant genetic makeup of all body cells	• Produces cells for reproduction (gametes) • Introduces genetic variability in gametes • Reduces chromosomal number by half so that fertilization can restore the normal diploid chromosome number ($2n = 46$).

Figure 27.4 Comparison of mitosis and meiosis in a parent cell with a diploid number ($2n$) of 4. (Not all the phases of mitosis and meiosis are shown, and only one possible alignment of the tetrads at metaphase I is illustrated.)

In meiosis II, the sister chromatids in the two daughter cells of meiosis I are simply parceled out equally among four resulting daughter cells.

Meiosis Compared with Mitosis

Now that you have followed meiosis to its conclusion, take a moment to compare mitosis and meiosis using **Figure 27.4**. Make sure you understand the different functions of these processes in the body. Mitosis ensures that all cells in the body have the same complement of DNA so that they are capable of normal growth and repair. In contrast, meiosis accomplishes two important tasks:

- It reduces the chromosomal number by half.
- It introduces genetic variability.

The random alignment of the homologous pairs during meiosis I (Figure 27.3) provides tremendous variability in the resulting gametes by scrambling genetic characteristics of the two parents in different combinations. Variability is also increased by crossing over during late prophase I. (We will revisit this process in Chapter 29.) As a result, it is likely that no two gametes are exactly alike and all are different from the original parent cells, which is the whole point of sexual reproduction.

Check Your Understanding

1. What is the HPG axis?
2. What is the final outcome of meiosis?
3. DRAW Consider a cell with a diploid number of six. Draw this cell at metaphase I of meiosis and its daughter cells at anaphase II. Show the correct number and placement of chromosomes.

PART 1
ANATOMY OF THE MALE REPRODUCTIVE SYSTEM

The sperm-producing *male gonads* are the **testes** (tes′tez) that lie within the *scrotum*. From the testes, the sperm are delivered out of the body through a system of ducts:

1. The *epididymis*
2. The *ductus deferens*
3. The *ejaculatory duct*
4. The *urethra*, which opens to the outside at the tip of the *penis*

The accessory sex glands, which empty their secretions into the ducts during ejaculation, are:

- The *seminal glands*
- *Prostate*
- The *bulbo-urethral glands*

Take a moment to trace the duct system in **Figure 27.5**, and identify the testis and accessory glands before continuing.

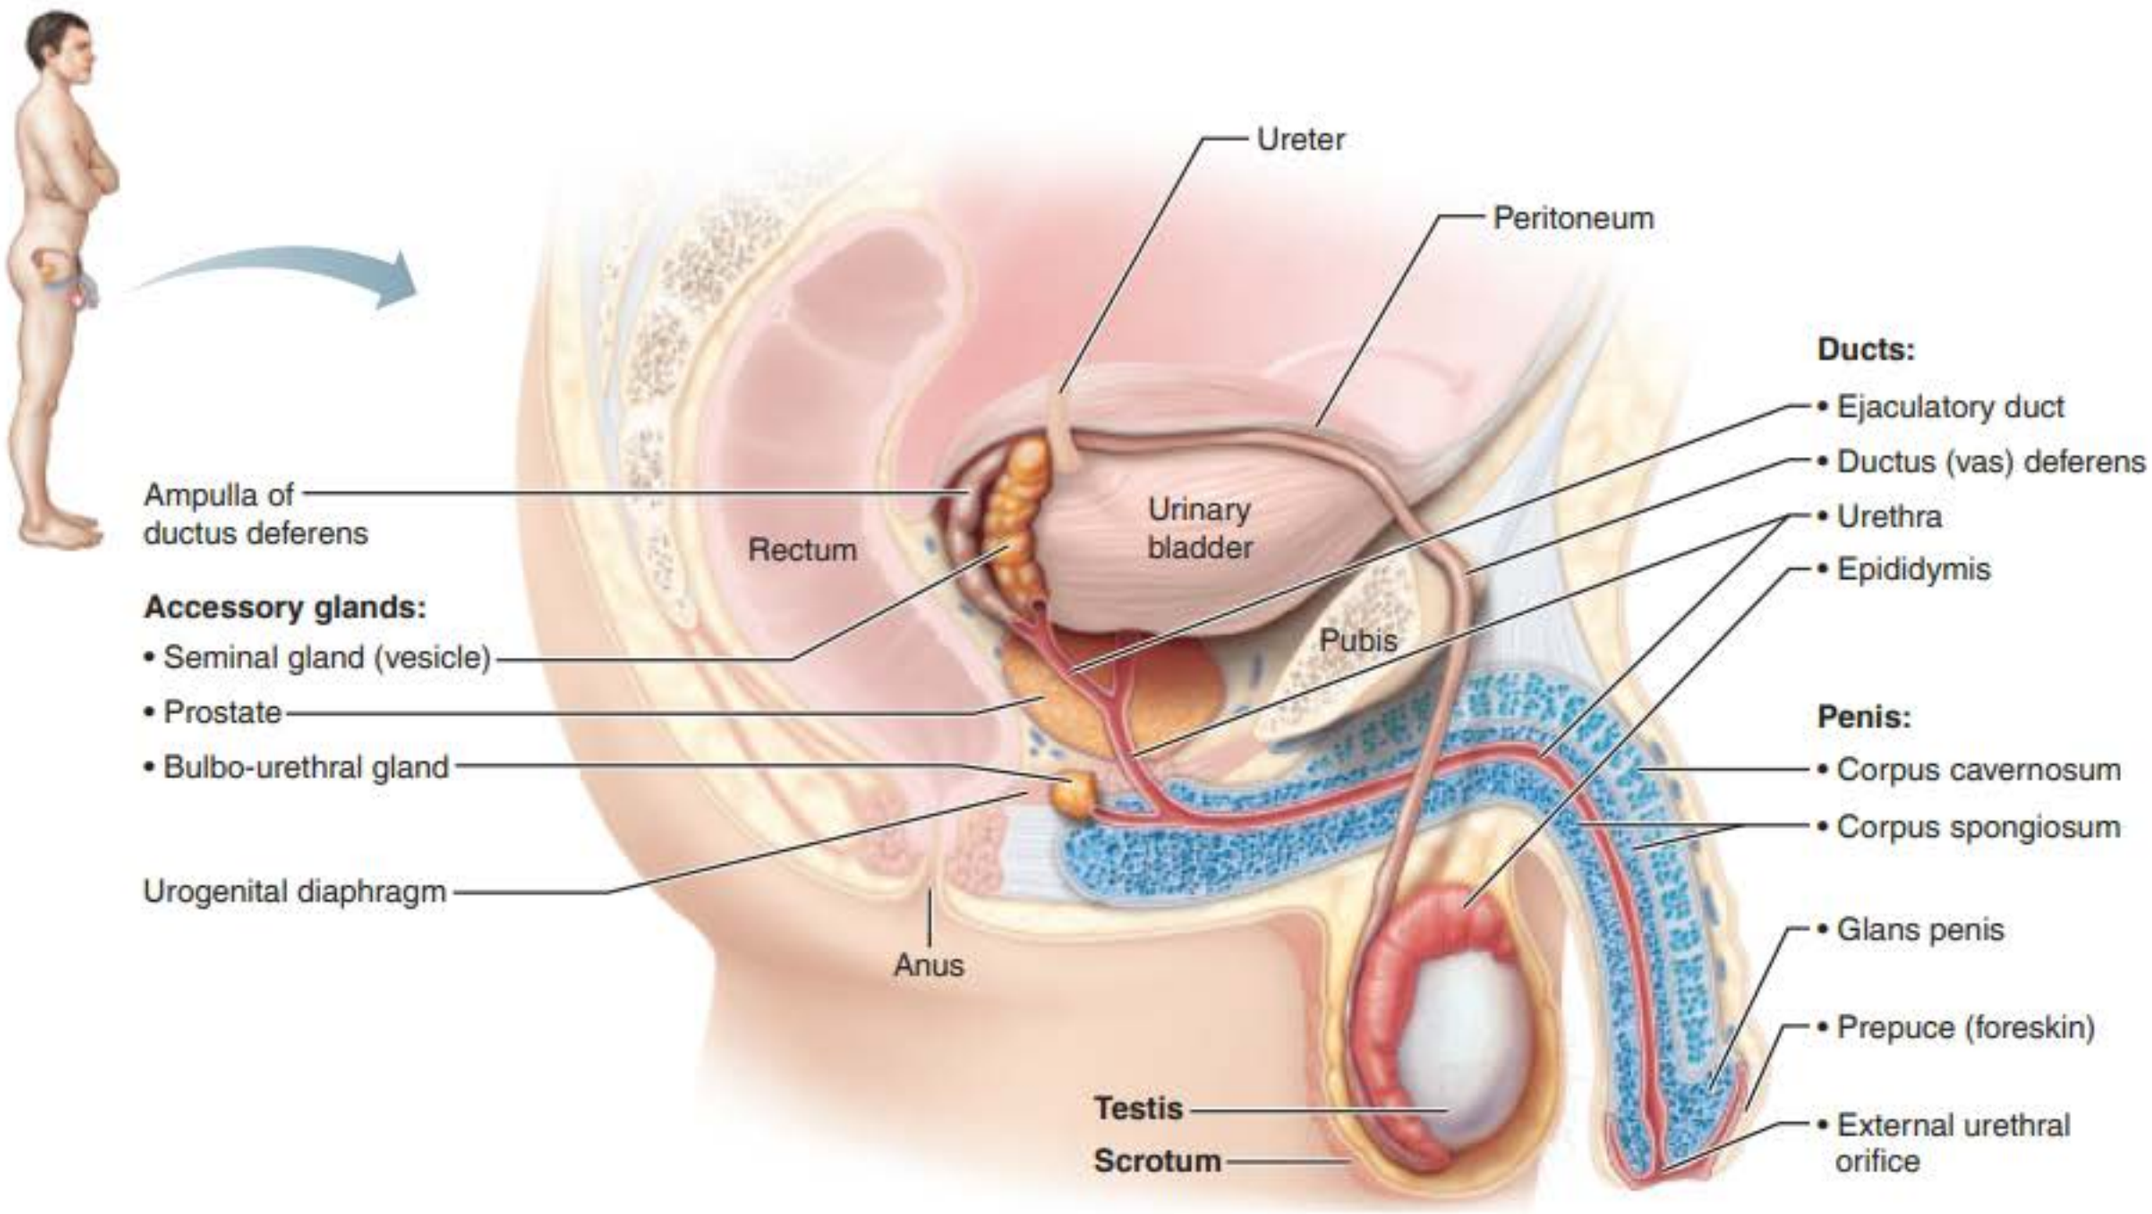

Figure 27.5 Reproductive organs of the male, sagittal view. A portion of the pubis is shown to illustrate the position of the ductus deferens as it enters the pelvic cavity.

27.2 The testes are enclosed and protected by the scrotum

Learning Outcome

- **Describe the structure and function of the testes, and explain the importance of their location in the scrotum.**

The Scrotum

The **scrotum** (skro′tum; "pouch") is a sac of skin and superficial fascia that hangs outside the abdominopelvic cavity at the root of the penis (Figure 27.5 and **Figure 27.6**). It is covered with sparse hairs, and contains paired oval testes. A midline *septum* divides the scrotum, providing a compartment for each testis.

This seems a rather vulnerable location for a man's testes, which contain his entire ability to father offspring. However, because viable sperm cannot be produced in abundance at core body temperature (37°C), the superficial location of the scrotum, which provides a temperature about 3°C lower, is an essential adaptation.

Furthermore, the scrotum is affected by temperature changes. When it is cold, the testes are pulled closer to the warm body wall. The scrotal skin wrinkles, decreasing its surface area and increasing its thickness to reduce heat loss. Two sets of muscles act to help maintain a fairly constant intrascrotal temperature:

- The **dartos muscle** (dar′tos; "skinned"), a layer of smooth muscle in the superficial fascia, wrinkles the scrotal skin.
- The **cremaster muscles** (kre-mas′ter; "a suspender"), bands of skeletal muscle that arise from the internal oblique muscles of the trunk, elevate the testes.

The Testes

Each testis is approximately 4 cm (1.6 inches) long by 2.5 cm (1 inch) wide and is surrounded by two tunics. The outer two-layered **tunica vaginalis** (vaj″ĭ-nal′is) is derived from an outpocketing of the peritoneum (Figure 27.6 and **Figure 27.7a**). Deep to this serous layer is the **tunica albuginea** (al″bu-jin′e-ah; "white coat"), the fibrous capsule of the testis.

Septa extending inward from the tunica albuginea divide the testis into about 250 wedge-shaped *lobules*. Each contains one to four tightly coiled **seminiferous tubules** (sem″ĭ-nif′er-us; "sperm-carrying"), the actual "sperm factories."

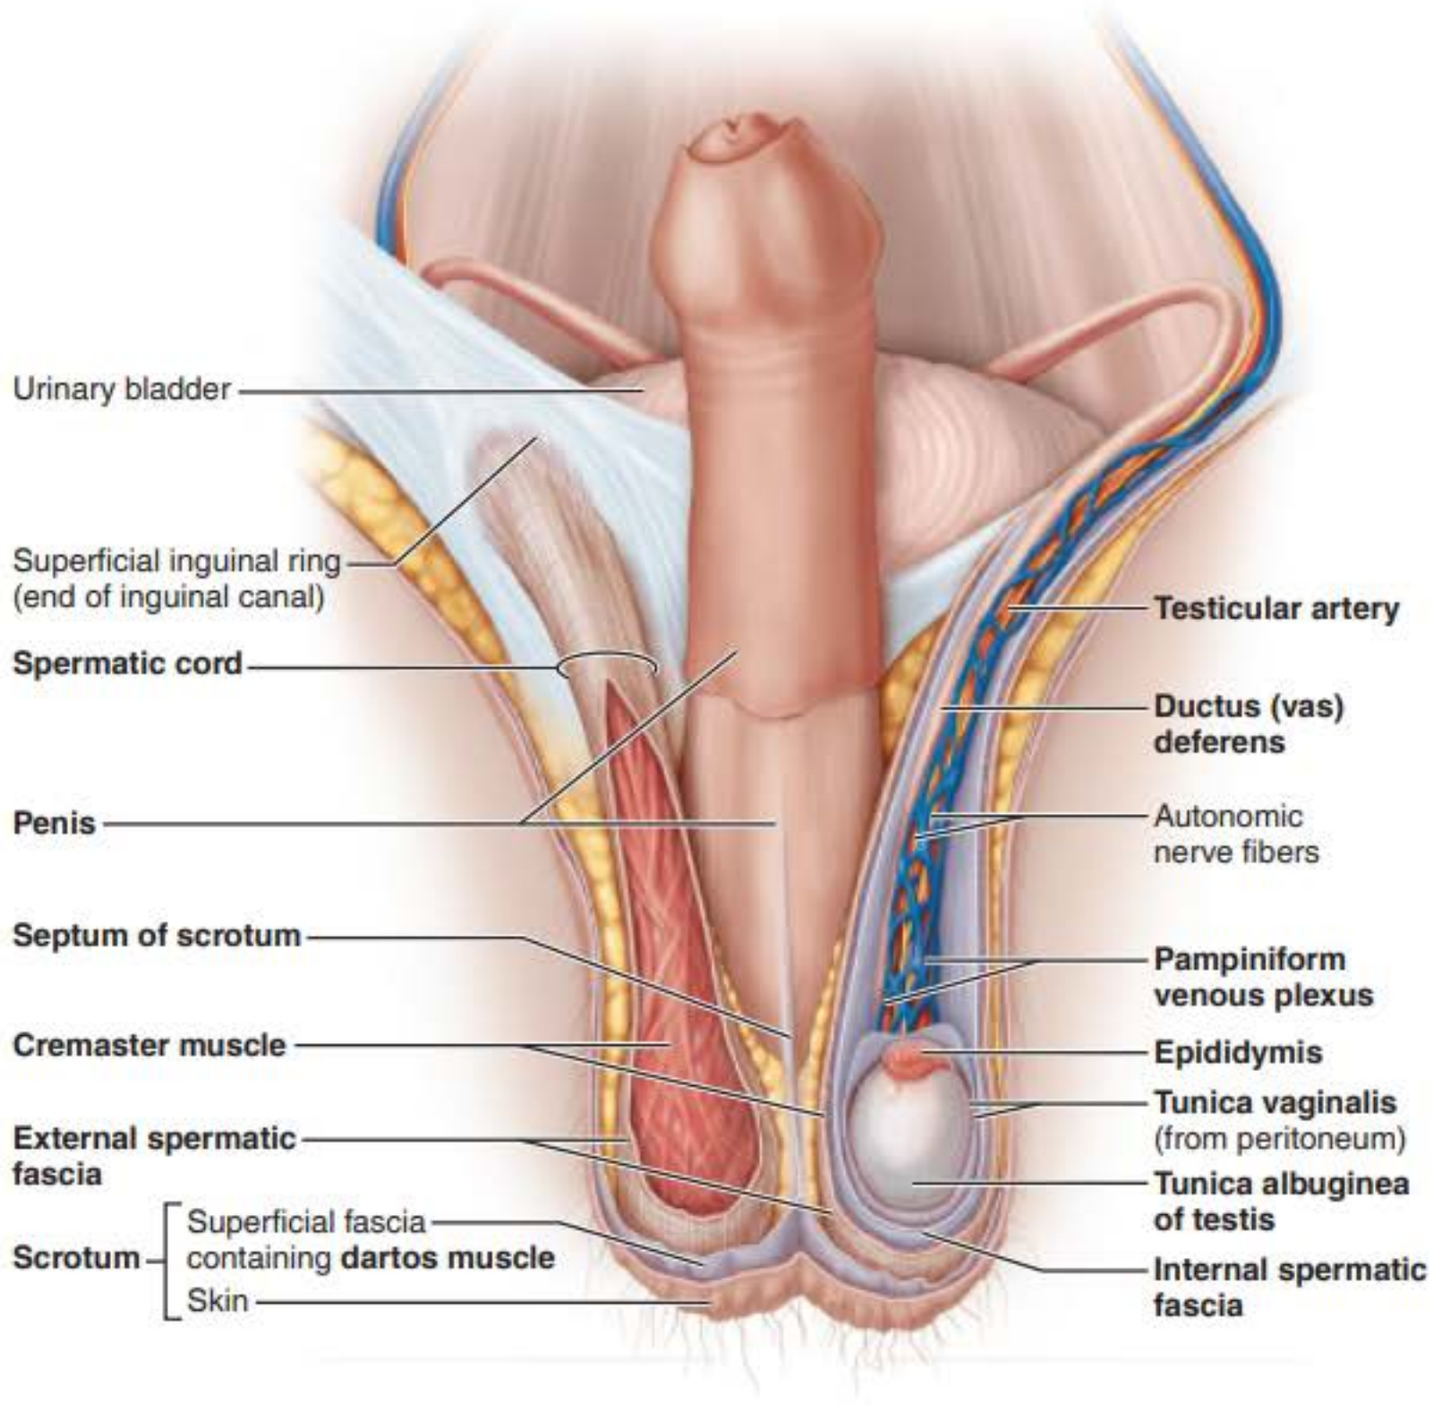

Figure 27.6 Relationships of the testis to the scrotum and spermatic cord. The scrotum has been opened and its anterior portion removed.

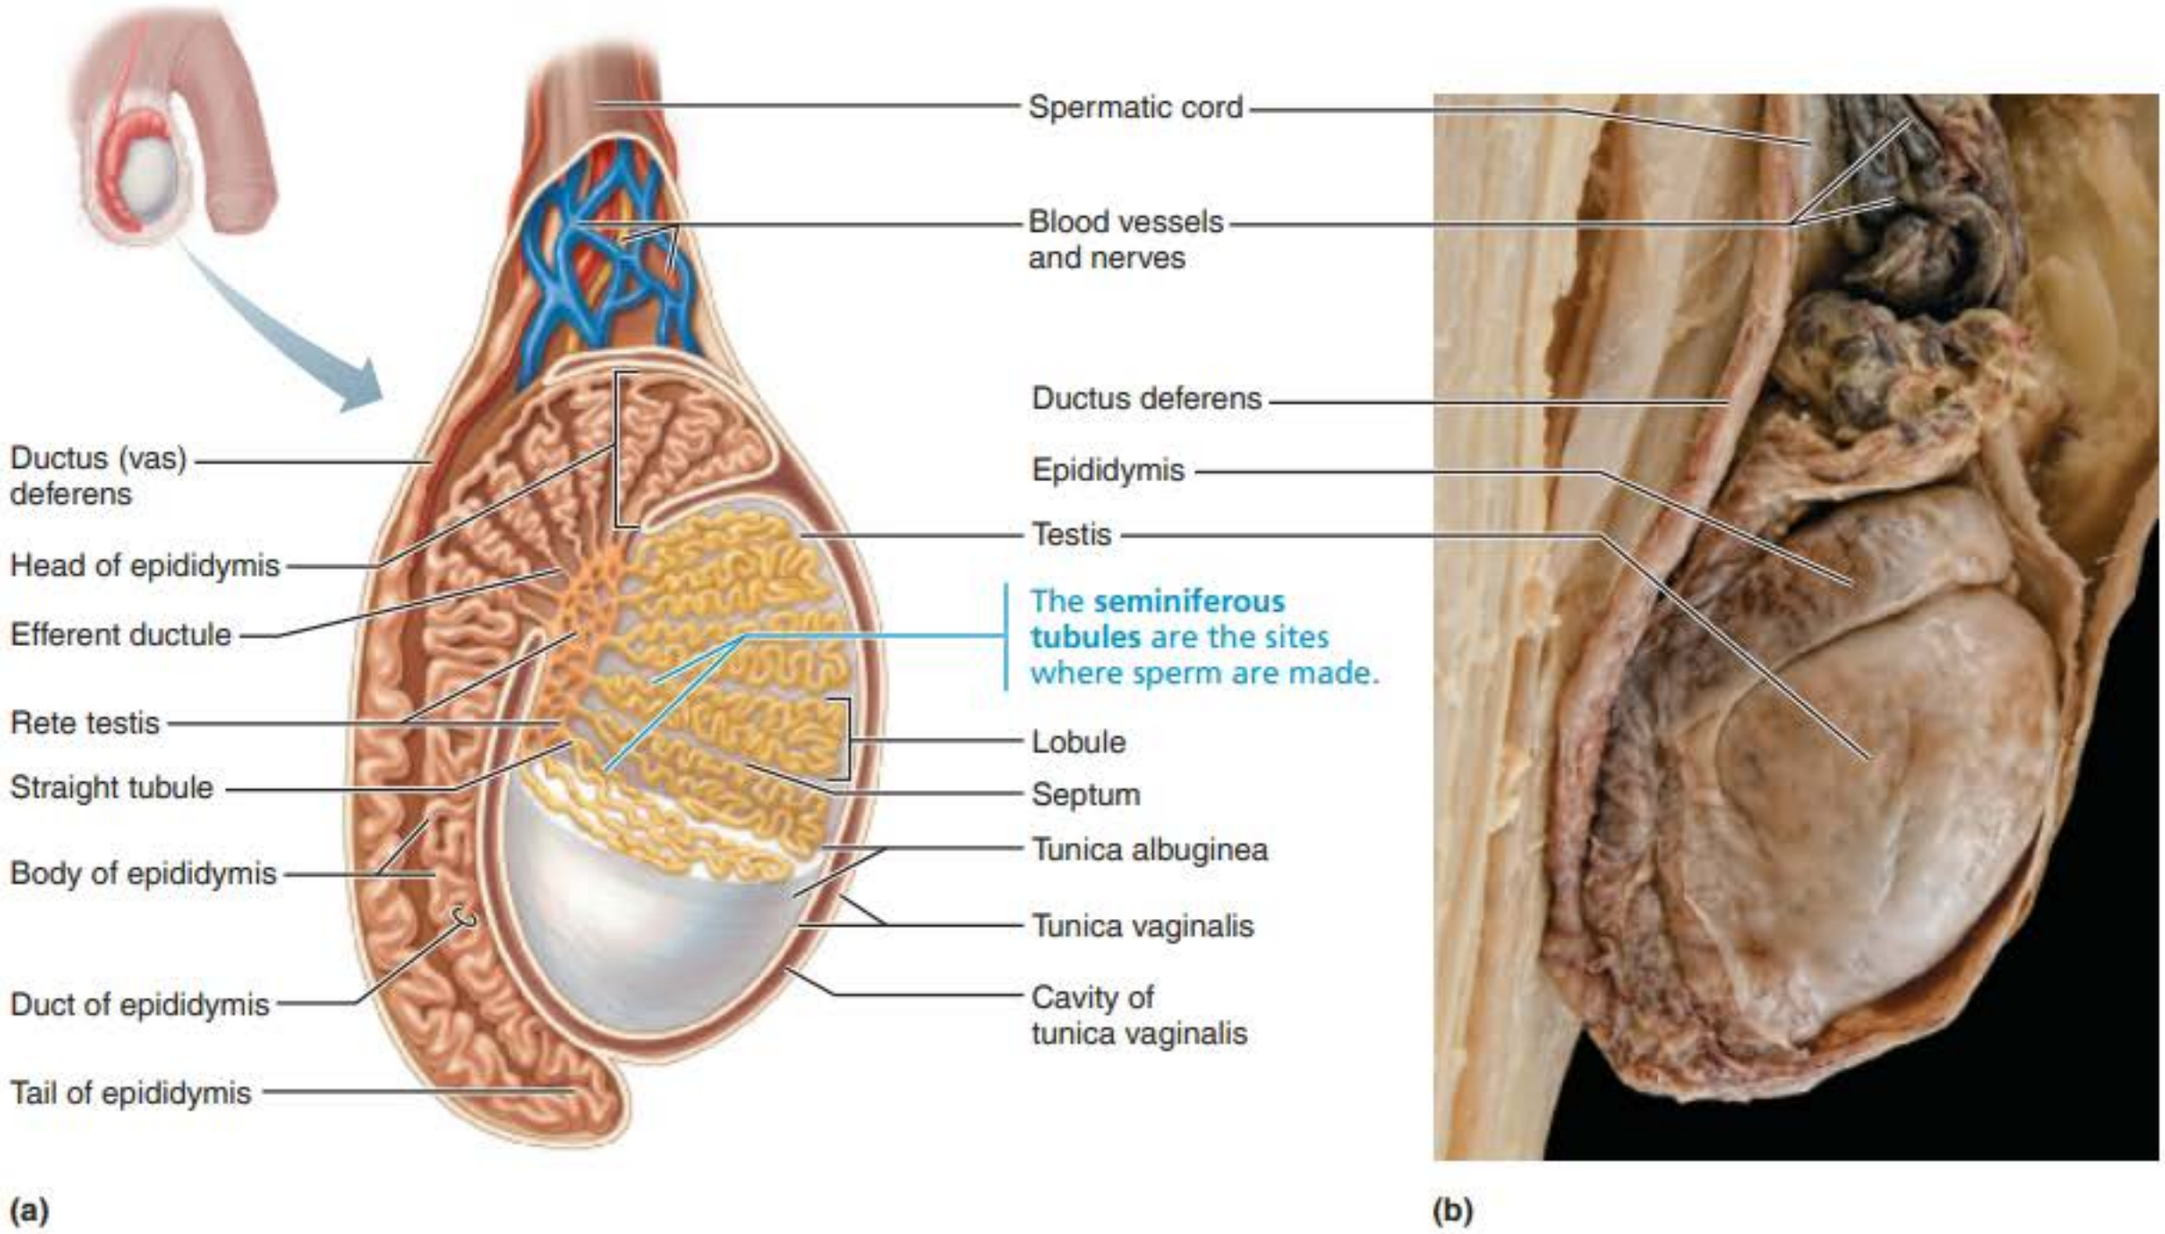

Figure 27.7 Structure of the testis. (a) Partial sagittal section through the testis and epididymis. The anterior aspect is to the right. **(b)** External view of a testis from a cadaver; same orientation as in (a).

The seminiferous tubules of each lobule converge to form a **straight tubule** that conveys sperm into the **rete testis** (re′te), a tubular network on the posterior side of the testis. From the rete testis, sperm leave the testis through the *efferent ductules* and enter the *epididymis* (ep″ĭ-did′ĭ-mis), which hugs the external testis surface posteriorly. The immature sperm pass through the head, the body, and then move into the tail of the epididymis, where they are stored until ejaculation.

The long **testicular arteries**, which branch from the abdominal aorta superior to the pelvis (see *gonadal arteries*, ◀ Figure 19.26c, p. 746), supply the testes. The **testicular veins** draining the testes arise from a network called the **pampiniform venous plexus** (pam-pin′ĭ-form; "tendril-shaped") that surrounds the portion of each testicular artery within the scrotum like a climbing vine (Figure 27.6). The cooler venous blood in each pampiniform plexus absorbs heat from the arterial blood, cooling it before it enters the testes. In this way, these plexuses help to keep the testes at their cool homeostatic temperature.

Both divisions of the autonomic nervous system serve the testes, and when the testes are hit forcefully, associated sensory nerves transmit impulses that result in agonizing pain and nausea. A connective tissue sheath encloses nerve fibers, blood vessels, and lymphatics. Together with the ductus deferens, these structures make up the **spermatic cord**, which passes through the inguinal canal (Figure 27.6).

HOMEOSTATIC IMBALANCE 27.1 CLINICAL

Although *testicular cancer* is relatively rare (affecting one of every 40,000 males each year), it is the most common cancer in young men ages 15 to 35. The most important risk factor for this cancer is *cryptorchidism* (nondescent of the testes, see p. 1084).

The most common sign of testicular cancer is a painless solid mass. Testicular cancer has an impressive cure rate. Over 96% of cases are cured by surgical removal of the cancerous testis (*orchiectomy*) alone or in combination with radiation therapy or chemotherapy.

Check Your Understanding

4. Name the tubular structures in the testes that act as "sperm factories."
5. Muscle activity and the pampiniform venous plexus help to keep the temperature of the testes at homeostatic levels. How do they do that?
6. APPLY Carlos and Jennifer have been trying to start a family. Carlos spends his daily two-hour commute working with his laptop on his lap. How might this affect his fertility?

For answers, see Answers Appendix.

27.3 Sperm travel from the testes to the body exterior through a system of ducts

Learning Outcome

- **Compare and contrast the roles of each part of the male reproductive duct system.**

In order (proximal to distal), the **accessory ducts** are the epididymis, ductus deferens, ejaculatory duct, and urethra.

The Epididymis

Sperm are not yet fully functional when they leave the testes. The **epididymis** (*epi* = beside; *didym* = the testes) is where sperm mature. It is a comma-shaped organ that arches over the posterior and lateral side of the testis (Figures 27.5 and 27.7). Its *head* contains efferent ductules that empty into the **duct of the epididymis**, a highly coiled duct that completes the head and forms all of the *body* and *tail* of this organ. With an uncoiled length of over 6 m (20 feet), the duct of the epididymis is longer than the entire intestine!

Some pseudostratified epithelial cells of the duct mucosa exhibit long, nonmotile microvilli (*stereocilia*). The huge surface area of these stereocilia allows them to absorb excess testicular fluid and to pass nutrients to the many sperm stored temporarily in the lumen.

The immature, nearly nonmotile sperm that leave the testis are moved slowly along the duct of the epididymis through fluid that contains several kinds of antimicrobial proteins, including defensins. As they move along its tortuous course (a trip that takes about 20 days), the sperm gain the ability to swim.

Sperm can be stored in the epididymis for several months. If they are held longer, epithelial cells of the epididymis eventually phagocytize them.

Sperm are ejaculated from the epididymis, not the testes. When a male ejaculates, the smooth muscle in the ducts of the epididymis contracts, expelling sperm into the next segment of the duct system, the *ductus deferens*.

The Ductus Deferens and Ejaculatory Duct

The **ductus deferens** (duk′tus def′er-ens; "carrying away"), or *vas deferens*, transports sperm during ejaculation. From the epididymis, it runs upward (as part of the spermatic cord) through the inguinal canal into the pelvic cavity, a distance of about 45 cm (18 inches) (Figure 27.5). Easily palpated as it passes anterior to the pubic bone, it then loops medially over the ureter and descends along the posterior bladder wall (**Figure 27.8**). Its end expands to form the **ampulla** of the ductus deferens and then joins with the duct of the seminal gland to form the short **ejaculatory duct**. After entering the prostate, each ejaculatory duct empties into the urethra.

Like that of the epididymis, the mucosa of the ductus deferens is pseudostratified epithelium. However, its muscular layer is extremely thick and the duct feels like a hard wire when squeezed between the fingertips. During ejaculation, the smooth muscle in its walls creates strong peristaltic waves that squeeze the sperm forward along the tract and into the urethra.

As Figure 27.7 illustrates, part of the ductus deferens lies in the scrotal sac. Some men opt for permanent birth control by having a **vasectomy** (vah-sek′to-me; "cutting the vas"). In this relatively minor operation, the physician makes a small incision into the scrotum and then cuts through and ligates (ties off) or cauterizes each ductus deferens. Sperm are still produced, but they can no longer reach the body exterior. Instead, they deteriorate and are phagocytized.

The Urethra

The **urethra** is the terminal portion of the male duct system (Figures 27.5 and 27.8). It transports urine and semen (at different times), so it serves both the urinary and reproductive systems. As we saw in Chapter 25 (◀ p. 1004), its three regions are:

- *Prostatic urethra*, the portion surrounded by the prostate.
- *Intermediate part of the urethra* (or membranous urethra) in the urogenital diaphragm.
- *Spongy urethra*, which runs through the penis and opens to the outside at the *external urethral orifice*. The spongy urethra accounts for 75% of urethral length. Its mucosa contains scattered *urethral glands* that secrete lubricating mucus into the lumen just before ejaculation.

Check Your Understanding

7. Name the organs of the male duct system in order, from the epididymis to the body exterior. Which of these organs runs from the scrotum into the pelvic cavity?
8. What are two functions of the stereocilia on the epididymal epithelium?

For answers, see Answers Appendix.

27.4 The penis is the copulatory organ of the male

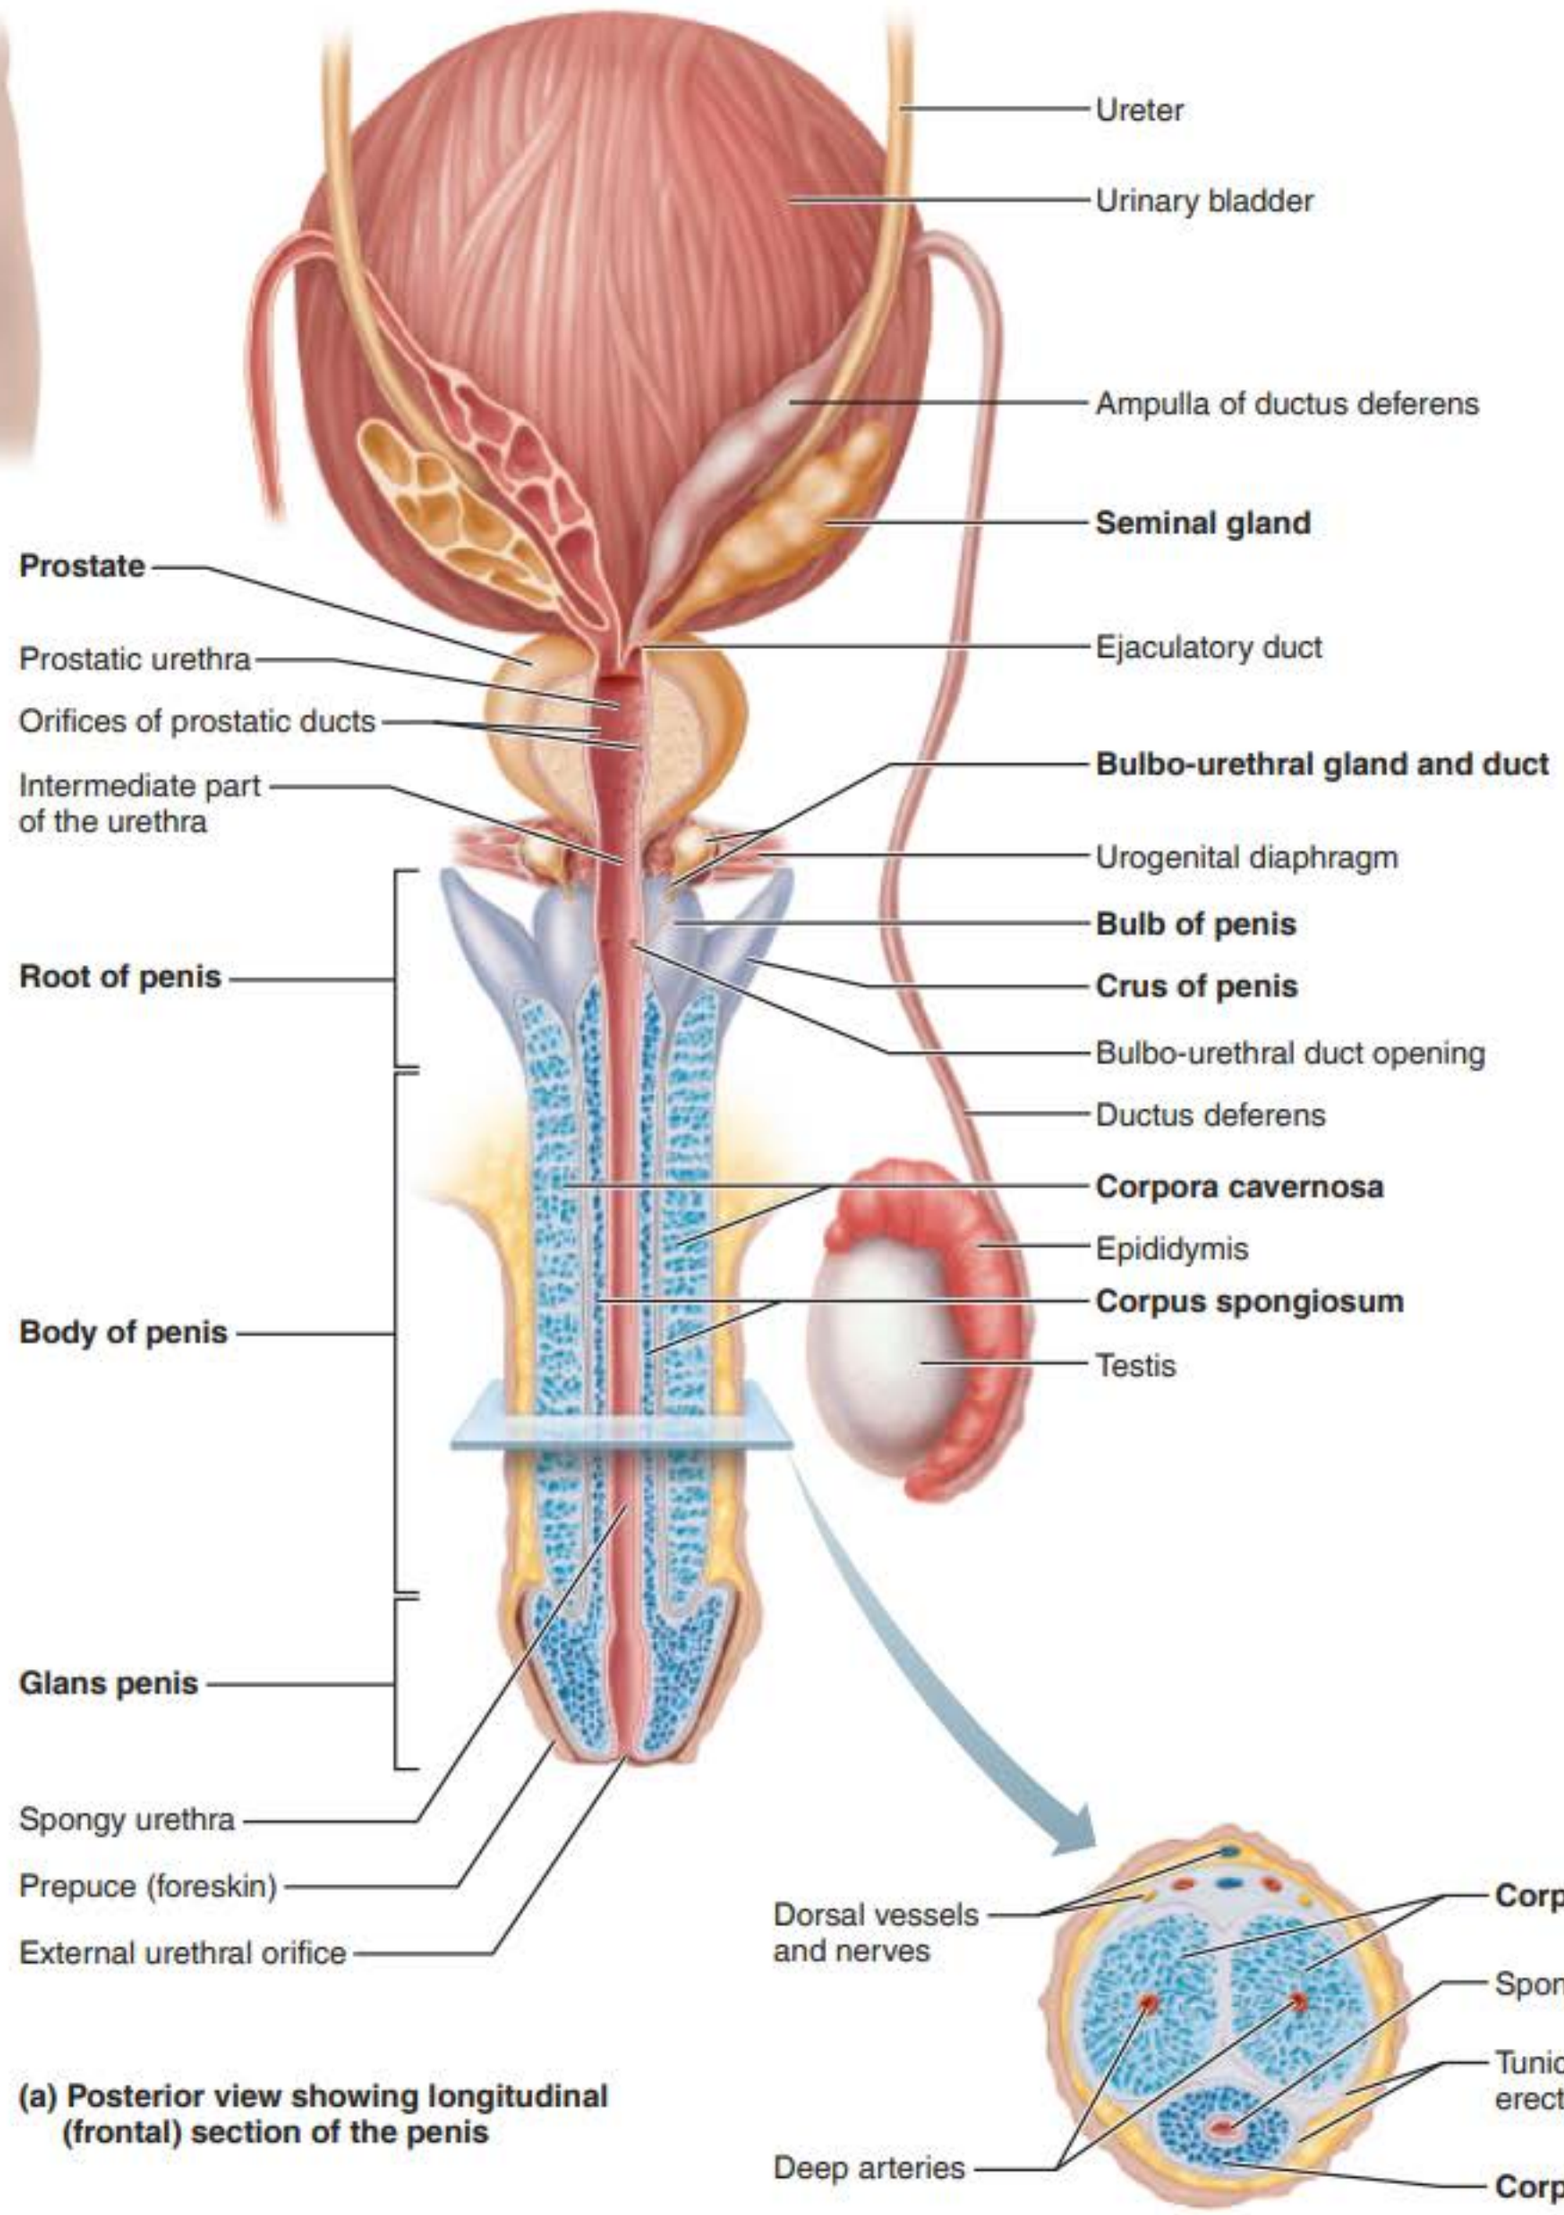
Learning Outcome

- **Describe the location, structure, and function of the penis.**

The **penis** is a copulatory organ that delivers sperm into the female reproductive tract (Figures 27.5 and 27.8). The penis and scrotum, which hang suspended from the perineum, make up the **external genitalia** of the male.

The penis consists of an attached root and a free *body* that ends in an enlarged tip, the **glans penis**. The skin covering the penis is loose, and extends distally around the glans to form a cuff called the **prepuce** (pre′pūs), or **foreskin**. Sometimes, the foreskin is surgically removed shortly after birth, a procedure called *circumcision* ("cutting around"). While circumcision is not medically necessary, it has been shown to decrease the risk of acquiring HIV. It also significantly reduces the risk of other reproductive system infections. About 60% of newborn boys in the United States are circumcised.

To understand penile anatomy, it is important to know that its dorsal and ventral surfaces are named in reference to the erect penis. Internally, the penis contains the spongy urethra and three long cylindrical bodies (*corpora*) of erectile tissue,



(a) Posterior view showing longitudinal (frontal) section of the penis

(b) Cross section of the penis with dorsal surface at top

Figure 27.8 Male reproductive structures.

each covered by a sheath of dense fibrous connective tissue. This *erectile tissue* is a spongy network of connective tissue and smooth muscle riddled with vascular spaces. During sexual excitement, the vascular spaces fill with blood, causing the penis to enlarge and become rigid. This condition, called *erection*, enables the penis to serve as the organ of copulation.

The midventral erectile body, the **corpus spongiosum** (spon″je-o′sum; "spongy body"), surrounds the urethra. It expands distally to form the glans and proximally to form the part of the root called the **bulb of the penis**. The sheetlike bulbospongiosus muscle covers the bulb externally and secures it to the urogenital diaphragm.

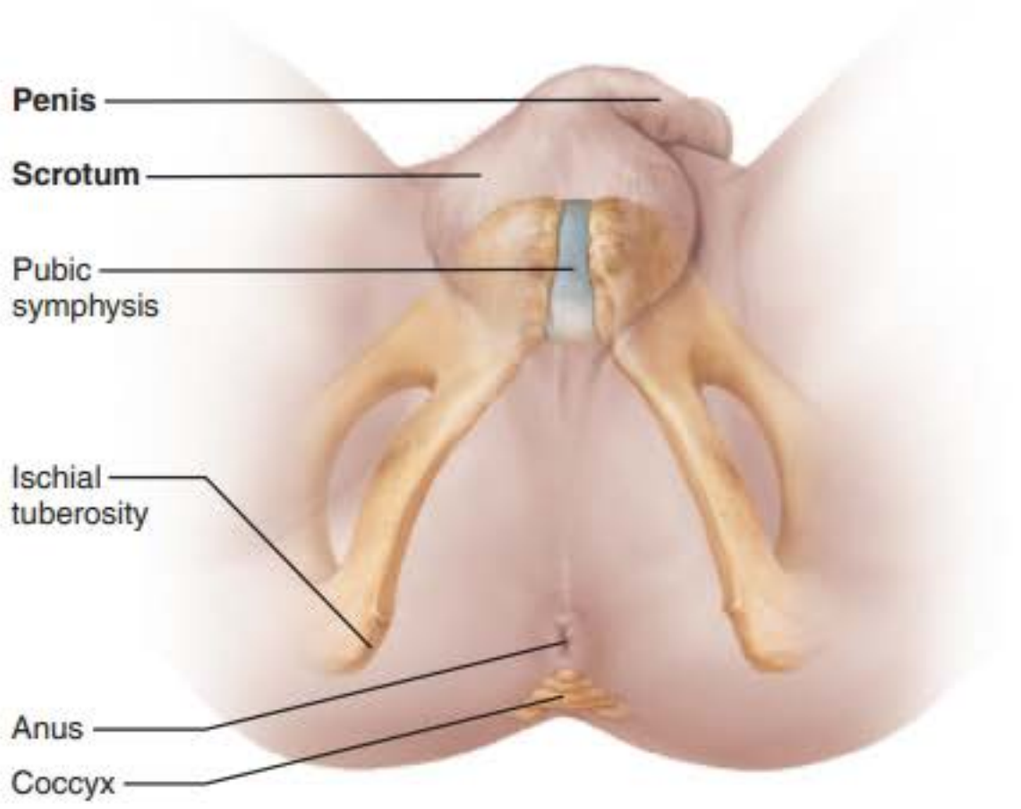


Figure 27.9 The male perineum.

The paired dorsal erectile bodies, called the **corpora cavernosa** (kor′por-ah kă-ver-no′sah; "cavernous bodies"), make up most of the penis and are bound by the fibrous tunica albuginea. Their proximal ends form the **crura of the penis** (kroo′rah; "legs"; singular: crus). Each crus is surrounded by an ischiocavernosus muscle and anchors to the pubic arch of the bony pelvis.

The Male Perineum

The male **perineum** (per″ĭ-ne′um; "around the anus") suspends the scrotum and contains the root of the penis, and the anus. More specifically, it is the diamond-shaped region located between the pubic symphysis anteriorly, the coccyx posteriorly, and the ischial tuberosities laterally (**Figure 27.9**). The floor of the perineum is formed by muscles described in Chapter 10 (◀ pp. 348–349).

Check Your Understanding

9. What is the function of the corpora cavernosa?
10. What name is given to the external region where the penis and scrotum are suspended?

For answers, see Answers Appendix.

27

27.5 The male accessory glands produce the bulk of semen

Learning Outcomes

- **Compare the roles of the seminal glands and the prostate.**
- **Discuss the sources and functions of semen.**

The **accessory glands** include the paired seminal glands and bulbo-urethral glands and the single prostate (Figures 27.5 and 27.8).

Male Accessory Glands

The Seminal Glands

The secretions of the **seminal glands** (sem′ĭ-nul), or **seminal vesicles**, account for some 70% of semen volume. These glands lie on the posterior bladder surface. Each of these fairly large, hollow glands is about the shape and length (5–8 cm) of a little finger. However, because a seminal gland is pouched, coiled, and folded back on itself, its uncoiled length is actually about 15 cm. Its fibrous capsule encloses a thick layer of smooth muscle that contracts during ejaculation to empty the gland.

The seminal gland mucosa is a secretory pseudostratified columnar epithelium. Stored within the mucosa's honeycomb of blind alleys is a yellowish viscous alkaline fluid containing fructose sugar, citric acid, a coagulating enzyme, prostaglandins, and other substances that increase sperm motility or fertilizing ability. The yellow color of seminal fluid is due to a yellow pigment that fluoresces under UV light, a capability that allows investigators to recognize a sperm trail or residue in instances of sexual attack.

As noted, the duct of each seminal gland joins that of the ductus deferens on the same side to form the ejaculatory duct. Sperm and seminal fluid mix in the ejaculatory duct and enter the prostatic urethra together during ejaculation.

The Prostate

The **prostate** (pros′tāt) is a single doughnut-shaped gland about the size of a peach pit (Figures 27.5 and 27.8). It encircles the urethra just inferior to the bladder. Enclosed by a thick connective tissue capsule, it is made up of 20 to 30 compound tubuloalveolar glands embedded in a mass (stroma) of smooth muscle and dense connective tissue.

During ejaculation, prostatic smooth muscle contracts, squeezing the prostatic secretion into the prostatic urethra via several ducts. This fluid plays a role in activating sperm and accounts for up to one-third of the semen volume. It is a milky, slightly acidic fluid that contains citrate (a nutrient source) and several enzymes including one called prostate-specific antigen (PSA).

HOMEOSTATIC IMBALANCE 27.2 — CLINICAL

Benign prostatic hyperplasia (BPH) is a common prostatic disease, affecting about 50% of men at age 50 and 80% of men at age 70. It is characterized by benign growth of both the stroma and glands. As a result, the prostatic urethra is constricted. This makes urination difficult and can lead to incomplete bladder emptying. This in turn can cause frequent urinary tract infections and kidney damage due to the backup of urine. Treatment usually begins with drugs that relax the smooth muscle in the stroma and drugs that inhibit testosterone's stimulation of prostate growth. *Transurethral resection of the prostate* is a surgical procedure used to widen the prostatic urethra when drug treatment is insufficient.

Prostatitis, a common reason for a man to consult a urologist, is described in Related Clinical Terms on p. 1086.

Prostate cancer is the third most common cause of cancer death in men, and 1 in 6 men in the U.S. will develop it. Despite these seemingly alarming statistics, most men with prostate cancer die *with* it rather than *from* it. Prostate cancers range from extremely slow-growing tumors to highly aggressive fatal tumors. This cancer is usually symptomless in the early stages, but can be detected by a digital rectal exam. A blood test to detect the levels of prostate-specific antigen (PSA) was once used routinely for screening. However, its use for routine screening is no longer generally recommended because of its high rate of falsely positive results (elevated PSA, but no cancer).

Because many prostate cancers are slow growing and develop late in life, an acceptable treatment option for some early stage prostate cancers is simply to watch and wait. For more advanced cancers, surgery alone or in conjunction with radiation therapy is used. In a few men, prostate cancer spreads beyond the prostate, often into bone (◀ p. 16, PET scan). These prostate cancer metastases are often dependent on testosterone, so blocking testosterone synthesis or action can slow the progression of metastatic prostate cancer.

The Bulbo-Urethral Glands

The paired **bulbo-urethral glands** (bul″bo-u-re′thral) are pea sized. They are located inferior to the prostate in the urogenital diaphragm (Figures 27.5 and 27.8). They produce a thick, clear mucus, some of which drains into the spongy urethra where it neutralizes traces of acidic urine. In addition, this mucus lubricates the glans penis when a man becomes sexually excited.

Semen

Semen (se′men) is a milky white, somewhat sticky mixture of accessory gland secretions and sperm. The accessory gland secretions provide a transport medium and nutrients. They also contain chemicals that protect and activate the sperm and facilitate their movement. Mature sperm cells are streamlined cellular "torpedos" containing little cytoplasm or stored nutrients. Catabolism of the fructose in seminal gland secretions provides nearly all the fuel needed for sperm ATP synthesis.

Semen contains several substances that play many roles:

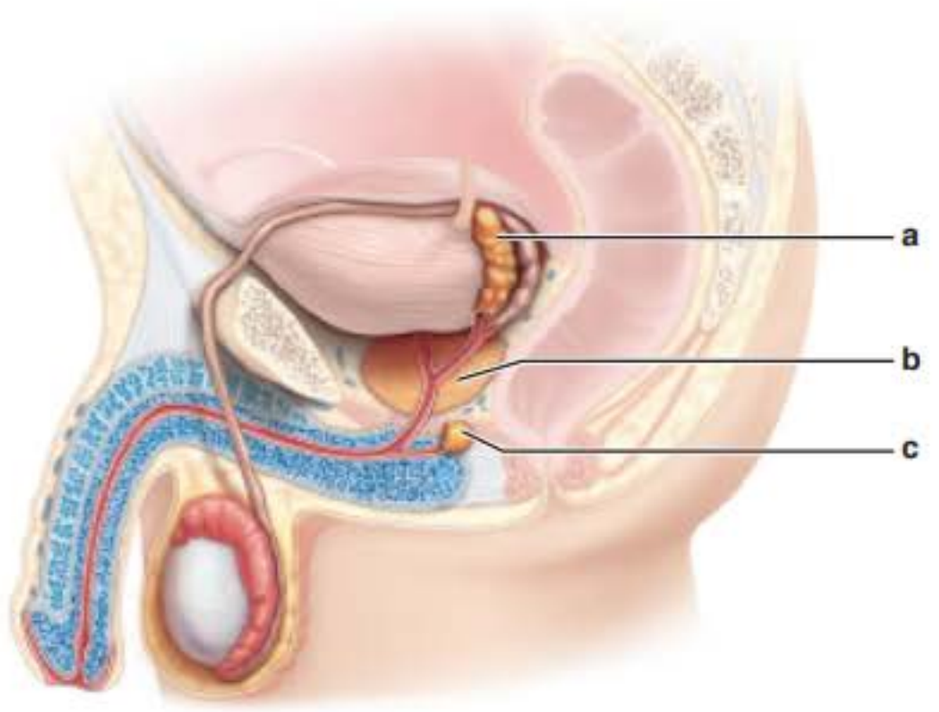
- Prostaglandins (◀ pp. 47–48) cause the viscosity of mucus guarding the entry (cervix) of the uterus to decrease. They also stimulate reverse peristalsis in the uterus, facilitating sperm movement through the female reproductive tract.
- The hormone relaxin and certain enzymes in semen enhance sperm motility.
- ATP provides energy.
- Certain ingredients suppress the immune response in the female's reproductive tract.
- Antibiotic chemicals destroy some bacteria.
- Clotting factors in semen coagulate it just after it is ejaculated. Coagulation causes the sperm to stick to the walls of the vagina and prevents the initially immobile sperm from draining out of the vagina. Soon after semen coagulates, enzymes liquefy the sticky mass and the sperm swim out and begin their journey through the female duct system.

Semen, as a whole, is alkaline (pH 7.2–8.0), which helps neutralize the acid environment of the male's urethra and the female's vagina, protecting the delicate sperm and enhancing their motility. Sperm are sluggish under acidic conditions (below pH 6).

The amount of semen propelled out of the male duct system during ejaculation is relatively small, only 2–5 ml and only 10% sperm, but there are between 20 and 150 million sperm per milliliter.

Check Your Understanding

11. For each of the following questions, name the glandular accessory organ and identify its location in the figure below: Which gland produces primarily mucus? Which gland produces the largest fraction of semen volume? Which gland is located at the junction of the ejaculatory duct and urethra?



12. What is semen?

13. PREDICT Arthur, age 68, has trouble urinating. What is his most probable condition?

For answers, see Answers Appendix.

PART 2 PHYSIOLOGY OF THE MALE REPRODUCTIVE SYSTEM

27.6 The male sexual response includes erection and ejaculation

Learning Outcome

▶ **Describe the phases of the male sexual response.**

Although there is more to it, the chief phases of the male sexual response are:

1. *Erection* of the penis, which allows it to penetrate the female vagina
2. *Ejaculation*, which expels semen into the vagina

These events are an example of cooperation between the two branches of the autonomic nervous system (◀ p. 545).

- Erection is under parasympathetic control.
- Ejaculation is under sympathetic control.

Erection

Erection, enlargement and stiffening of the penis, results from engorgement of the erectile bodies with blood. When a man is not sexually aroused, arterioles supplying the erectile tissue are constricted and the penis is flaccid. However, sexual excitement triggers a parasympathetic reflex that promotes release of nitric oxide (NO) (◀ pp. 423–424) locally. NO relaxes smooth muscle in the penile blood vessel walls, dilating these arterioles,* and the erectile bodies fill with blood. Expansion of the corpora cavernosa of the penis compresses their drainage veins, retarding blood outflow and maintaining engorgement. The corpus spongiosum expands as well, but not nearly as much as the cavernosa. Its main job is to keep the urethra open during ejaculation. Parasympathetic input also stimulates secretion from the bulbourethral glands.

Various sexual stimuli can initiate erection—tactile stimulation, and erotic sights, sounds, and smells. The CNS responds by activating parasympathetic neurons that innervate the internal pudendal arteries serving the penis. Sometimes erection is induced solely by emotional or higher mental activity (the thought of a sexual encounter). Emotions and thoughts can also inhibit erection, causing vasoconstriction and returning the penis to its flaccid state.

Ejaculation

Ejaculation (*ejac* = to shoot forth) is the propulsion of semen from the male duct system. When impulses provoking erection reach a critical level, a spinal reflex is initiated, and a massive discharge of nerve impulses occurs over the sympathetic nerves serving the genital organs (largely at the level of L_1 and L_2). As a result:

1. The ductus deferens, prostate, and seminal glands contract, emptying their contents into the prostatic urethra. At the same time, the bladder internal sphincter muscle constricts, preventing expulsion of urine or reflux of semen into the bladder.
2. Semen in the urethra triggers a spinal reflex through somatic motor neurons. The bulbospongiosus muscles of the penis undergo a rapid series of contractions, propelling semen from the urethra at a speed of about 500 cm/s (11 mi/h). These rhythmic contractions are accompanied by intense pleasure (**orgasm**, or **climax**) and many systemic changes, such as generalized muscle contraction, rapid heartbeat, and elevated blood pressure.

Ejaculation is quickly followed by **resolution**, a period of muscular and psychological relaxation. Activity of sympathetic nerve fibers constricts the *internal pudendal arteries* (and penile arterioles), reducing blood flow into the penis, and activates small muscles that squeeze the cavernous bodies, forcing blood from the penis into the general circulation. Although the erection may persist a little longer, the penis soon becomes flaccid again. After ejaculation, there is a *latent*, or *refractory, period* that ranges from minutes to hours, during which a man is unable to achieve another orgasm. The latent period lengthens with age.

*Erection of the penis is one of the rare examples of parasympathetic control of arterioles.

HOMEOSTATIC IMBALANCE 27.3 — CLINICAL

Approximately 50% of American men over age 40 have some degree of **erectile dysfunction (ED)**, the inability to attain an erection. Temporary ED can be caused by psychological factors, alcohol, or certain drugs (antihypertensives, antidepressants, and others). Chronic ED is largely the result of problems with blood vessels (atherosclerosis, varicose veins) or the nervous system (stroke, penile nerve damage, multiple sclerosis). Diabetes mellitus, which damages both blood vessels and nerves, is often an underlying cause.

As we've just described, attaining erection depends on parasympathetic stimulation triggering NO release. Sildenafil (Viagra®) and similar drugs enhance the effect of existing NO. Taken orally, these drugs can enhance blood flow to the penis, allowing erection to occur.

Check Your Understanding

14. What is erection and which division of the ANS regulates it?
15. What occurs during resolution and what brings it about?

For answers, see Answers Appendix.

27.7 Spermatogenesis is the sequence of events that leads to formation of sperm

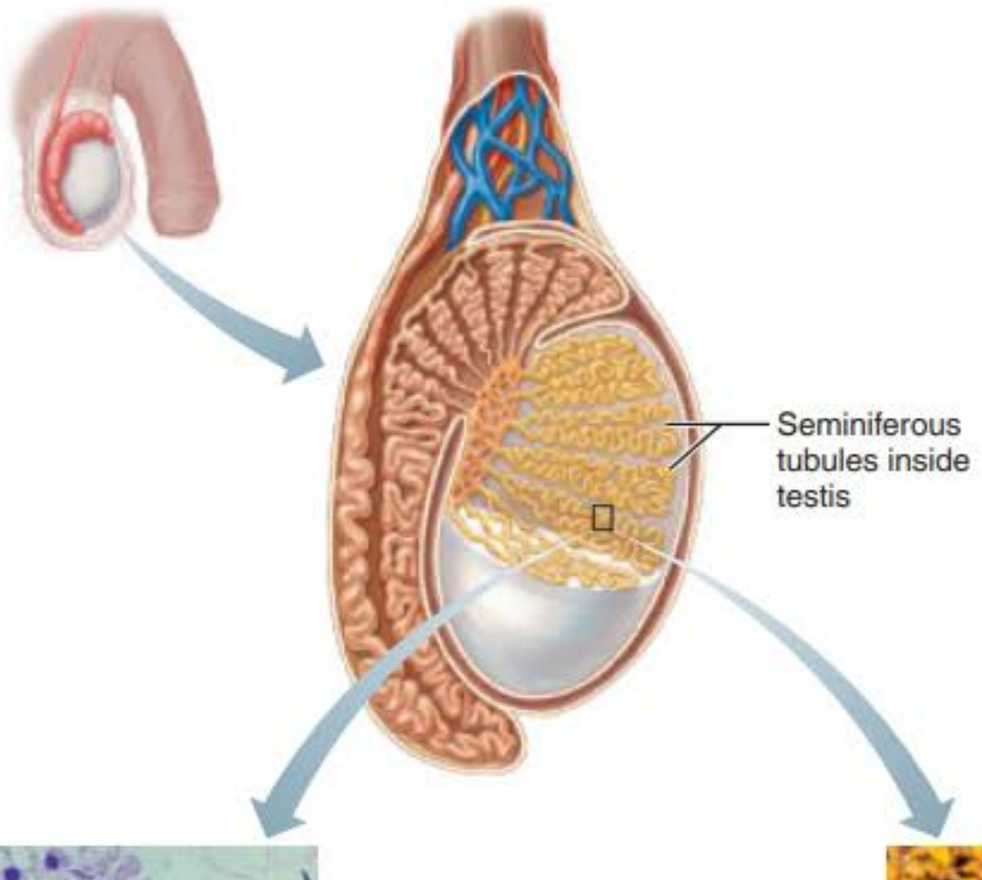
Learning Outcomes

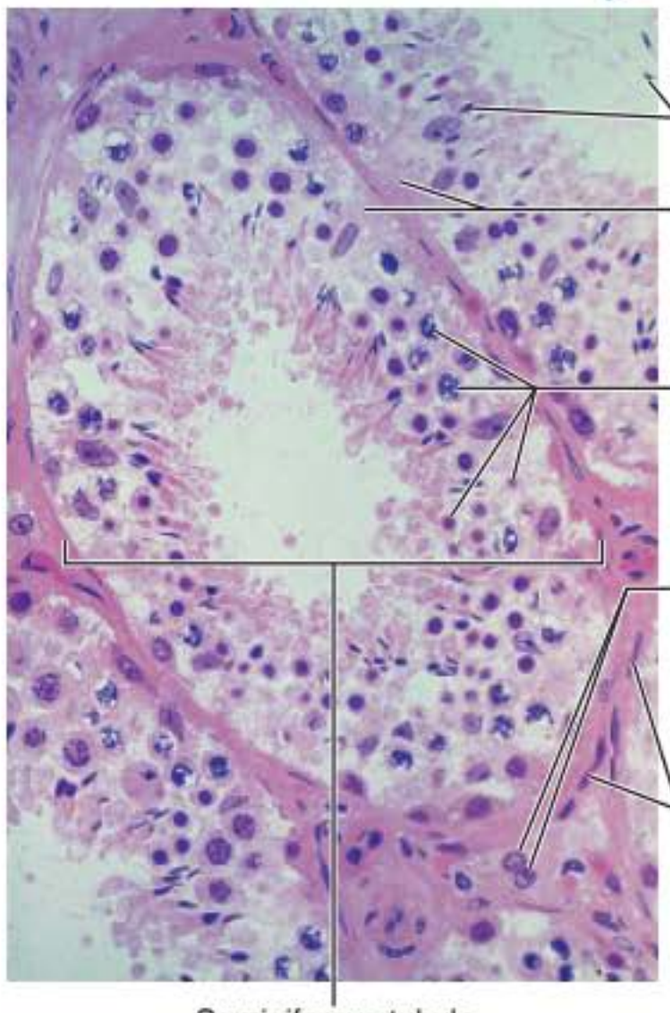
- **Describe the histology of the seminiferous tubules of the testes and the roles of sustentocytes.**
- **Outline the events of spermatogenesis.**

Spermatogenesis (sper″mah-to-jen′ĕ-sis; "sperm formation") is the process of forming male gametes. It occurs in the seminiferous tubules of the testes and is the hallmark of sexual maturity. Spermatogenesis begins at puberty, around the age of 14 years, and continues throughout life. Every day, a healthy adult male makes about 90 million sperm. It seems that nature has made sure that the human species will not be endangered for lack of sperm!

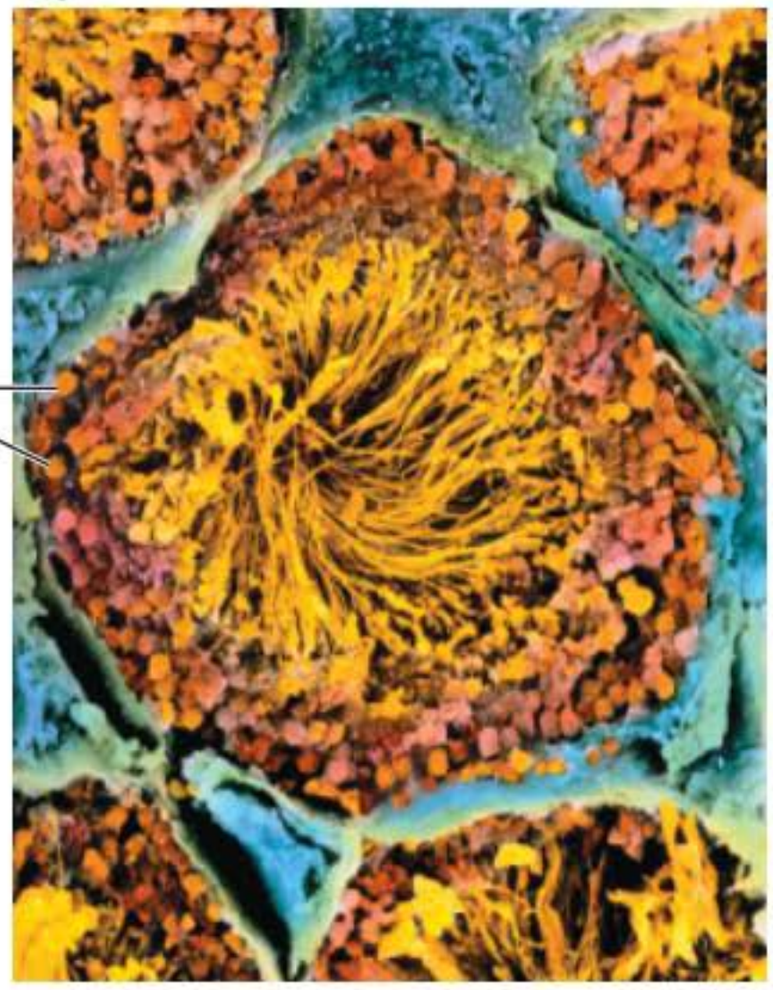
Histology of the Seminiferous Tubules

Recall from p. 1048 that the seminiferous tubules are the "sperm factories" of the testes. Each seminiferous tubule consists of a thick stratified epithelium surrounding a central fluid-containing lumen (**Figure 27.10**). A cross section through a tubule reveals four important types of cells:





(a)

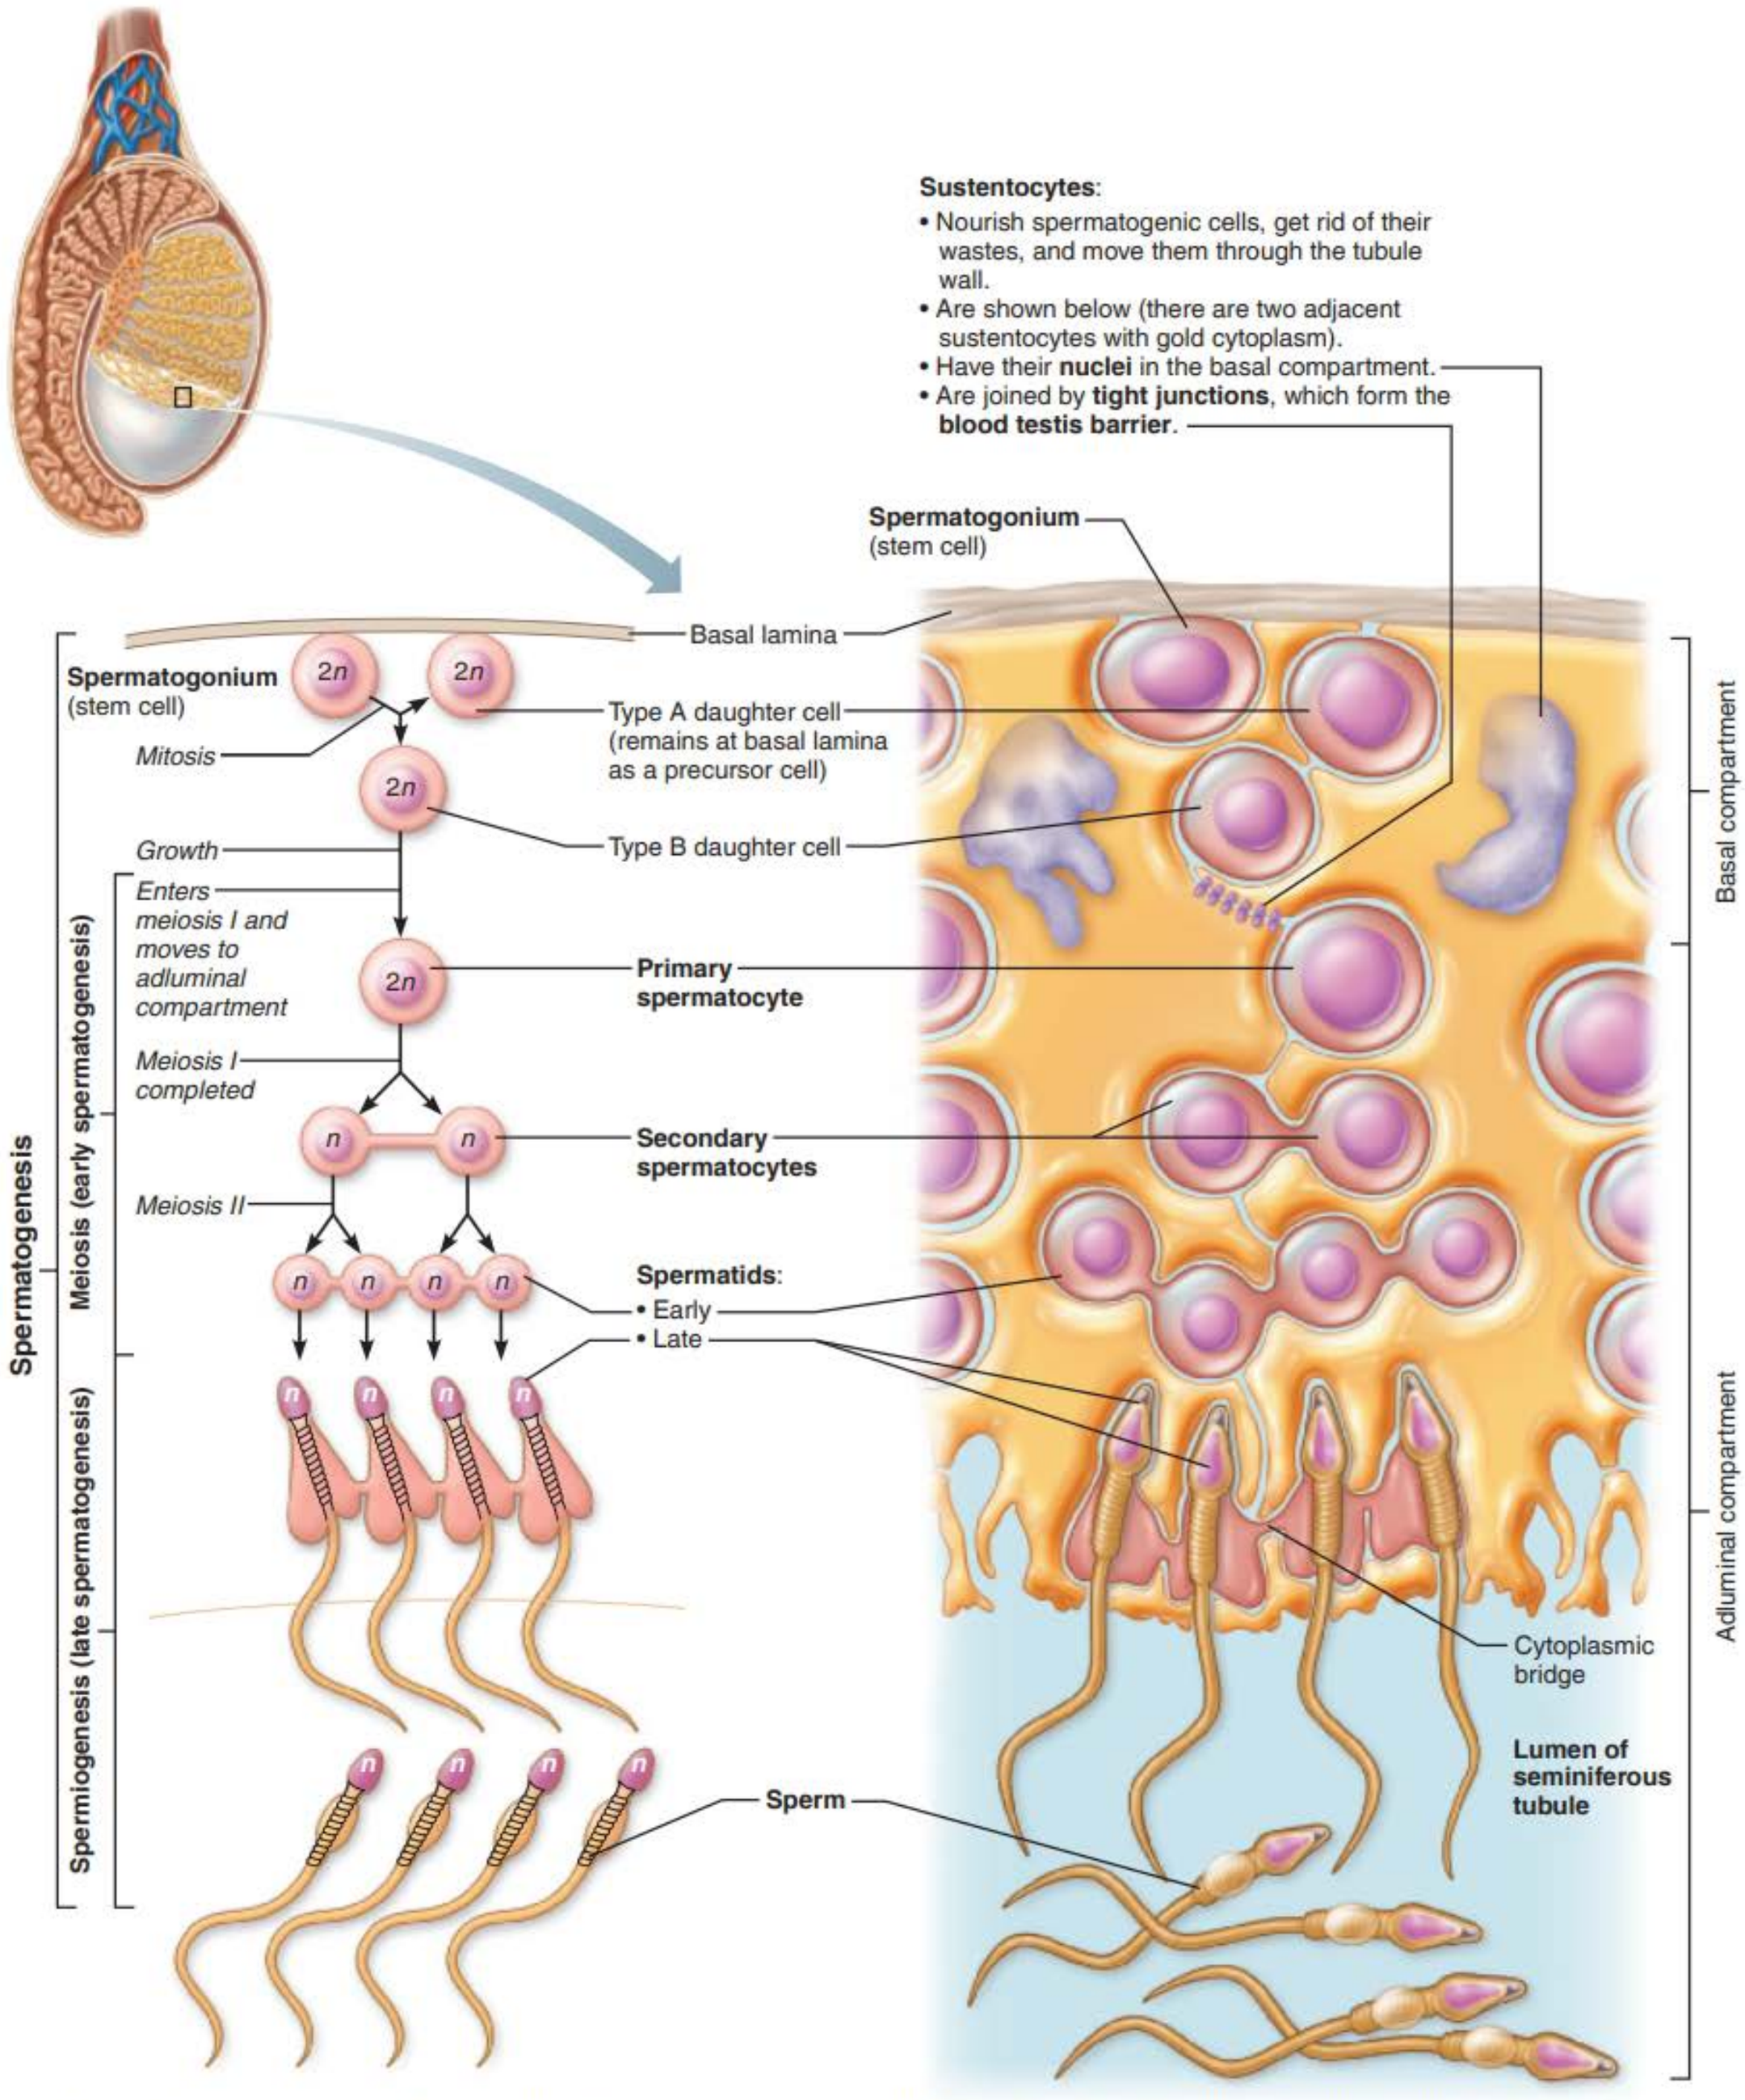


(b)

Figure 27.10 Histology of the seminiferous tubule. Cross sections. **(a)** Photomicrograph (270×). **(b)** Scanning electron micrograph (215×).

Practice Histology questions: MasteringA&P® Study Area > Lab Tools > PAL

- **Sustentocytes** are large, columnar cells. They act as supporting cells and play several roles in sperm formation, as described shortly.
- **Spermatogenic cells** (*spermatogenic* = sperm forming) are cells that give rise to sperm. They are found enveloped by the sustentocytes and can be seen at many different stages of cell division. We will describe them shortly as well.
- **Myoid cells** are smooth muscle–like cells that surround each seminiferous tubule in three to five layers. By contracting rhythmically, myoid cells may help to squeeze sperm and testicular fluids through the tubules and out of the testes.
- **Interstitial endocrine cells**, also called *Leydig cells*, lie in the soft connective tissue surrounding the seminiferous tubules. These cells produce androgens (most importantly *testosterone*) and small amounts of estrogens, which they secrete into the surrounding interstitial fluid. Notice that completely different cell populations carry out the sperm-producing and hormone-producing functions of the testis.



(a) Events of spermatogenesis, showing the relative position of various spermatogenic cells

(b) A portion of the seminiferous tubule wall, showing the spermatogenic cells surrounded by sustentocytes

Figure 27.11 Spermatogenesis.

Spermatogenesis: Summary of Events in the Seminiferous Tubules

Spermatogenic cells give rise to sperm via the series of divisions and cellular transformations described next (**Figure 27.11**).

Mitosis of Spermatogonia: Forming Spermatocytes

The outermost tubule cells, which are in direct contact with the epithelial basal lamina, are stem cells called **spermatogonia** (sper″mah-to-go′ne-ah; "sperm seed"). The spermatogonia divide more or less continuously by *mitosis* and, until puberty, all their daughter cells become spermatogonia.

Spermatogenesis begins during puberty, and from then on, each mitotic division of a spermatogonium results in two distinctive daughter cells:

- The **type A daughter cell** remains at the basal lamina to maintain the pool of dividing germ cells.
- The **type B daughter cell** gets pushed toward the lumen, where it becomes a **primary spermatocyte** destined to produce four sperm.

(To keep these cell types straight, remember that just as the letter A is always at the beginning of our alphabet, a type A cell is always at the tubule basal lamina ready to begin a new generation of gametes.)

Meiosis: Spermatocytes to Spermatids

Each primary spermatocyte undergoes meiosis I, forming two smaller haploid cells called **secondary spermatocytes** (Figure 27.11). The secondary spermatocytes continue on rapidly into meiosis II. Their daughter cells, called **spermatids** (sper′mah-tidz), are small round cells, with large spherical nuclei, seen closer to the lumen of the tubule. Midway through spermatogenesis, the developing sperm "turn off" nearly all their genes and compact their DNA into dense pellets.

Spermiogenesis: Spermatids to Sperm

Each spermatid has the correct chromosomal number for fertilization (n), but is nonmotile. It still must undergo a streamlining process called **spermiogenesis**, during which it elongates, sheds its excess cytoplasmic baggage, and forms a tail. Follow the details of this process in **Figure 27.12a** ①–⑦.

Each resulting **sperm** has a head, midpiece, and tail, which correspond roughly to *genetic*, *metabolic*, and *locomotor regions*,

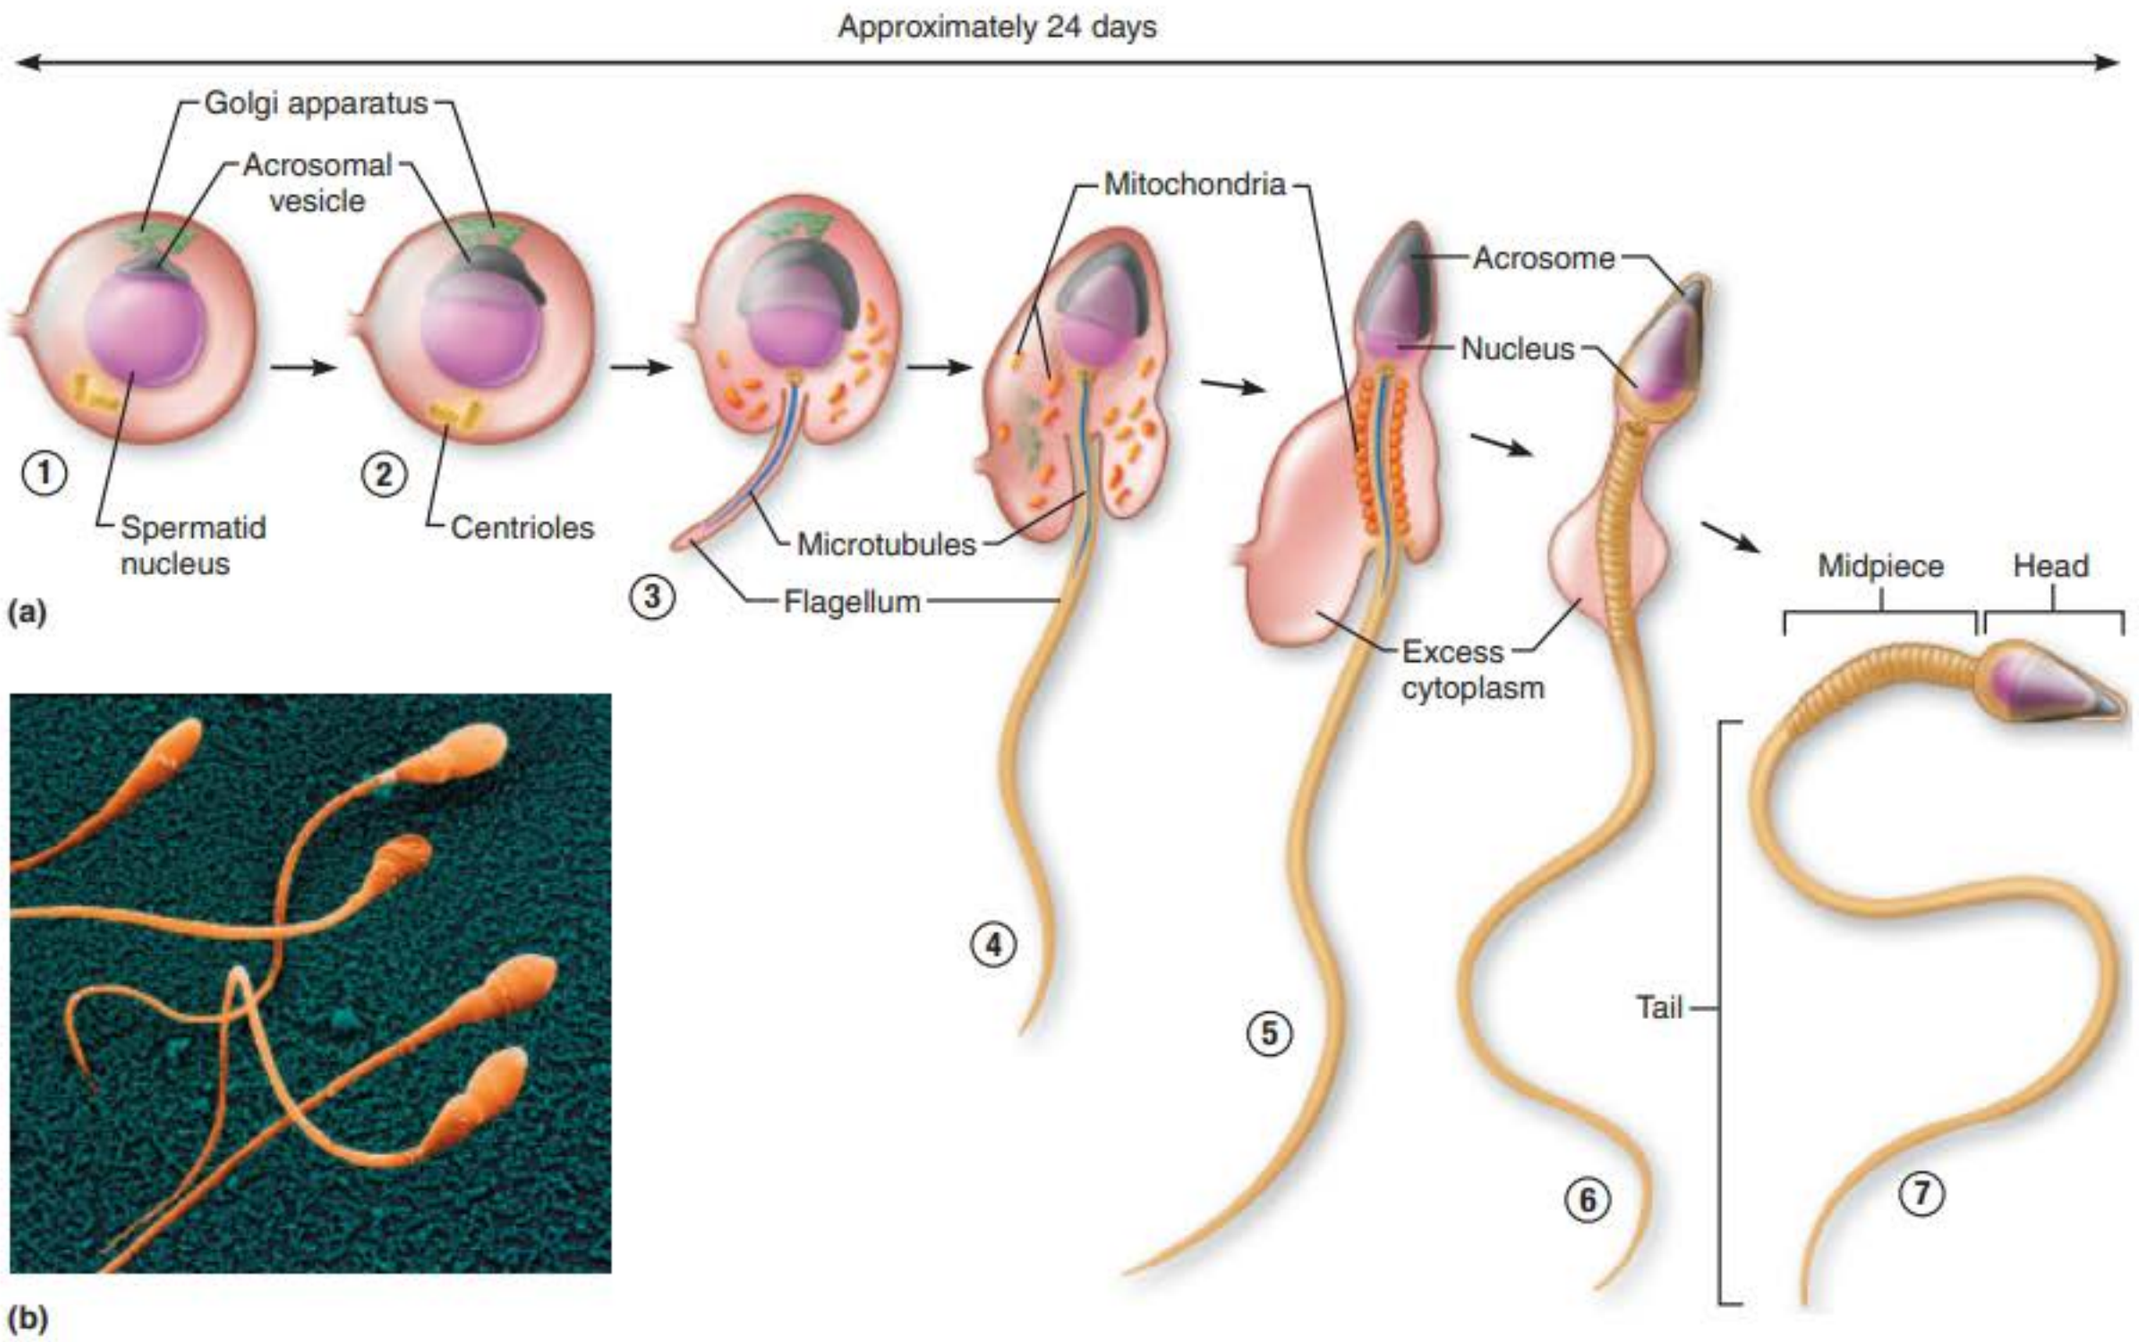


Figure 27.12 Spermiogenesis: transformation of a spermatid into a functional sperm. (a) During the process of spermiogenesis: ① The Golgi apparatus packages the acrosomal enzymes, ② the acrosome forms at the anterior end of the nucleus and the centrioles gather at the opposite end, ③ microtubules form the flagellum, ④ mitochondria multiply and cluster around the proximal portion of the flagellum, and ⑤ excess cytoplasm sloughs off. ⑥ An immature sperm that has just been released from a sustentocyte. ⑦ Structure of a fully mature sperm. **(b)** Scanning electron micrograph of mature sperm (1400×).

respectively (Figure 27.12a ⑦). Sperm "pack" lightly—they only carry what they absolutely need.

The **head** of a sperm consists almost entirely of its flattened nucleus, which contains the compacted DNA. A helmetlike **acrosome** (ak′ro-sōm; "tip piece") adheres to the top of the nucleus (Figure 27.12a ⑤ and ⑥). Like a lysosome, the acrosome contains hydrolytic enzymes that, in this case, enable the sperm to penetrate and enter an egg.

The sperm **midpiece** contains mitochondria spiraled tightly around the microtubules of the tail. The long **tail** is a typical flagellum (◀ p. 90). The mitochondria provide the metabolic energy (ATP) needed for the whiplike movements of the tail that will propel the sperm along its way in the female reproductive tract.

Spermatogenesis—from formation of a primary spermatocyte to release of immature sperm into the lumen—takes 64 to 72 days. Sperm in the lumen are unable to "swim" and are incapable of fertilizing an egg. The pressure of the testicular fluid pushes them through the tubular system of the testes into the epididymis, where they gain increased motility and fertilizing power.

Role of the Sustentocytes

Throughout spermatogenesis, descendants of the same spermatogonium remain closely attached to one another by cytoplasmic bridges (see Figure 27.11). They are also surrounded by and connected to nonreplicating supporting cells called **sustentocytes** (or *Sertoli cells*) that extend from the basal lamina to the tubule lumen.

The sustentocytes are bound to each other laterally by tight junctions (◀ p. 67). In this way, they divide the seminiferous tubule into two compartments:

- The **basal compartment** extends from the basal lamina to the tight junctions and contains spermatogonia and the earliest primary spermatocytes.
- The **adluminal compartment** lies internal to the tight junctions and includes the meiotically active cells and the tubule lumen (see Figure 27.11b).

The tight junctions between the sustentocytes form the **blood testis barrier**. This barrier prevents the membrane antigens of differentiating sperm from escaping through the basal lamina into the bloodstream where they could activate the immune system. (This activation could occur because sperm are not formed until puberty, well after the immune system has been programmed to recognize a person's own tissues.) The spermatogonia, which are recognized as "self," are outside the barrier and for this reason can be influenced by bloodborne chemical messengers that prompt spermatogenesis. Following mitosis of the spermatogonia, the tight junctions of the sustentocytes open to allow type B daughter cells to pass into the adluminal compartment—much as the air locks between spacecraft allow an astronaut to pass.

In addition to forming the blood testis barrier, sustentocytes:

- Provide nutrients and essential signals to the dividing cells, even telling them to live or die.
- Move spermatocytes and spermatids along to the lumen.
- Secrete **testicular fluid** (rich in androgens and metabolic acids) that provides the transport medium for sperm in the lumen.
- Phagocytize faulty spermatogenic cells and excess cytoplasm sloughed off as the spermatids transform into sperm.
- Produce two proteins that help regulate spermatogenesis. **Androgen-binding protein (ABP)** keeps the concentration of testosterone near the spermatogenic cells high, which stimulates spermatogenesis. The hormone *inhibin* (◀ p. 1043) inhibits FSH release from the anterior pituitary, and so inhibits spermatogenesis. Levels of inhibin are proportional to sperm counts in males—the higher the sperm count, the higher the level of inhibin.

HOMEOSTATIC IMBALANCE 27.4 CLINICAL

Roughly one in seven American couples seek treatment for *infertility*, often because of problems with sperm quality or quantity. According to some studies, a gradual decline in male fertility has been occurring in the past 50 years.

Some believe the main culprit is foreign molecules that have invaded our lives in a variety of forms—environmental toxins, phthalates (oily solvents that make plastics flexible), pesticides, and herbicides, all of which can have estrogenic effects. These estrogen-like compounds, which block the action of male sex hormones as they program sexual development, are now found in our food supply as well as in the air.

Common antibiotics such as tetracycline may suppress sperm formation, and radiation, lead, marijuana, and excessive alcohol can cause abnormal (two-headed, multiple-tailed, etc.) sperm to be produced. Male infertility may also be caused by defects in specific Ca^{2+} channels, hormonal imbalances, and oxidative stress (which fragments sperm DNA). Thermal-related events that inhibit sperm maturation include fever and overusing hot tubs.

Check Your Understanding

16. Describe the major structural and functional regions of a sperm.
17. What is the role of sustentocytes? Of interstitial endocrine cells?
18. MAKE CONNECTIONS Caleb and Sarah have been unable to conceive. An analysis of Caleb's semen reveals that his sperm are nonmotile (cannot propel themselves). Further investigation uncovers a defect in the motor protein dynein (◀ p. 90). In addition to infertility, what problems might Caleb have?

For answers, see Answers Appendix.

27.8 Male reproductive function is regulated by hypothalamic, anterior pituitary, and testicular hormones

Learning Outcome

- **Discuss hormonal regulation of testicular function and the physiological effects of testosterone on male reproductive anatomy.**

As we discussed previously (◀ p. 1042), hormonal interactions along the HPG axis regulate the production of gametes and sex hormones. You are now ready to delve into the details of the regulatory axis in males, shown schematically in **Figure 27.13**. Study this figure before you go on.

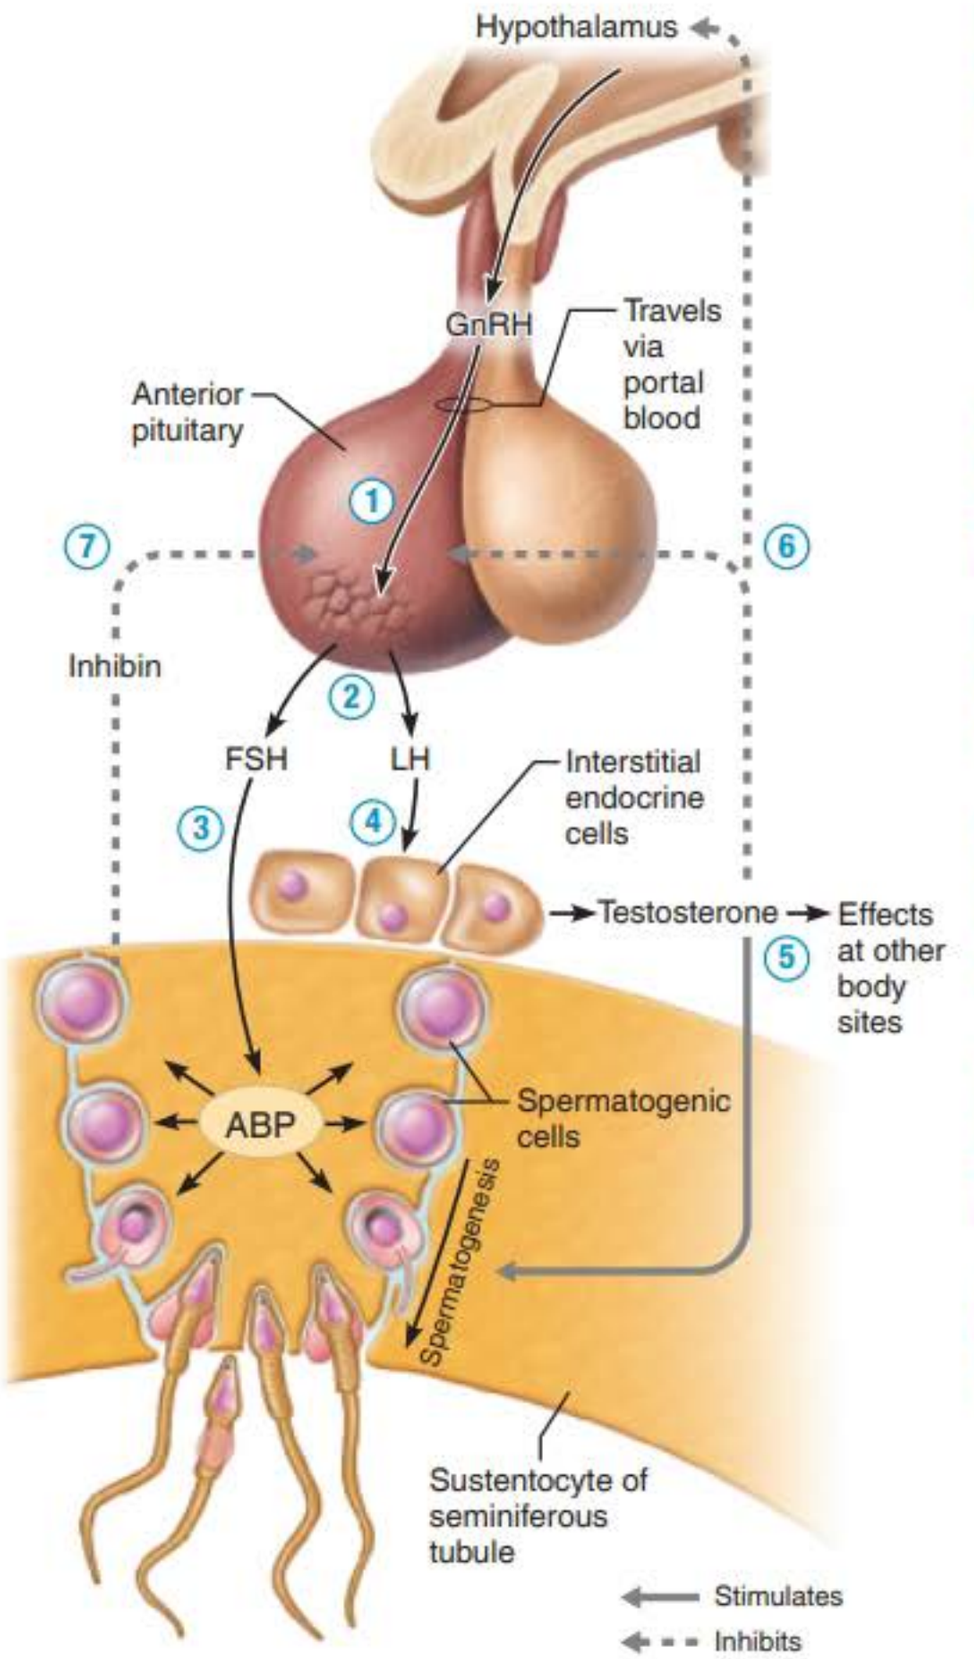

Figure 27.13 Hormonal regulation of testicular function by the hypothalamic-pituitary-gonadal (HPG) axis. GnRH = gonadotropin-releasing hormone; FSH = follicle-stimulating hormone; LH = luteinizing hormone; ABP = androgen-binding protein.

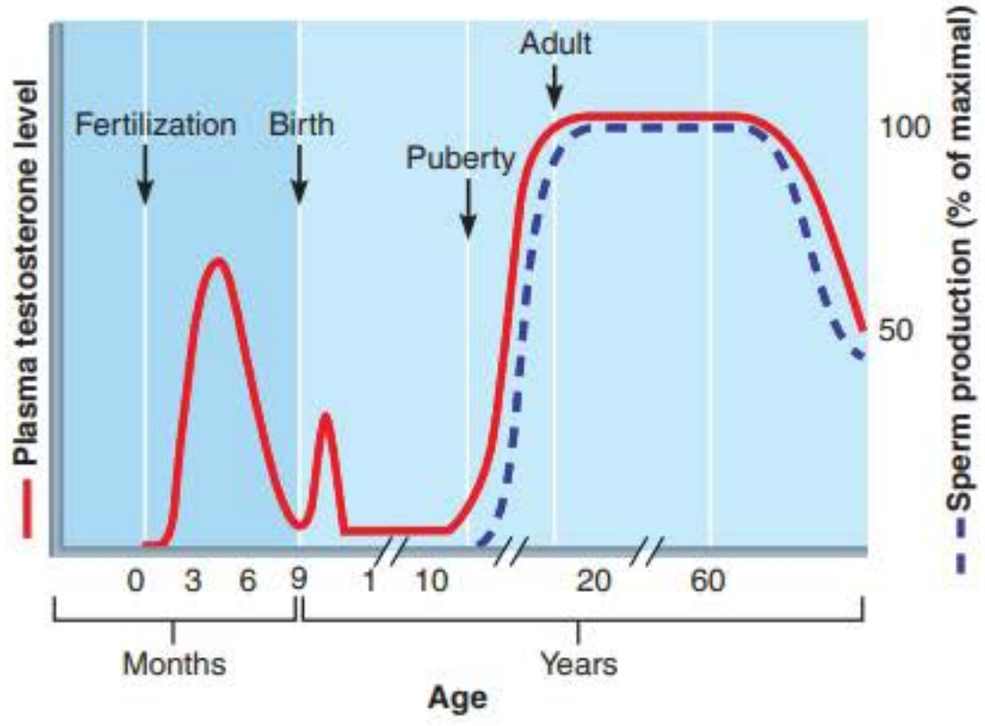

Figure 27.14 Plasma testosterone and sperm production levels versus age in males.

Because input from other brain areas also influences the hypothalamus, the whole HPG axis is under CNS control. In the absence of GnRH and gonadotropins, the testes atrophy, and sperm and testosterone production cease.

Development of male reproductive structures depends on prenatal secretion of male hormones, and for a few months before birth, a male infant has plasma gonadotropin and testosterone levels nearly two-thirds those of an adult male (**Figure 27.14**). After a brief rise in early infancy, blood levels of these hormones recede and they remain low throughout childhood. As puberty nears, higher levels of testosterone are required to suppress hypothalamic release of GnRH and the adult pattern of hormone interaction is established as we described on p. 1043.

The amount of testosterone and semen produced by the adult testes reflects a balance among the interacting hormones of the HPG axis. Once this balance is established during puberty (a process that takes about three years), the amount of testosterone and sperm produced remains fairly stable until late in life.

Mechanism and Effects of Testosterone Activity

Like all steroid hormones, testosterone is synthesized from cholesterol (◀ pp. 47–48, 603). It exerts its effects by activating specific genes, which results in enhanced synthesis of certain proteins in the target cells. (See Chapter 16, ◀ p. 606, for mechanisms of steroid hormone action.)

In some target cells, testosterone must be transformed into another steroid to exert its effects. In the prostate, testosterone is converted to *dihydrotestosterone* (*DHT*) before it can bind in the cell nucleus. In certain parts of the body (e.g., brain, bone, fat), testosterone is converted to *estradiol* (es″trah-di′ol), a female sex hormone, to bring about its effects.

As puberty ensues, testosterone not only prompts spermatogenesis but also has multiple anabolic effects throughout the body (see Table 27.2, p. 1079). It targets accessory reproductive organs—ducts, glands, and the penis—causing them to grow to adult size and function. In adult males, normal plasma levels of testosterone maintain these organs. When the hormone is deficient or absent, all accessory organs atrophy, semen volume declines, and erection and ejaculation are impaired. Testosterone replacement therapy can remedy this situation.

Male secondary sex characteristics—that is, features induced in *nonreproductive* organs by the male sex hormones (mainly testosterone)—develop at puberty. These include:

- The appearance of pubic, axillary, and facial hair
- Enhanced hair growth on the chest or other body areas in some men
- Larynx enlargement, which causes deepening of the voice
- Thicker and oilier skin (which predisposes young men to acne)
- Increased size and density of bones
- Increased size and mass of skeletal muscles

The last two effects are often referred to as the *somatic effects* of testosterone (*soma* = body). Testosterone also boosts basal metabolic rate and influences behavior. It is the basis of the male libido (sex drive).

The testes are not the only source of androgens. The adrenal glands of both sexes also release them as gonadocorticoids (◀ p. 626). However, the relatively small amounts of adrenal androgens are insufficient to support normal testosterone-mediated functions.

Check Your Understanding

19. How does FSH indirectly stimulate spermatogenesis?
20. What are three secondary sex characteristics promoted by testosterone?
21. WHAT IF? Suppose the interstitial endocrine cells became dysregulated and secreted large amounts of testosterone. What would happen to blood levels of GnRH, FSH, and LH? Explain.

For answers, see Answers Appendix.

PART 3

27

ANATOMY OF THE FEMALE REPRODUCTIVE SYSTEM

The reproductive role of the female is far more complex than that of a male. Not only must she produce gametes, but her body must prepare to nurture a developing fetus for approximately nine months. **Ovaries**, the *female gonads*, produce female gametes (ova) and the sex hormones, **estrogens** and **progesterone** (pro-ges′tĕ-rōn). Estrogens include *estradiol*, *estrone*, and *estriol*, but estradiol is the most abundant and is most responsible for estrogenic effects in humans.

As illustrated in **Figure 27.15**, a female's **internal genitalia**—her ovaries and duct system—are mostly located in the pelvic cavity. The female's accessory ducts, from the vicinity of the ovary to the body exterior, are the *uterine tubes*, the *uterus*, and the *vagina*. They transport or otherwise serve the needs of the reproductive cells and a developing fetus. The external sex organs of females are referred to as **external genitalia**.

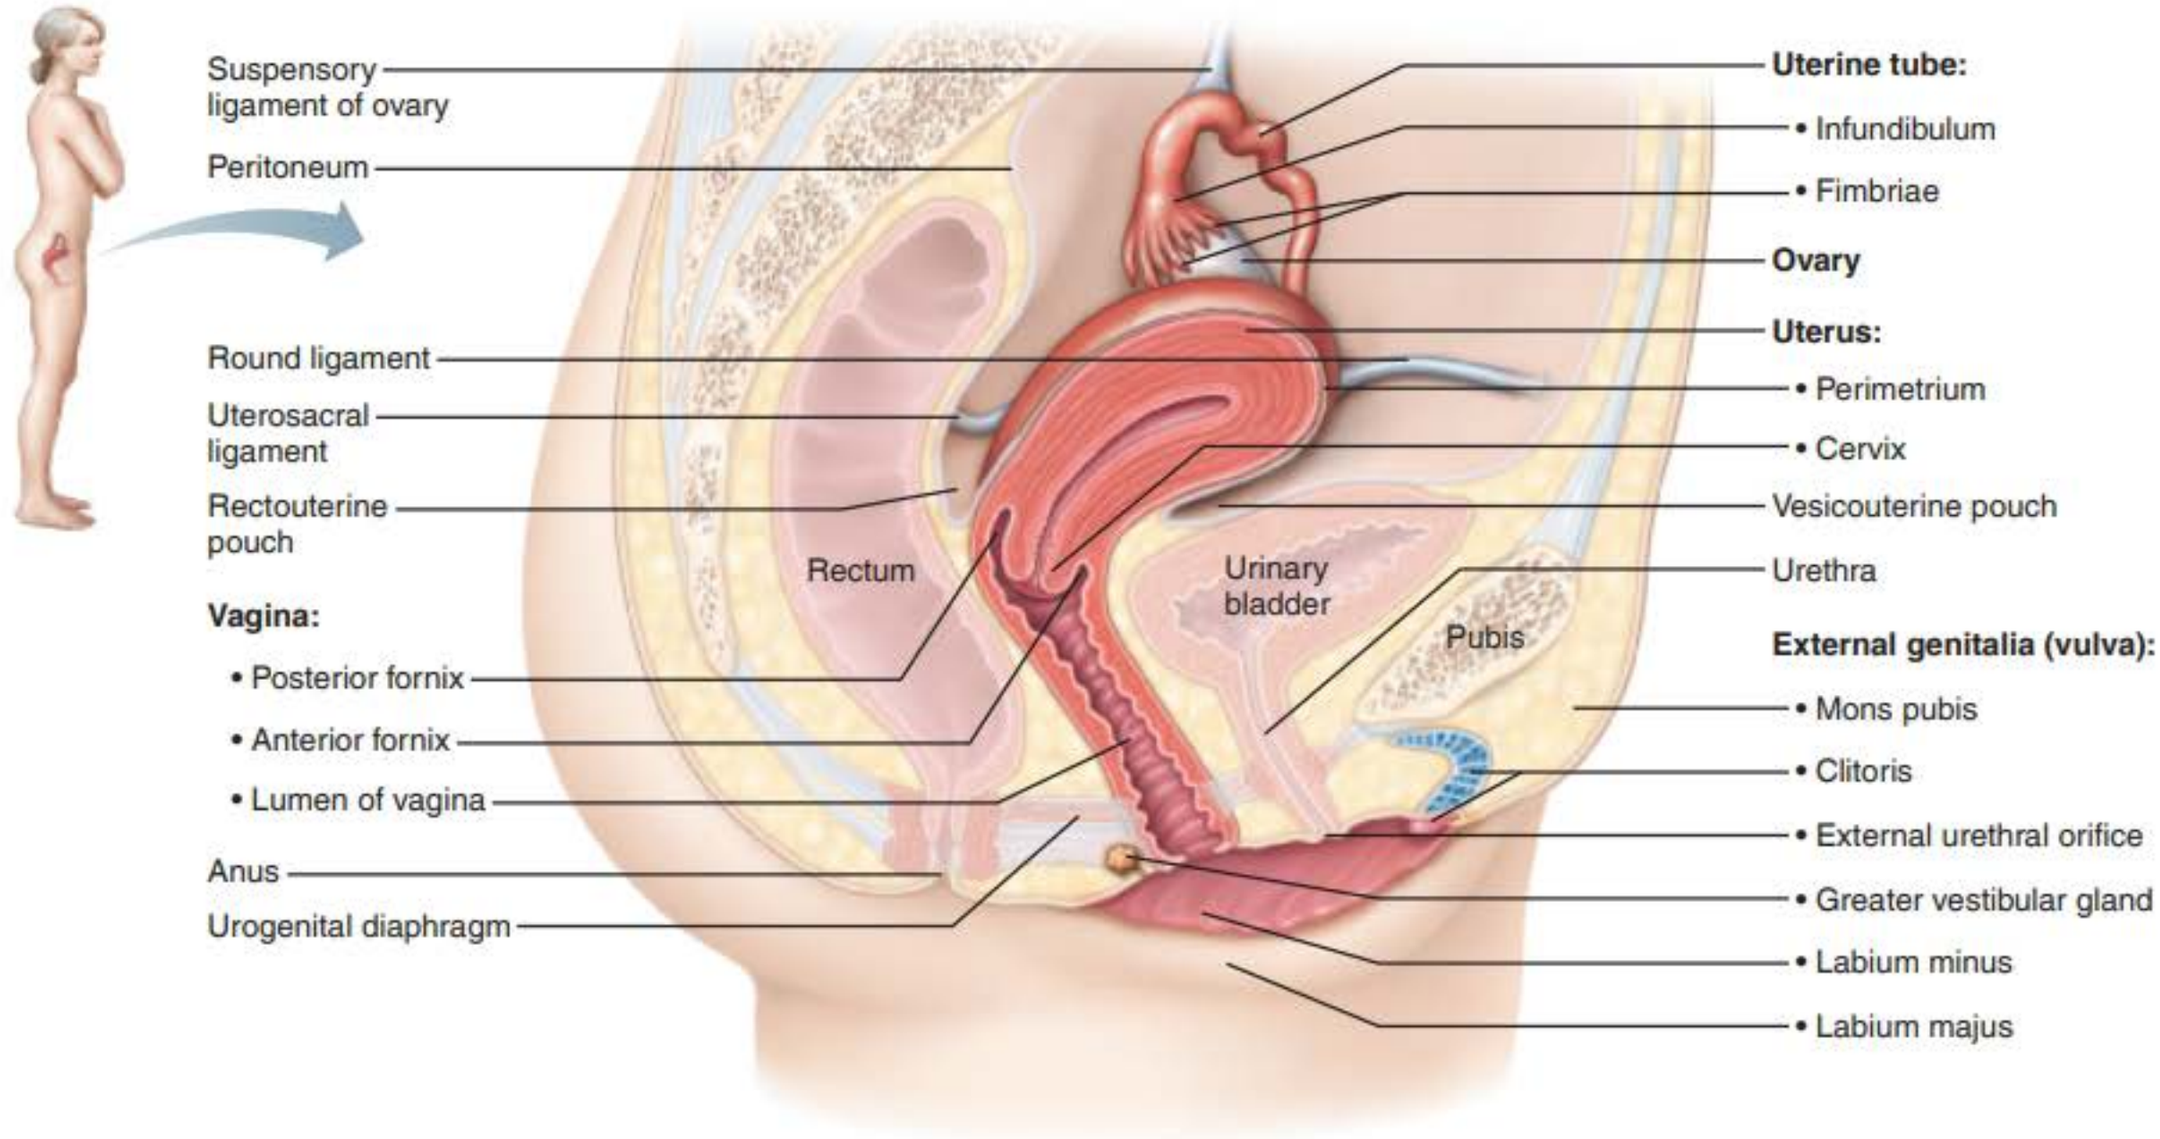

Figure 27.15 **Organs of the female reproductive system, midsagittal section.**

27.9 Immature eggs develop in follicles in the ovaries

Learning Outcome

- **Describe the location, structure, and function of the ovaries.**

The paired ovaries flank the uterus (**Figure 27.16**). Shaped like an almond and about twice as large, each ovary is held in place by several ligaments in the peritoneal cavity. The **ovarian ligament** anchors the ovary medially to the uterus; the **suspensory ligament** anchors it laterally to the pelvic wall; and the **mesovarium** (mez″o-va′re-um) suspends it in between (see Figures 27.15 and 27.17). The mesovarium is part of the **broad ligament**, a peritoneal fold that "tents" over the uterus and supports the uterine tubes, uterus, and vagina. The broad ligament encloses the ovarian ligaments.

The ovaries are served by the **ovarian arteries**, branches of the abdominal aorta (◀ Figure 19.26c, p. 746), and by the *ovarian branch of the uterine arteries*. The

Practice Histology questions: MasteringA&P® Study Area > Lab Tools > PAL

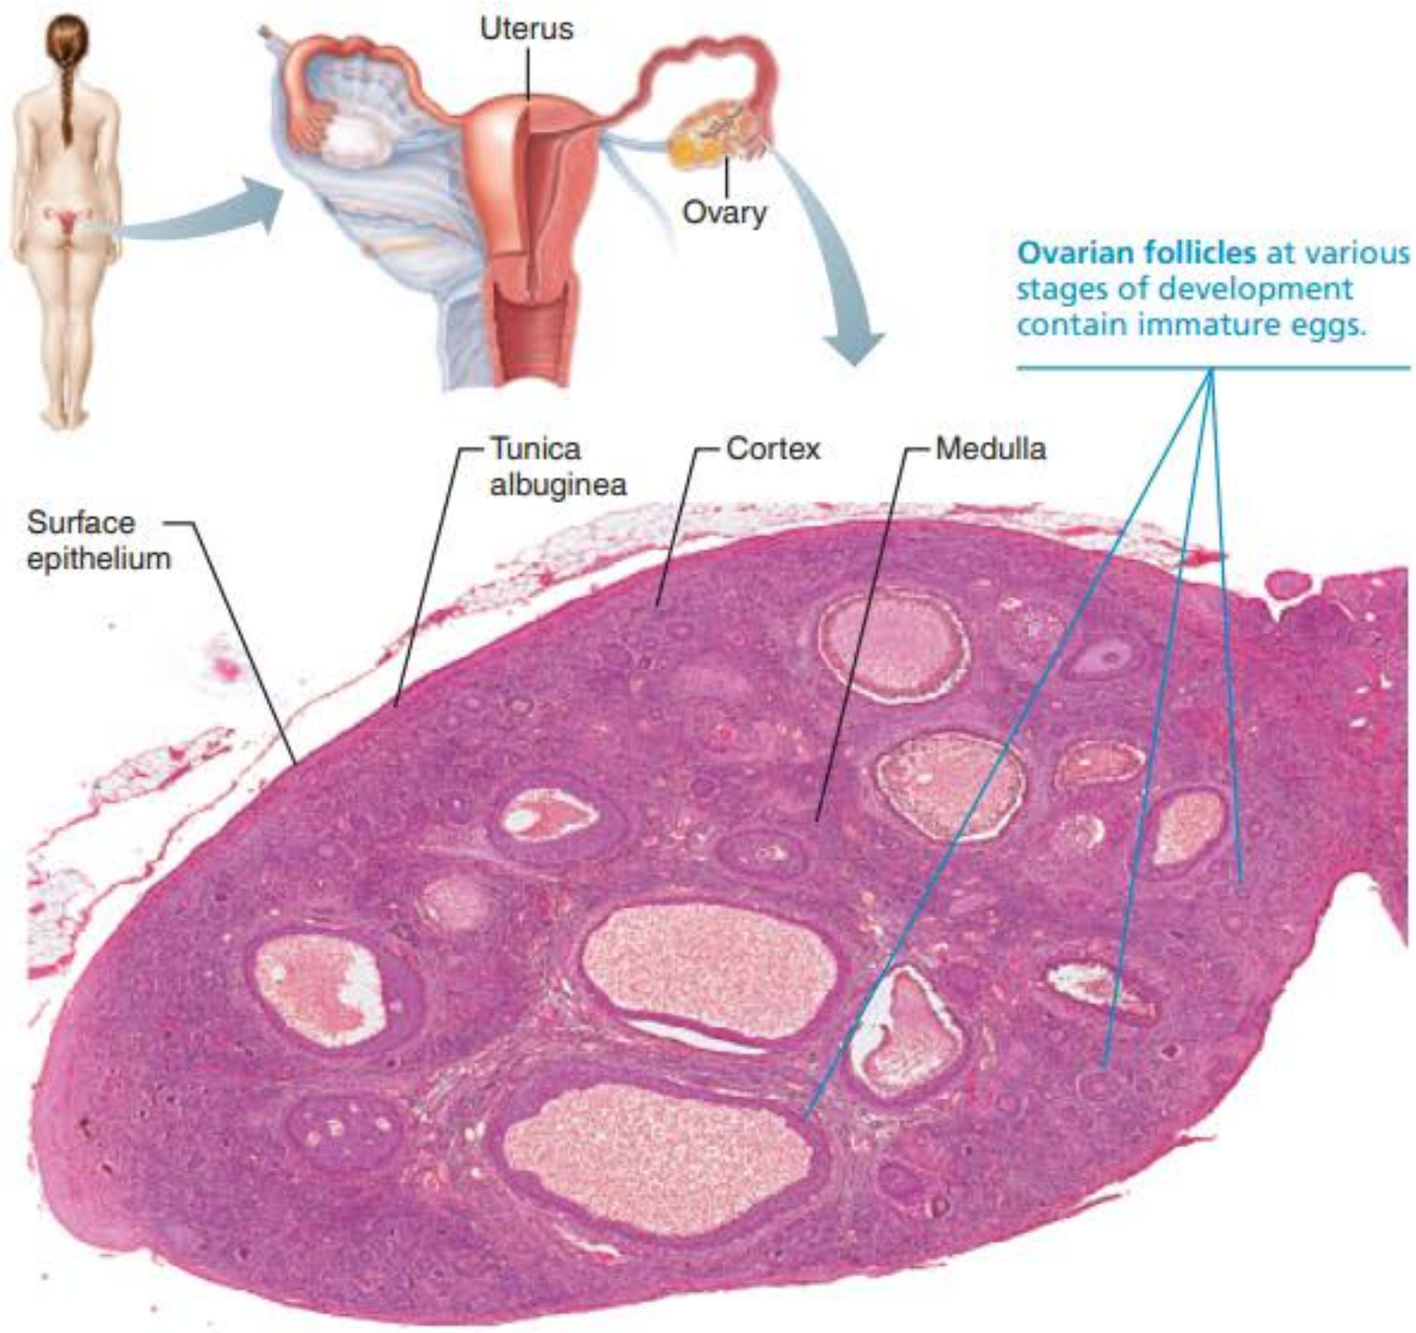

Figure 27.16 **Photomicrograph of a mammalian ovary.** (3×).

ovarian blood vessels reach the ovaries by traveling through the suspensory ligaments and mesovaria (**Figure 27.17a**).

Like each testis, each ovary is surrounded externally by a fibrous **tunica albuginea** (Figure 27.16). This, in turn, is covered externally by a layer of cuboidal epithelial cells called the surface epithelium (previously called the *germinal epithelium*) that is actually a continuation of the peritoneum. The ovary has an outer *cortex*, which houses the forming gametes, and an inner *medulla* containing the largest blood vessels and nerves.

Embedded in the highly vascular connective tissue of the ovary cortex are many tiny saclike structures called **ovarian follicles**. Each follicle consists of an immature egg, called an **oocyte** (o′o-sīt; *oo* = egg), encased by one or more layers of very different cells that we will describe later (pp. 1070, 1073).

As a rule, follicles of various sizes and stages of development can be seen in an ovary of a woman of child-bearing age (Figure 27.16). Each month, one of the ripening follicles ejects its oocyte from the ovary, an event called *ovulation* (see Figure 27.23 ⑤). In older women, the surfaces of the ovaries are scarred and pitted, revealing that many oocytes have been released.

Check Your Understanding

22. Briefly, what are the internal genitalia of a woman?
23. What are the two main things that the ovaries do?

For answers, see Answers Appendix.

27.10 The female duct system includes the uterine tubes, uterus, and vagina

Learning Outcome

- **Describe the location, structure, and function of each of the organs of the female reproductive duct system.**

Unlike the male duct system, which is continuous with the tubules of the testes, the female duct system has little or no actual contact with the ovaries. An ovulated oocyte is released into the peritoneal cavity, and some oocytes may be lost there.

The Uterine Tubes

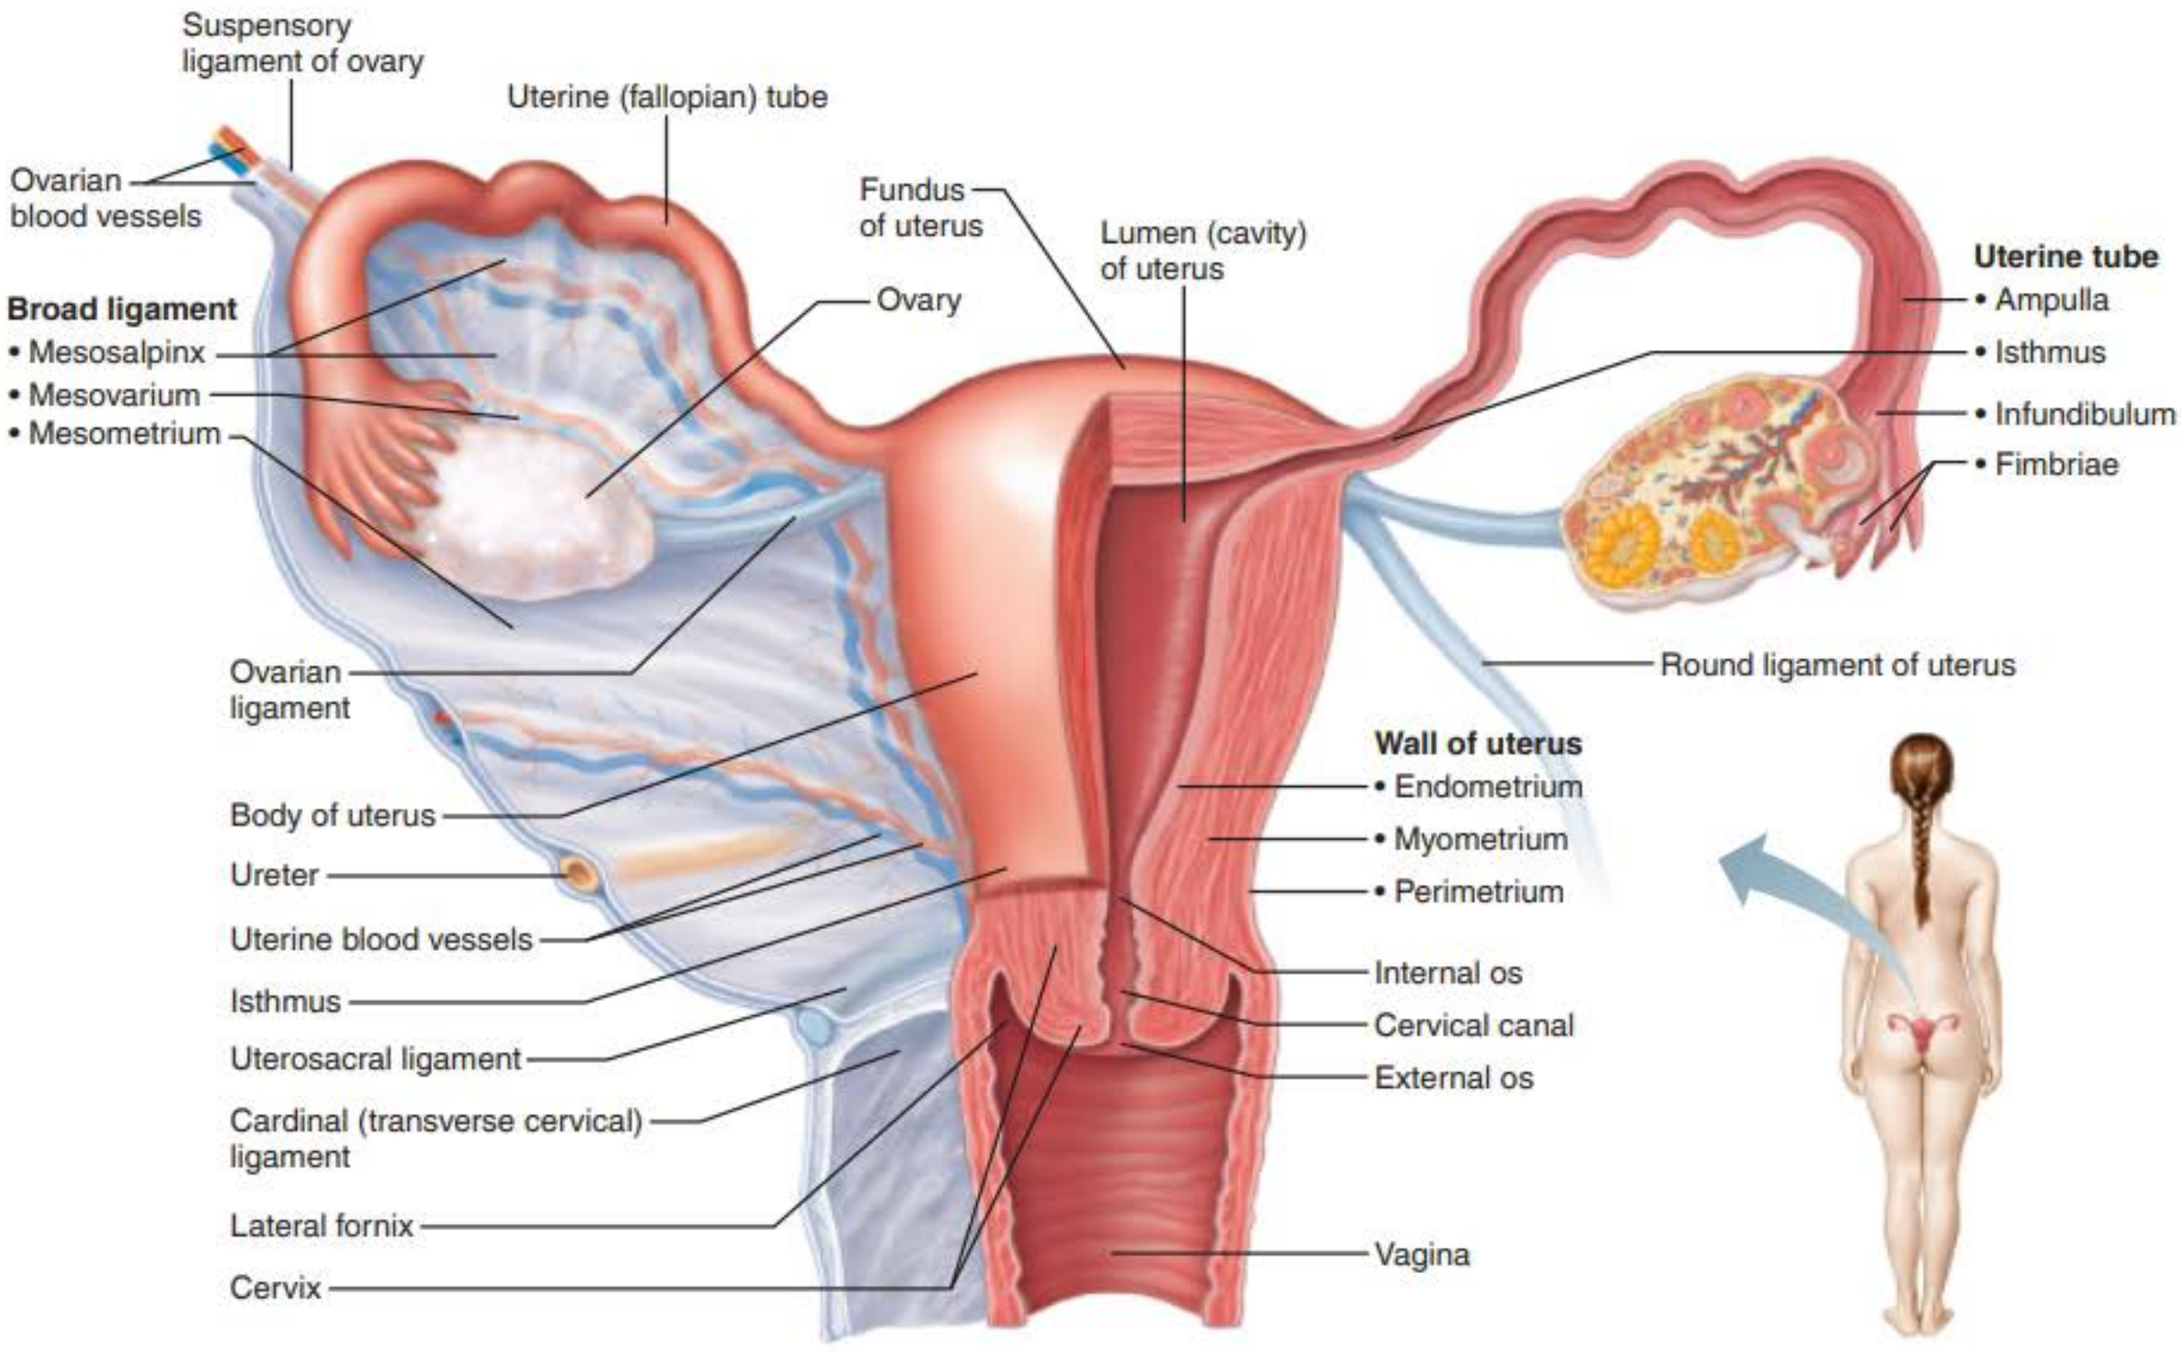
The **uterine tubes** (u′ter-in), also called *fallopian tubes* or *oviducts*, form the initial part of the female duct system (Figures 27.15 and 27.17). They receive the ovulated oocyte and are the site where fertilization generally occurs.

Each uterine tube begins laterally near an ovary and ends medially where it empties into the superior part of the uterus. It has three regions:

- Laterally, the **infundibulum** (in″fun-dib′u-lum), a funnel-shaped region, is the opening of the uterine tube into the peritoneal cavity. The margin of the infundibulum is surrounded by ciliated, fingerlike projections called *fimbriae* (fim′bre-e; "fringe") that drape over the ovary.
- Next to the infundibulum is the wide **ampulla**. It forms half of the length of the uterine tube, and is the site where fertilization usually occurs.
- The **isthmus** (is′mus) forms the narrow medial third of the uterine tube. It empties into the superolateral region of the uterus.

Around the time of ovulation, the uterine tube performs a complex "dance" to capture oocytes. It bends to drape over the ovary while the fimbriae stiffen and sweep the ovarian surface. The beating cilia on the fimbriae create currents in the peritoneal fluid that carry an oocyte into the uterine tube, where it begins its journey toward the uterus.

The uterine tube contains sheets of smooth muscle, and its thick, highly folded mucosa contains both ciliated and nonciliated cells. The oocyte is carried toward the uterus by a combination of muscular peristalsis and the beating cilia. Nonciliated cells of the mucosa



(a) Posterior view

Figure 27.17 Internal female reproductive organs. (a) The posterior walls of the vagina, uterus, and uterine tubes, and the broad ligament (a peritoneal fold) have been removed on the right side to reveal the shape of the lumen of these organs.

have dense microvilli and produce a secretion that keeps the oocyte (and sperm, if present) moist and nourished.

Externally, the uterine tubes are covered by peritoneum and supported along their length by a short mesentery (part of the broad ligament) called the **mesosalpinx** (mez″o-sal′pinks; "mesentery of the trumpet"; *salpin* = trumpet), a reference to the trumpet-shaped uterine tube it supports (Figure 27.17).

HOMEOSTATIC IMBALANCE 27.5 CLINICAL

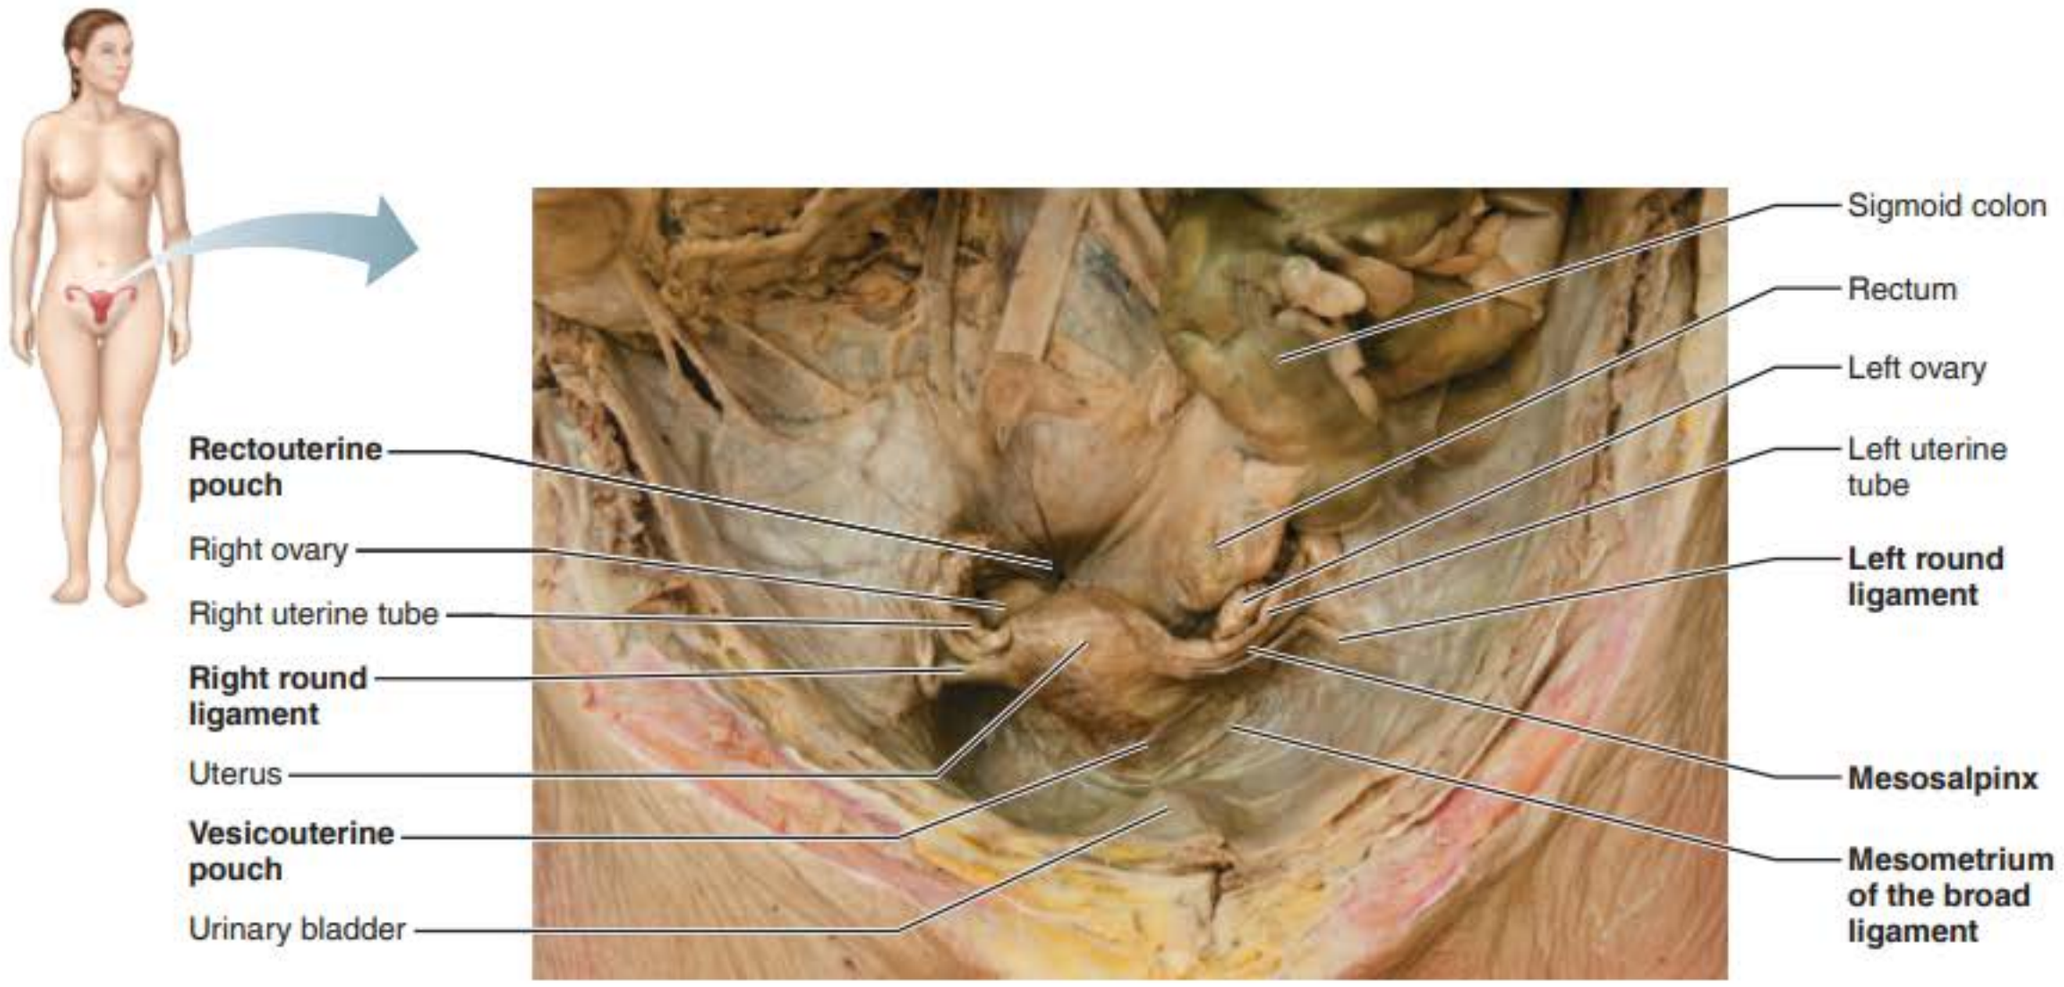
The fact that the uterine tubes are not continuous with the ovaries places women at risk for *ectopic pregnancy*, in which an oocyte fertilized in the peritoneal cavity or distal portion of the uterine tube begins developing there. Because the tube lacks adequate mass and vascularization to support a full-term pregnancy, ectopic pregnancies tend to naturally abort, often with substantial bleeding. Because this situation is dangerous, it is important to seek medical attention.

Another potential problem is infection spreading into the peritoneal cavity from other parts of the reproductive tract. Sexually transmitted microorganisms, including chlamydia and gonorrhea bacteria, sometimes infect the peritoneal cavity in this way, causing an extremely severe inflammation called **pelvic inflammatory disease (PID)**. Unless treated promptly with broad-spectrum antibiotics, PID can cause scarring of the narrow uterine tubes, resulting in sterility, and can even be fatal. PID is one of the major causes of female infertility.

The Uterus

The **uterus** (womb) lies in the pelvic cavity, anterior to the rectum and posterosuperior to the bladder (Figures 27.15 and 27.17). It is a hollow, thick-walled, muscular organ that receives, retains, and nourishes a fertilized ovum. In women who have never been pregnant, the uterus is about the size and shape of an inverted pear, but it is usually larger in women who have borne children. Normally, the uterus tilts anteriorly where it joins the vagina (see Figure 27.15), causing the uterus as a whole to be inclined forward, or *anteverted*. However, the organ is sometimes tilted backward, or *retroverted*.

The major portion of the uterus is referred to as the **body** (Figure 27.17). The rounded region superior to the entrance of the uterine tubes is the **fundus**, and the slightly narrowed region between the body and the cervix is the *isthmus*. The **cervix** of



(b) Superoanterior view

Figure 27.17 *(continued)* **(b)** Photo of female pelvic organs *in situ*.

the uterus is its narrow neck, or outlet, which projects into the vagina inferiorly.

The cavity of the cervix, called the **cervical canal**, empties into the vagina via the *external os* (*os* = mouth) and connects with the cavity of the uterine body via the *internal os*. The mucosa of the cervical canal contains *cervical glands* that secrete a mucus that fills the cervical canal and covers the external os. This helps block the spread of bacteria from the vagina into the uterus. Cervical mucus also blocks sperm entry except at midcycle, when it becomes less viscous and allows sperm to pass through.

HOMEOSTATIC IMBALANCE 27.6 CLINICAL

Cancer of the cervix strikes about 450,000 women worldwide each year, killing about half. It is most common among women between the ages of 30 and 50. Risk factors include frequent cervical inflammations, sexually transmitted infections [particularly human papillomavirus (HPV) that causes genital warts], and multiple pregnancies. The cancer cells arise from the epithelium covering the cervical tip.

In a *Papanicolaou* (*Pap*) *smear*, or cervical smear test, some of these cells are scraped away and examined for abnormalities. A Pap smear is the most effective way to detect this slow-growing cancer. Regular Pap smears are recommended for women between ages 21 and 65.

Vaccination can protect against HPV-induced cervical cancer. It is recommended for all 11- and 12-year-old girls. In girls who have not been exposed to HPV, the vaccine specifically blocks two cancer-causing kinds of HPV as well as two additional types not associated with cervical cancer. HPV vaccination is also recommended for boys.

Supports of the Uterus

The uterus is supported laterally by the **mesometrium** ("mesentery of the uterus") portion of the broad ligament (Figure 27.17). More inferiorly, the **cardinal (transverse cervical) ligaments** extend from the cervix and superior vagina to the lateral walls of the pelvis, and the paired **uterosacral ligaments** secure the uterus to the sacrum posteriorly (Figure 27.17a). The uterus is bound to the anterior body wall by the **round ligaments**, which run through the inguinal canals to anchor in the subcutaneous tissue of the labia majora (Figure 27.15). These flexible ligaments allow the uterus to move as the underlying bladder and rectum fill and empty.

HOMEOSTATIC IMBALANCE 27.7 CLINICAL

Despite its many anchoring ligaments, the uterus is principally supported by the muscles of the pelvic floor, namely those of the urogenital and pelvic diaphragms (◀ Table 10.7, pp. 348–349). These muscles stretch and sometimes tear during childbirth. Subsequently, the unsupported uterus may sink inferiorly, sometimes until the tip of the cervix protrudes through the external vaginal opening. This condition is called **prolapse of the uterus**.

The undulating course of the peritoneum produces several blind-ended peritoneal pouches. The most important of these are the *vesicouterine pouch* (ves″i-ko-u′ter-in) between the bladder and uterus, and the *rectouterine pouch* between the rectum and uterus (see Figure 27.15).

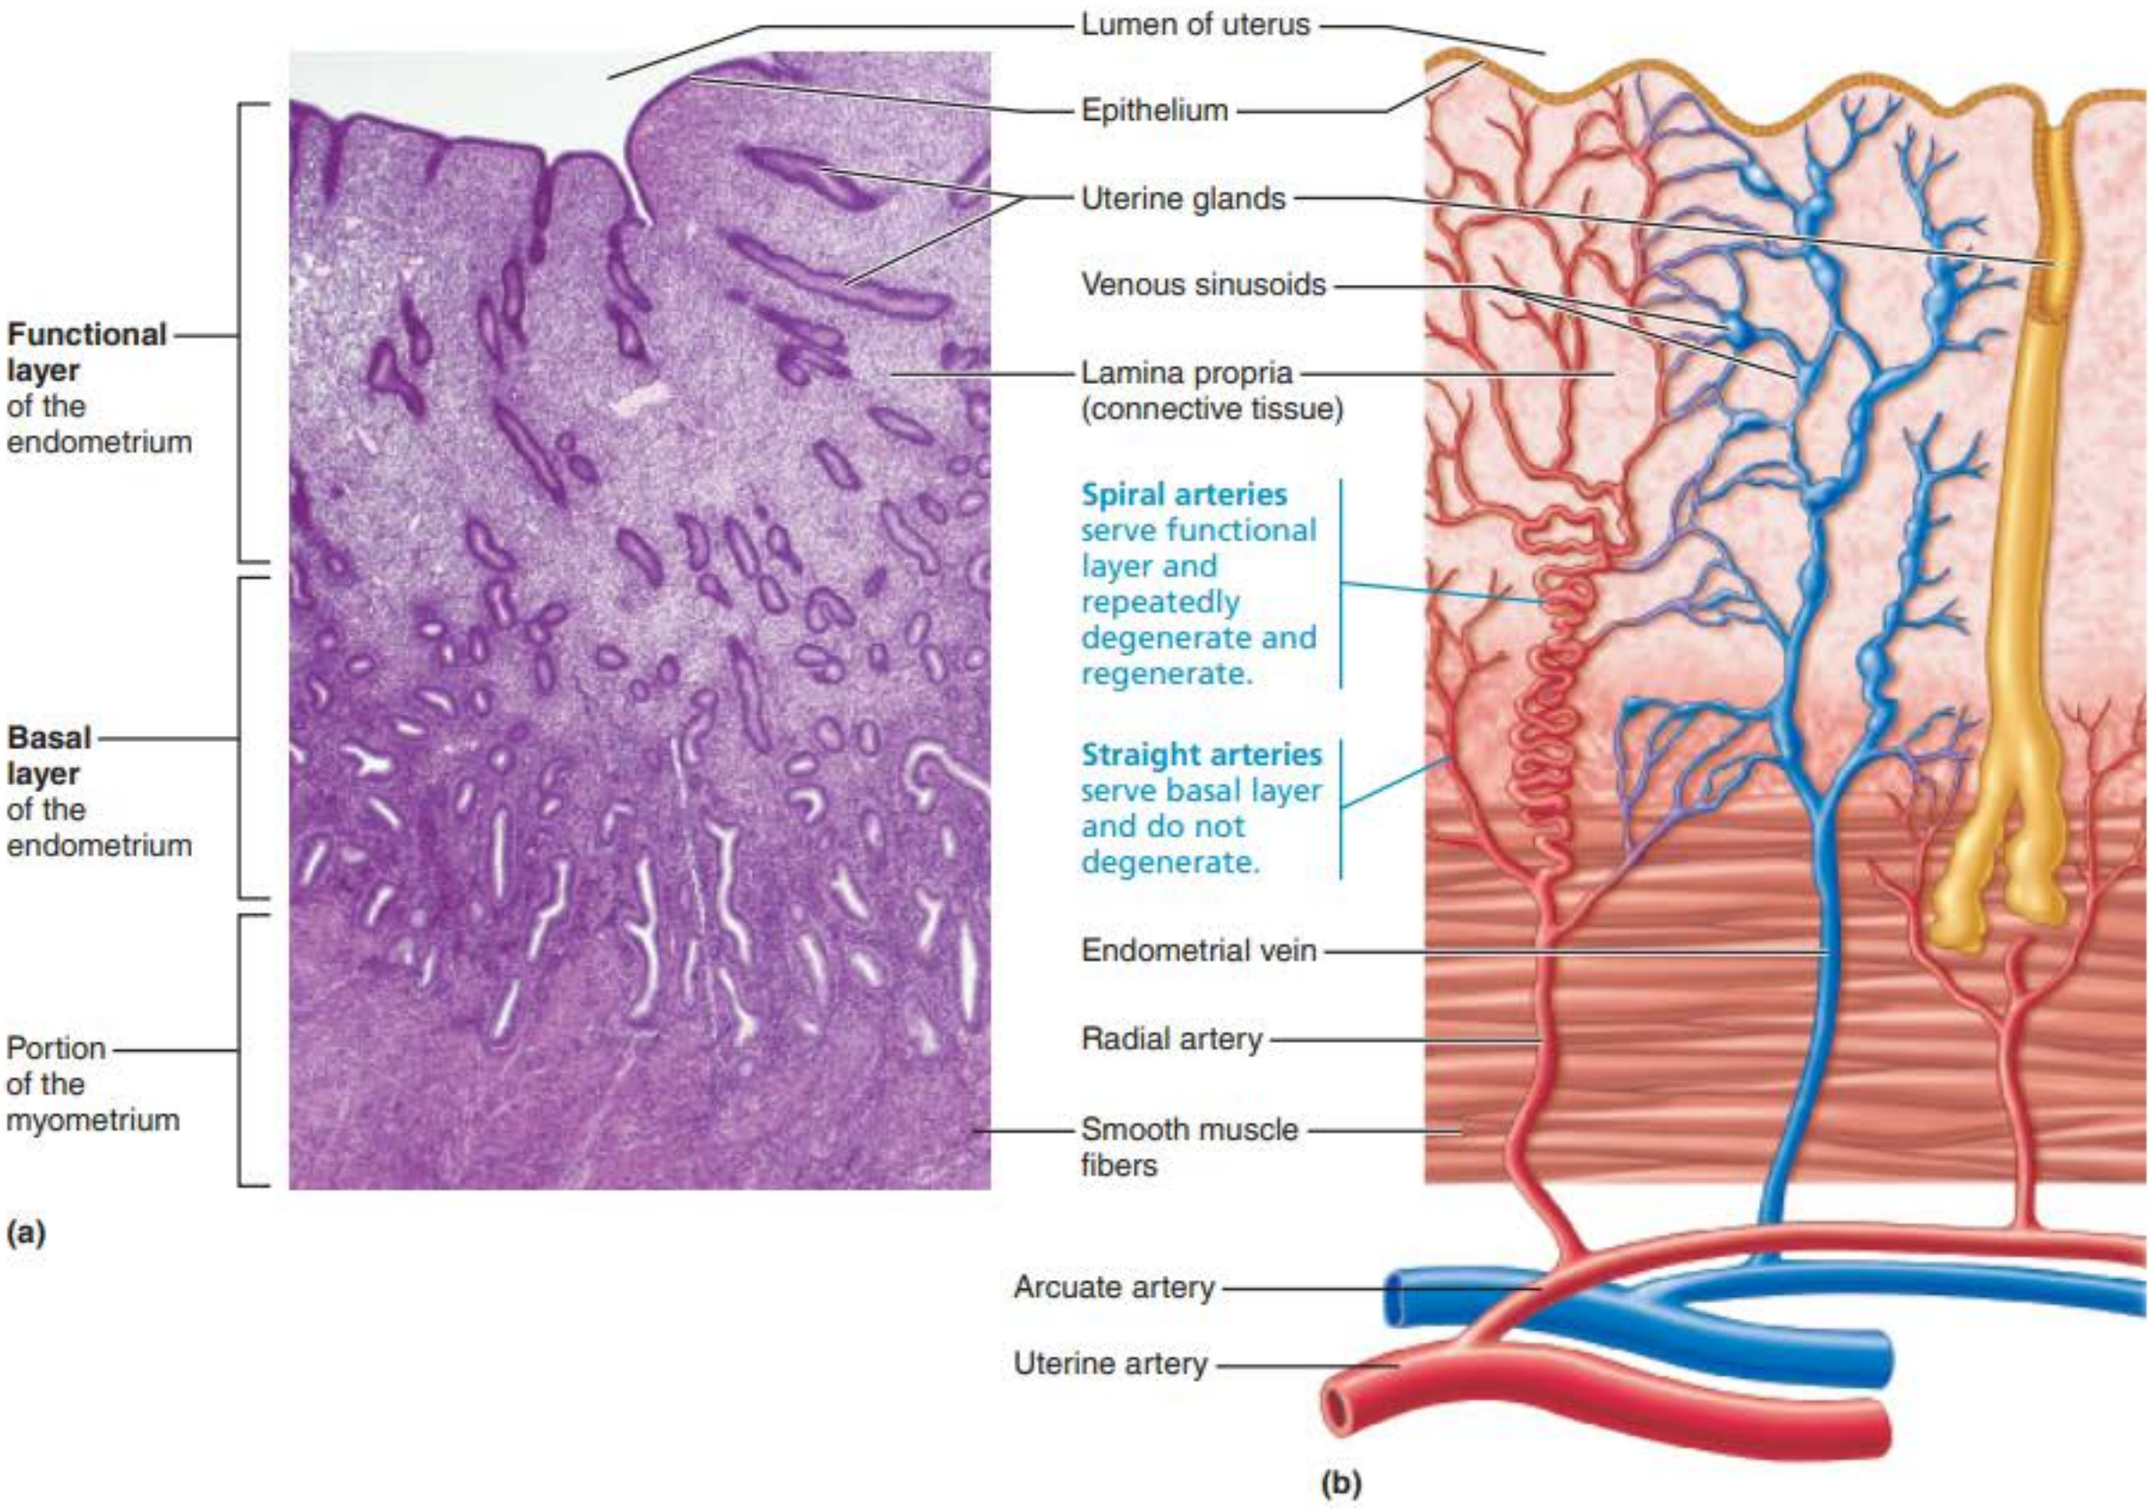


Figure 27.18 The endometrium and its blood supply. (a) Photomicrograph of the endometrium showing its functional and basal layers (28×). **(b)** Diagrammatic view. (While many spiral and straight arteries serve the endometrium, we only label one of each here.)

Practice Histology questions:
MasteringA&P® Study Area > Lab Tools > PAL

The Uterine Wall

The wall of the uterus is composed of three layers (Figure 27.17a):

- The **perimetrium** is the incomplete outermost serous layer.
- The **myometrium** (mi″o-me′tre-um; "muscle of the uterus") is the bulky middle layer, composed of interlacing bundles of smooth muscle. The myometrium contracts rhythmically during childbirth to expel the baby from the mother's body.
- The **endometrium** is the mucosa that lines the uterine cavity (**Figure 27.18**). This mucosa consists of a simple columnar epithelium and a thick lamina propria. If fertilization occurs, the young embryo burrows into the endometrium (implants) and resides there for the rest of its development.

The endometrium has two chief layers. The **functional layer**, or *stratum functionalis* (fungk-shun-a′lis), undergoes cyclic changes in response to blood levels of ovarian hormones and is shed during menstruation (about every 28 days). Stem cells found in the thinner, deeper **basal layer**, or *stratum basalis* (ba-să′lis), form a new functional layer after menstruation ends. The endometrium has numerous *uterine glands* that change in length as endometrial thickness changes during the menstrual cycle (see Figure 27.25).

The vascular supply of the uterus is key to understanding the cyclic changes of the uterine endometrium. The **uterine arteries** arise from the *internal iliacs* in the pelvis, ascend along the sides of the uterus, and send branches into the uterine wall (Figures 27.17a and 27.18b). These branches break up into several **arcuate arteries** (ar′ku-āt) within the myometrium. The arcuate arteries send **radial arteries** into the endometrium, where they give off **straight arteries** to the basal layer and **spiral arteries** (or *coiled arteries*) to the functional layer. The spiral arteries repeatedly degenerate and regenerate in response to changing hormone levels. It is their spasms that actually cause the functional layer to be shed during menstruation. Veins in the endometrium are thin walled and form an extensive network with occasional sinusoidal enlargements.

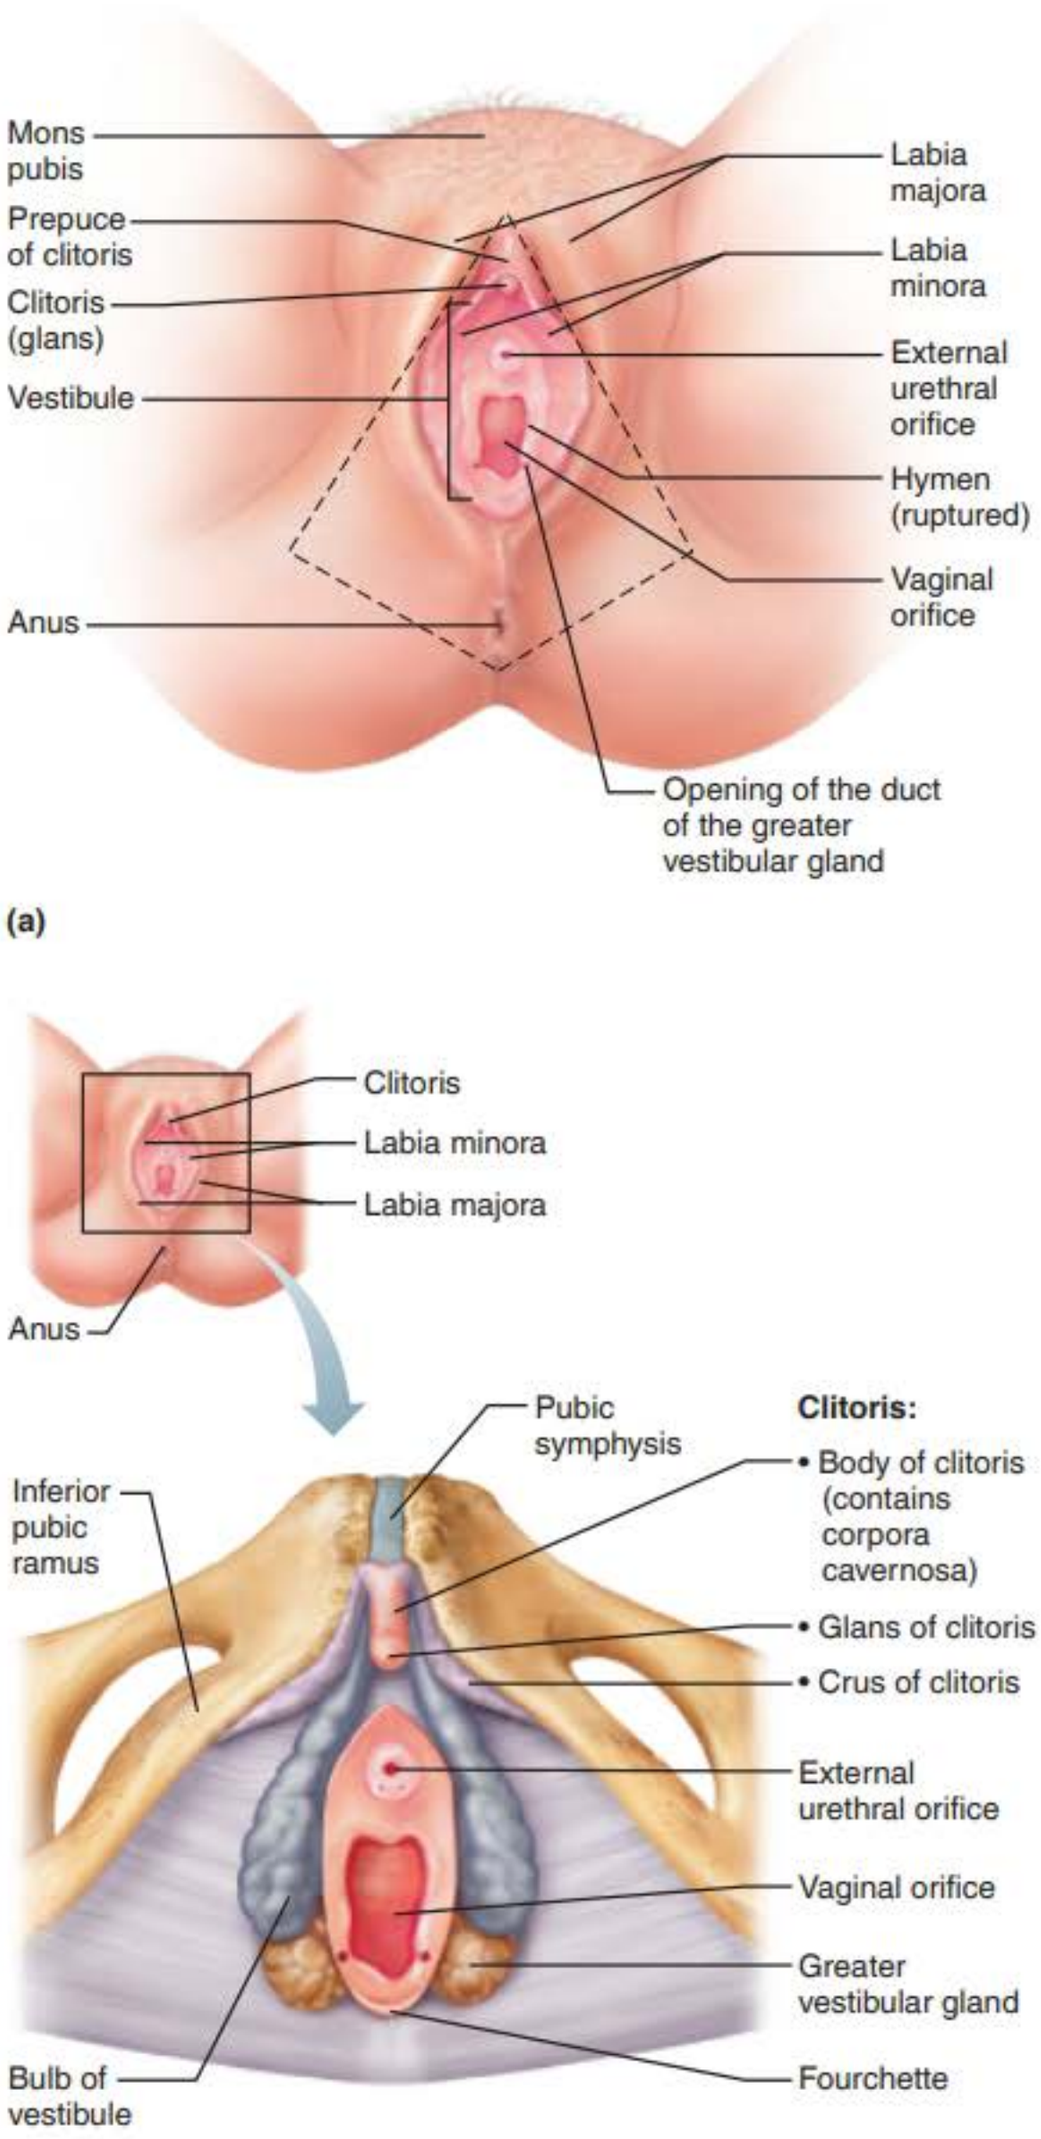

Figure 27.19 The external genitalia (vulva) of the female. **(a)** Superficial structures. The region enclosed by dashed lines is the perineum. **(b)** Deep structures. The labia and associated skin have been removed to show the underlying erectile bodies. See also the associated superficial muscles (◀ **Figure 10.13, p. 349**).

The Vagina

The **vagina** ("sheath") is a thin-walled tube that lies between the bladder and the rectum. It extends from the cervix to the body exterior (see Figure 27.15). The urethra parallels its course anteriorly. The vagina provides a passageway for delivery of an infant and for menstrual flow. Because it receives the penis (and semen) during sexual intercourse, it is the *female organ of copulation*.

The distensible wall of the vagina consists of three coats: an outer fibroelastic *adventitia*, a smooth muscle *muscularis*, and an inner *mucosa* marked by transverse ridges or rugae, which stimulate the penis during intercourse. The mucosa is a stratified squamous epithelium adapted to stand up to friction.

The vaginal mucosa has no glands. Instead, it is lubricated by the cervical mucous glands and the mucosal fluid that seeps from the vaginal walls. Glycogen from epithelial cells shed into the lumen is fermented by beneficial resident bacteria into lactic acid. Consequently, the pH of a woman's vagina is normally quite *acidic*. This acidity helps keep the vagina healthy and free of infection, but it is also hostile to sperm. Although vaginal fluid of adult females is acidic, it tends to be alkaline in adolescents, predisposing sexually active teenagers to sexually transmitted infections.

In women who have never participated in sexual intercourse, the mucosa near the distal **vaginal orifice** forms an incomplete partition called the **hymen** (hi′men) (**Figure 27.19a**). The hymen may bleed when it stretches or ruptures during the first sexual intercourse. However, its durability varies. In some females, it is ruptured by sports, inserting tampons, or pelvic examinations. Occasionally, it is so tough that it must be breached surgically if intercourse is to occur.

The upper end of the vaginal canal loosely surrounds the cervix of the uterus, producing a vaginal recess called the **vaginal fornix**. The posterior part of this recess, the *posterior fornix*, is much deeper than the *lateral* and *anterior fornices* (see Figures 27.15 and 27.17a). Generally, the lumen of the vagina is quite small and, except where the cervix holds it open, its posterior and anterior walls touch each other. Although the vagina stretches considerably during copulation and childbirth, its lateral distension is limited by the ischial spines and the sacrospinous ligaments.

HOMEOSTATIC IMBALANCE 27.8 CLINICAL

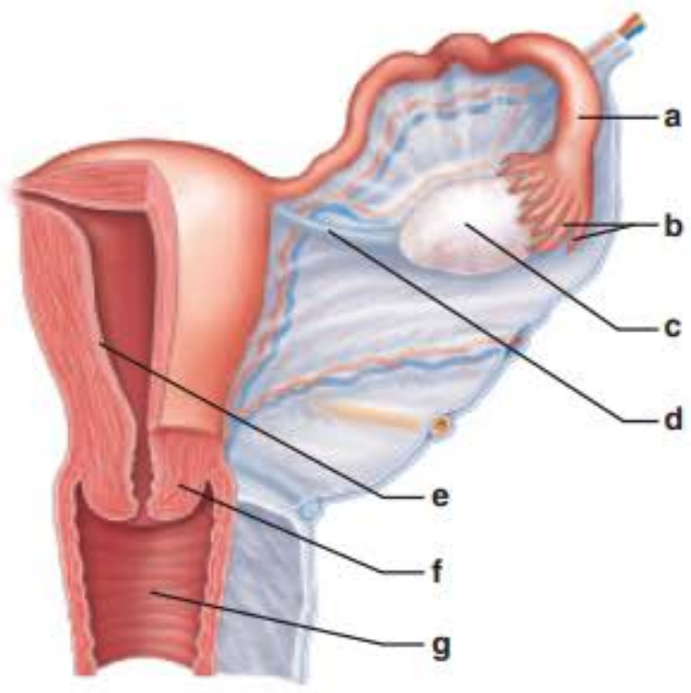
The uterus tilts away from the vagina. For this reason, attempts by untrained persons to induce an abortion by entering the uterus with a surgical instrument may puncture the posterior wall of the vagina. This causes hemorrhage and—if the instrument is unsterile—peritonitis.

Check Your Understanding

24. Why are women more at risk for PID than men?

25. Oocytes are ovulated into the peritoneal cavity and yet women do get pregnant. What action of the uterine tubes helps to direct the oocytes into the woman's duct system?

26. In the figure at right, identify structures a–g. Which structure is the usual site of fertilization? Which has spiral arteries?



For answers, see Answers Appendix.

27.11 The external genitalia of the female include those structures that lie external to the vagina

Learning Outcome

▶ **Describe the anatomy of the female external genitalia.**

The female reproductive structures that lie external to the vagina are the *external genitalia* (Figure 27.19), also called the **vulva** (vul′vah; "covering") or **pudendum** ("shameful"). These structures include the mons pubis, labia, clitoris, and structures associated with the vestibule.

The **mons pubis** (mons pu′bis; "mountain on the pubis") is a fatty, rounded area overlying the pubic symphysis. After puberty, pubic hair covers the skin of this area. Running posteriorly from the mons pubis are two elongated, hair-covered fatty skin folds, the **labia majora** (la′be-ah mah-jor′ah; "larger lips"). These are the homologues of the male scrotum (recall from p. 1042 that this means that they derive from the same embryonic tissue). The labia majora enclose the **labia minora** (mi-nor′ah; "smaller"), two thin, hair-free skin folds, homologous to the spongy urethra of the penis.

The labia minora enclose a recess called the **vestibule** ("entrance hall"), which contains the external openings of the urethra and the vagina. Flanking the vaginal opening are the pea-sized **greater vestibular glands** (Figure 27.19b), homologous to the bulbo-urethral glands of males. These glands release mucus into the vestibule and help to keep it moist and lubricated, facilitating intercourse. At the extreme posterior end of the vestibule the labia minora come together to form a ridge called the **fourchette**.

Just anterior to the vestibule is the **clitoris** (klit′o-ris; "hill"), a small, protruding structure composed largely of erectile tissue, which is homologous to the penis of the male. Its exposed portion is called the **glans of the clitoris**. It is hooded by a skin fold called the **prepuce of the clitoris**, formed by the junction of the labia minora folds.

The clitoris is richly innervated with nerve endings sensitive to touch. It becomes swollen with blood and erect during tactile stimulation, contributing to a female's sexual arousal. Like the penis, the **body of the clitoris** has dorsal erectile columns (corpora cavernosa) attached proximally by crura, but it lacks a corpus spongiosum that conveys a urethra.

In males the urethra carries both urine and semen and runs through the penis, but the female urinary and reproductive tracts are completely separate. Instead, the **bulbs of the vestibule** (Figure 27.19b), which lie along each side of the vaginal orifice and deep to the bulbospongiosus muscles, are the homologues of the single penile bulb and corpus spongiosum of the male. During sexual stimulation the bulbs of the vestibule engorge with blood. This may help the vagina grip the penis and also squeezes the urethral orifice shut, which prevents semen (and bacteria) from traveling superiorly into the bladder during intercourse.

The Female Perineum

The female **perineum** is a diamond-shaped region located between the pubic arch anteriorly, the coccyx posteriorly, and the ischial tuberosities laterally (Figure 27.19a). The soft tissues of the perineum overlie the muscles of the pelvic outlet, and the posterior ends of the labia majora overlie the *central tendon*, into which most muscles supporting the pelvic floor insert (◀ Table 10.7, pp. 348–349).

Check Your Understanding

27. What is the female homologue of the bulbo-urethral glands of males?

28. Cite similarities and differences between the penis and clitoris.

For answers, see Answers Appendix.

27.12 The mammary glands produce milk

Learning Outcome

- **Describe the structure and function of the mammary glands.**

Mammary glands are modified sweat glands that are present in both sexes. They normally function only in lactating females (**Figure 27.20**). At that time, they produce milk in response to hormonal stimulation to nourish an infant.

The Mammary Glands

Each mammary gland is contained within the subcutaneous tissue of a rounded, skin-covered breast, anterior to the pectoral muscles of the thorax. Slightly below the center of each breast is a ring of pigmented skin, the **areola** (ah-re′o-lah), which surrounds a central protruding **nipple**. Large sebaceous glands in the areola make it slightly bumpy and produce sebum that reduces chapping and cracking of the skin of the nipple. Autonomic nervous system controls of smooth muscle fibers in the areola and nipple cause the nipple to become erect when stimulated by tactile or sexual stimuli, or cold temperatures.

Internally, each mammary gland consists of 15 to 25 **lobes** that radiate around and open at the nipple. The lobes are padded and separated from each other by fibrous connective tissue and fat. The interlobar connective tissue forms **suspensory ligaments** that attach the breast to the underlying muscle fascia and the overlying dermis. As suggested by their name, the suspensory ligaments provide built-in support for the breasts.

Within the lobes are smaller units called **lobules**, which contain glandular **alveoli** that produce milk when a woman is lactating. These compound alveolar glands pass the milk into the **lactiferous ducts** (lak-tif′er-us), which open to the outside at the nipple. Just deep to the areola, each duct has a dilated region called a **lactiferous sinus** where milk accumulates during nursing. We describe the process of lactation in Chapter 28.

The description of mammary glands that we have just given applies only to nursing women or women in the last trimester of pregnancy. Glandular alveoli begin to form from the smallest ducts about halfway through pregnancy. In nonpregnant women, the glandular structure of the breast is largely undeveloped and the duct system is rudimentary. For this reason, breast size is largely due to the amount of fat deposits.

(c) Film of breast with tumor

Figure 27.21 Mammograms.

Breast Cancer CLINICAL

Breast cancer is the second most common cancer in U.S. women—about one in eight women will develop breast cancer in their lifetime. Breast cancer usually arises from the epithelial cells of the smallest ducts, eventually becoming a lump in the breast from which cells often metastasize.

The risk of breast cancer is proportional to a woman's lifetime exposure to estrogens. Early puberty, late menopause, no or delayed pregnancies, and hormone replacement therapy after menopause all increase the risk. In addition, a family history of breast cancer or genetic mutations in one of two genes (*BRCA1* and *BRCA2*) predispose women to this cancer. Nevertheless, more than 70% of women who develop breast cancer have no known risk factors for the disease.

Most breast cancers are discovered by a routine X-ray examination called a **mammogram** (**Figure 27.21**). Since most breast cancers occur later in life, the U.S. Preventive Services Task Force on Breast Cancer Screening recommends mammograms every two years for women between ages 50 and 74.

Breast cancer treatment often begins with a surgical procedure called a *lumpectomy* and may include radiation therapy, chemotherapy, or both. If the cancer cells are stimulated to divide by estrogens, drugs that block estrogen receptors or their effects can be used.

New therapies that target specific molecular characteristics of an individual's cancer cells are now in use and more are being developed. These targeted therapies are more specific than traditional chemotherapy and cause fewer side effects. Over the last 20 years, breast cancer survival rates have been steadily increasing. The 5-year survival rate is now greater than 90%.

Check Your Understanding

29. Developmentally, mammary glands are modifications of certain skin glands. Which type?

30. When does the glandular portion of the breast develop in females?

For answers, see Answers Appendix.

PART 4 PHYSIOLOGY OF THE FEMALE REPRODUCTIVE SYSTEM

27.13 Oogenesis is the sequence of events that leads to the formation of ova

Learning Outcomes

- **Describe the process of oogenesis and compare it to spermatogenesis.**
- **Describe the stages of follicle development.**

We are now ready to explore the details of **oogenesis** (o″o-gen′ĕ-sis; "the beginning of an egg"), the process by which female gametes are produced in the ovary. The process of oogenesis parallels that of spermatogenesis because the underlying processes—mitosis and then meiosis—are the same for both:

Oogonia (diploid stem cells)
↓ Divide by mitosis to produce
Primary oocytes
↓ Undergo meiosis I to produce
Secondary oocytes
↓ Undergo meiosis II to produce
Ova

Oogonia are the diploid stem cells in females, and just like spermatogonia in males, they multiply rapidly by mitosis. Then the oogonia transform into **primary oocytes** that begin the first meiotic division, just like primary spermatocytes. However, there are three key differences in the time course of events between oogenesis and spermatogenesis:

- The production of primary oocytes occurs only in the fetus.
- In primary oocytes, meiosis is arrested (stops) in late prophase I and resumes only years later (if at all).
- In secondary oocytes, meiosis is arrested in metaphase II and is only completed if fertilization occurs.

At birth, a female is presumed to have her lifetime supply of primary oocytes. Of the original 7 million fetal oocytes, approximately 2 million escape programmed cell death and remain in place in the cortical region of the ovary at birth. By puberty, an endowment of about 400,000 oocytes remains.

The Relationship between Oocytes and Follicles

Recall that in spermatogenesis, multiple developing sperm are surrounded by one sustentocyte. In oogenesis, a single oocyte is surrounded by many cells, and all of these cells are enclosed in a basal lamina to form an **ovarian follicle**. The surrounding cells are called **pre-granulosa cells** if a single layer of cells is present, and **granulosa cells** when more than one layer is present.

Follicles are the functional units of the ovary. They provide an environment where the developing oocyte and its surrounding cells can hold private "conversations" with each other (using paracrines and gap junctions). Follicles at different stages of maturation are distinguished by their size and by their structure (**Figure 27.22**, left side):

- **Primordial follicles** have a single layer of *squamous* pre-granulosa cells surrounding a primary oocyte.

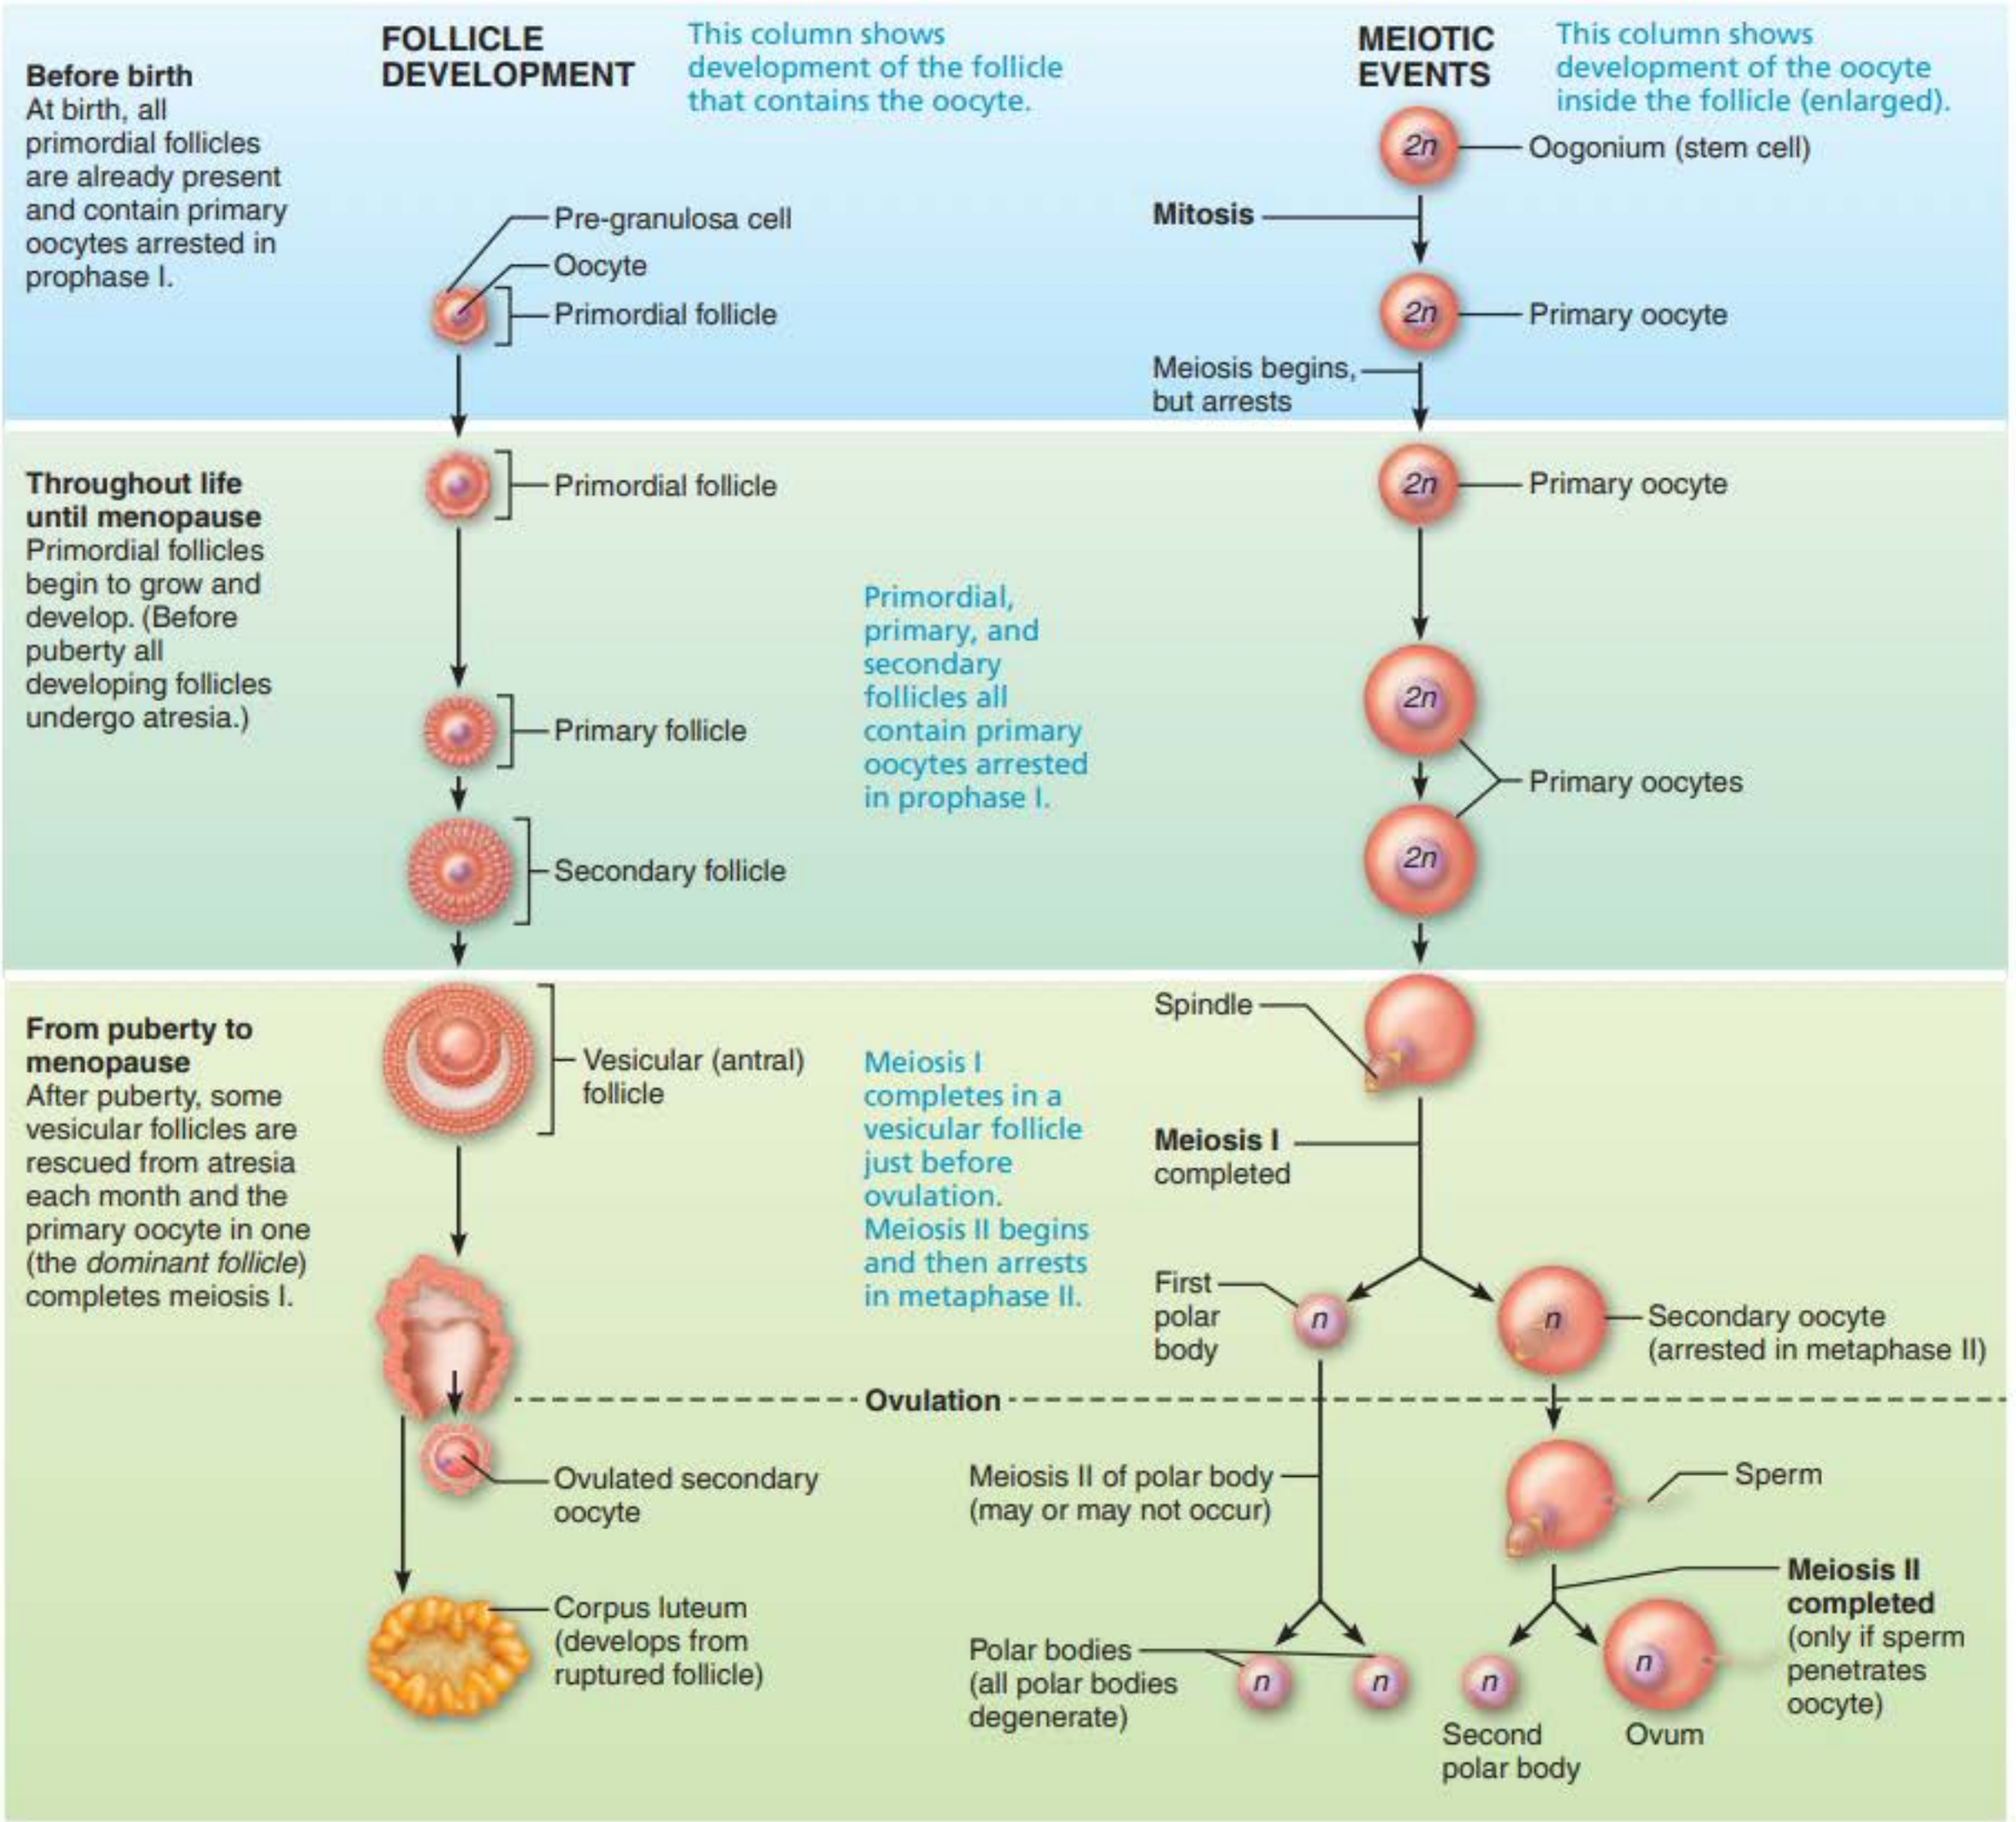

Figure 27.22 Events of oogenesis. At various stages, unsuccessful follicles undergo atresia (not shown).

- **Primary follicles** have a single layer of *cuboidal* pregranulosa cells surrounding a primary oocyte.
- **Secondary follicles** have multiple layers of granulosa cells surrounding a primary oocyte.
- **Vesicular (antral) follicles** (sometimes called *tertiary follicles*) have a fluid-filled cavity called an **antrum** ("cave"). Just before ovulation, the primary oocyte inside the vesicular follicle resumes meiosis and becomes a secondary oocyte.

The process of oogenesis begins during the fetal period and takes years to complete (Figure 27.22). The first follicles to develop in the fetus are primordial follicles. At any given time, the large majority of follicles in a woman's ovaries are dormant (functionally inactive) primordial follicles whose primary ooctyes are arrested in prophase I. Beginning in fetal life, a small fraction of the available dormant primordial follicles are *recruited* into a pool of growing follicles. This recruitment process begins during fetal life and continues throughout life until the supply of primordial follicles is effectively depleted, a time called menopause (see p. 1084). A follicle has one of two fates:

- **Atresia.** Atresia is apoptosis (programmed cell death) of the oocyte and its surrounding cells. This is the fate of over 99.9% of all follicles. Some primordial follicles undergo atresia without ever being recruited, and recruited follicles can undergo atresia at any stage in their development. Before puberty, *all* recruited follicles undergo atresia. This explains why only about 400,000 primordial follicles remain at puberty.
- **Ovulation.** After puberty, sufficiently high levels of hormones (particularly FSH) rescue a cohort (group) of fewer than 20 recruited follicles each month from atresia. Of these, typically only one follicle, the **dominant follicle**, is selected. It continues to escape atresia and achieves ovulation. As a result, only a small minority of recruited follicles are ever ovulated. Since the reproductive life of a woman is about 40 years and only one ovulation typically occurs each cycle, fewer than 500 oocytes are generally ovulated during a woman's lifetime.

Products of Meiosis in Females

As we mentioned previously, meiosis in the primary oocyte arrests in prophase I and this pause in meiosis can last for decades. Only the oocyte in the dominant follicle ever resumes meiosis I. This occurs just before ovulation and produces two haploid cells (each with 23 replicated chromosomes) that are quite dissimilar in size. The smaller cell, called the **first polar body**, may continue its development and undergo meiosis II, producing two even smaller polar bodies. The larger cell, which contains nearly all the cytoplasm of the primary oocyte, is the **secondary oocyte**.

The events of this first meiotic division ensure that the polar body receives almost no cytoplasm or organelles. Notice in Figure 27.22 (right) that a spindle forms at the very edge of the oocyte. A little "nipple" also appears at that edge, and the polar body chromosomes are cast into it.

The secondary oocyte arrests in metaphase II, and it is this cell (not a functional ovum) that is ovulated. If a sperm does not penetrate an ovulated secondary oocyte, the oocyte deteriorates. But if sperm penetration does occur, the oocyte quickly completes meiosis II, yielding one large **ovum** and a tiny **second polar body** (Figure 27.22). The union of the egg and sperm nuclei that constitutes fertilization is described in Chapter 28.

The unequal cytoplasmic divisions that occur during oogenesis ensure that a fertilized egg has ample nutrients for its six- to seven-day journey to the uterus. Lacking nutrient-containing cytoplasm, the polar bodies degenerate and die.

Comparison of Oogenesis and Spermatogenesis

There are many differences between spermatogenesis and oogenesis, which are summarized in **Table 27.1** and discussed below.

The potential end products of oogenesis are two or three tiny polar bodies, nearly devoid of cytoplasm, and one large ovum. All of these cells are haploid, but only the ovum is a *functional gamete*. This is quite different from spermatogenesis, where the product is four viable gametes—sperm.

Gamete production in males begins at puberty and continues throughout life. As a result, the number of gametes produced by a male during his lifetime is huge. In contrast, a female's total supply of eggs is already determined by the time she is born, and the time span during which she releases them extends only from puberty to menopause. (This dogma that the number of oocytes is fixed before birth has been challenged by the recent discovery in humans of ovarian stem cells that have the potential to form new oocytes under experimental conditions. However, their physiological role, if any, has yet to be established.)

Perhaps the most striking difference between male and female meiosis is the error rate. As many as 20% of oocytes (but only 5% of sperm) have the wrong number of chromosomes, a situation that often results from failure of the homologues to

Table 27.1 Spermatogenesis versus Oogenesis

	MALE	FEMALE
Total Time to Produce One Gamete	74 days	13–50 years
Occurrence during Lifetime	Puberty to old age	Begins in fetal life, ends in menopause
Number of Gametes per Meiotic Division	4 equal-size sperm	1 large ovum and 2–3 small polar bodies
Number of Gametes per Lifetime	>1 trillion	<500
Error Rate (wrong number of chromosomes)	5%	20%
Cells Surrounding Developing Gametes	One sustentocyte sustains many spermatocytes	Many granulosa cells sustain one oocyte

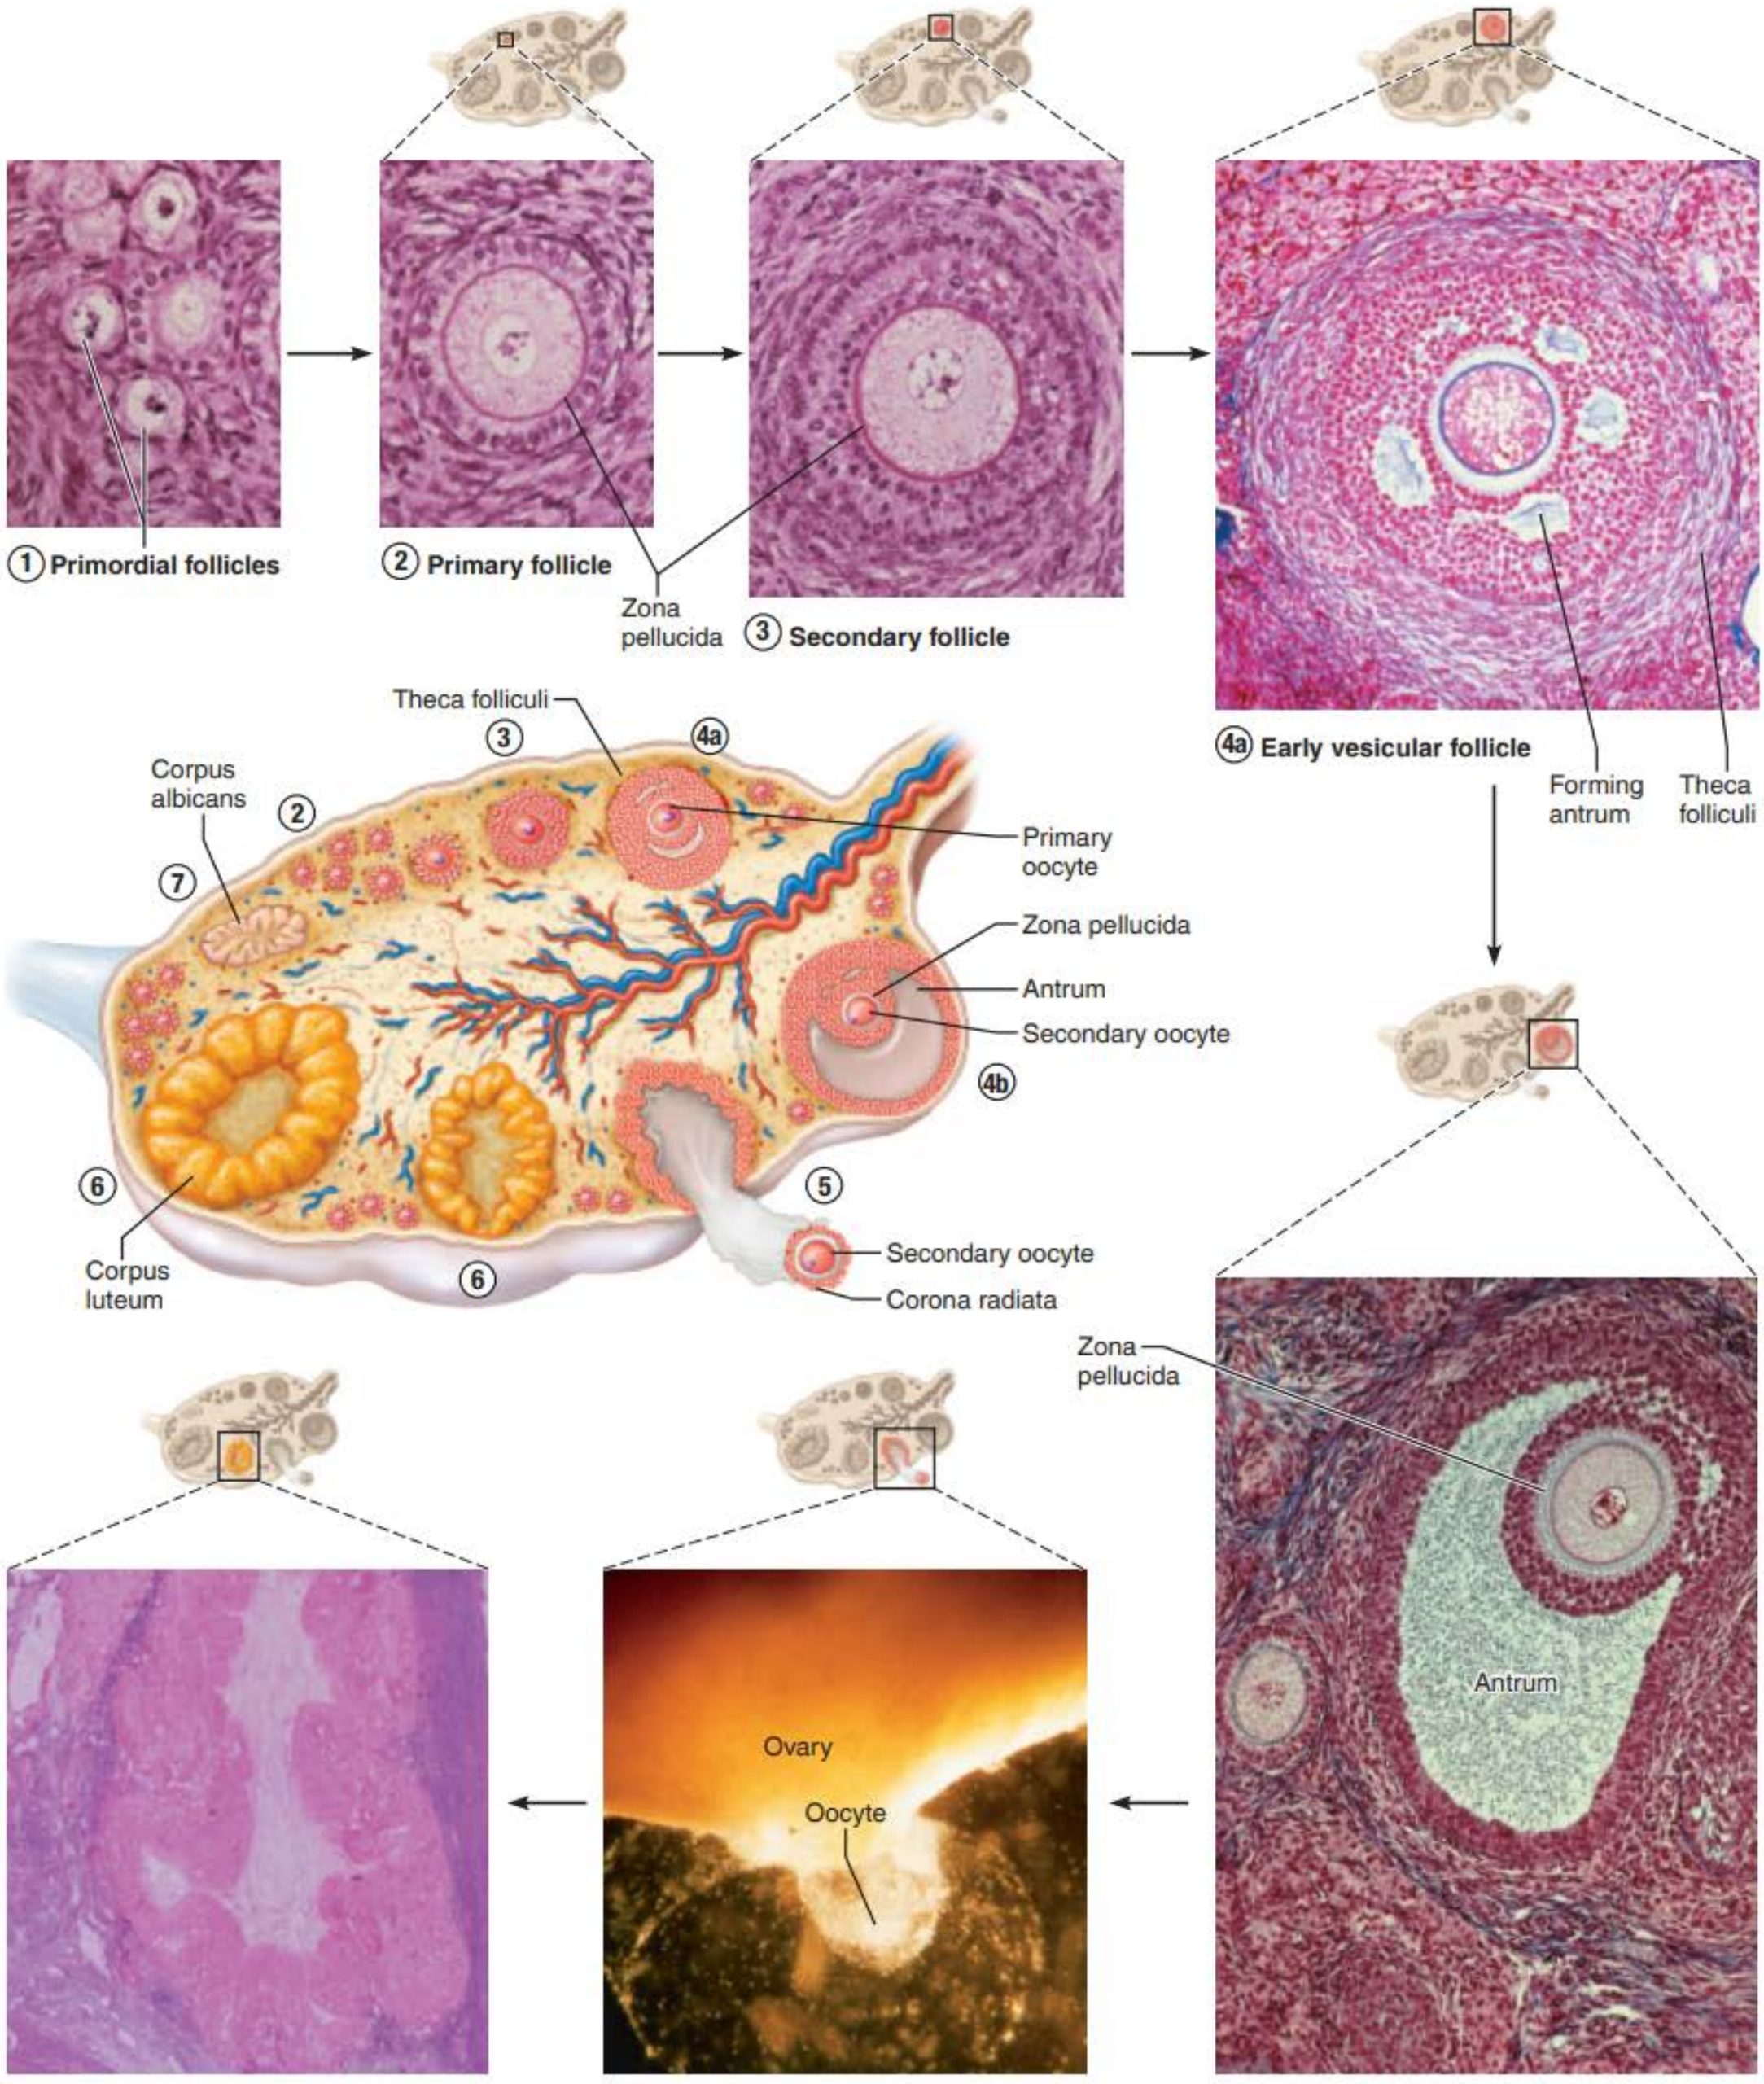

Figure 27.23 Development and fate of ovarian follicles. The numbers on the diagram indicate the sequence of follicle development, not the movement of a developing follicle within the ovary. Primordial follicles (1) not shown in central diagram.

Practice Histology questions:
MasteringA&P® Study Area > Lab Tools > PAL

separate during meiosis I. It appears that faced with meiotic disruption, meiosis in males grinds to a halt and the sperm dies, but in females it marches on, making a defective oocyte.

Stages of Follicle Development

Oocyte and follicle development go hand in hand. Once recruited, a follicle and its oocyte require nearly a year to mature to the point that the oocyte is ready to be ovulated. As a result, follicles at many different stages of development can be observed at any given time within an ovary (◀ Figure 27.16, p. 1061). The maturation process involves two phases:

- Phase 1 is the gonadotropin-independent *preantral phase*. During this phase, intrafollicular paracrines (such as cytokines and growth factors) control oocyte and follicle development.
- Phase 2 is the *antral phase*. During this phase, the follicles are stimulated by FSH and LH (◀ p. 616) and grow tremendously, the dominant follicle is selected, and the primary oocyte in the dominant follicle resumes meiosis I.

We are now ready to look more closely at the development of ovarian follicles as shown in Figure 27.22 and **Figure 27.23**.

- **A primordial follicle becomes a primary follicle.** When a primordial follicle (1) is recruited, the squamous cells surrounding the primary oocyte grow and become cuboidal cells. The oocyte enlarges. The follicle is now called a *primary follicle* (2). At the same time, the oocyte secretes a glycoprotein-rich substance that forms a thick transparent extracellular layer called the **zona pellucida** (pĕ-lu′sid-ah). The zona pellucida encapsulates the oocyte (2), (3).
- **A primary follicle becomes a secondary follicle.** The pregranulosa cells proliferate, forming a stratified cuboidal epithelium around the oocyte. As soon as more than one cell layer is present, the follicle is called a *secondary follicle* (3). The *granulosa cells* (as they are now called) are connected to the developing oocyte by gap junctions, through which ions, metabolites, and signaling molecules can pass. From this point on, bidirectional "conversations" occur between the oocyte and granulosa cells, so they guide one another's development. One of the signals passing from the granulosa cells tells the oocyte to grow. Other signals dictate polarity in the future egg. The oocyte grows tremendously during this stage.

  As the follicle grows, a layer of connective tissue and epithelial cells condenses around the follicle, forming the **theca folliculi** (the′kah fah-lik′u-li; "box around the follicle") (4a). Some of these **thecal cells** secrete steroid hormone in response to LH (see Figure 27.24).
- **A secondary follicle becomes a vesicular (antral) follicle.** The secondary follicle stage ends when a clear liquid begins to accumulate between the granulosa cells, producing the early *vesicular follicle* (4a). When six to seven layers of granulosa cells are present, the fluid between the granulosa cells coalesces to form an *antrum*, a large fluid-filled cavity (4b). The presence of the antrum distinguishes vesicular follicles from all prior follicles (*preantral follicles*). At this point, the preantral phase ends and the antral phase begins. The further maturation of the follicle depends on the presence of gonadotropic hormones.

  The antrum continues to expand with fluid until it almost completely surrounds the oocyte and its surrounding capsule of granulosa cells, which are now called a **corona radiata** ("radiating crown"). The oocyte remains attached to the rest of the follicle only by a column of cells on one side of the follicle. When a follicle is full size (about 2.5 cm, or 1 inch, in diameter), it bulges from the external ovarian surface like a pimple. This usually occurs just before ovulation.

After the oocyte with its corona radiata is ejected from the follicle during ovulation, the ruptured follicle transforms into a very different-looking glandular structure called the *corpus luteum* (lu′te-um; "yellow body"; plural: corpora lutea) (6), discussed on the next page.

Check Your Understanding

31. How do the haploid cells arising from oogenesis differ structurally and functionally from those arising from spermatogenesis?

32. What name is given to the fluid-filled cavity of a vesicular follicle?

33. Look at Figure 27.16 on p. 1061. Identify the stage of each of the follicles indicated in the figure.

For answers, see Answers Appendix.

27.14 The ovarian cycle consists of the follicular phase and the luteal phase

Learning Outcome

▶ **Describe ovarian cycle phases, and relate them to events of oogenesis.**

The monthly series of events associated with the maturation of an egg is called the **ovarian cycle**. The ovarian cycle is best described in terms of two consecutive phases:

- The **follicular phase** is the period when a cohort of vesicular follicles begins to secrete increasing amounts of estrogens and one of these follicles is selected as the dominant follicle. This phase generally lasts from the first to the fourteenth day of the ovarian cycle, at which point ovulation typically occurs.
- The **luteal phase**, days 14–28, is the period during which the corpus luteum (discussed on the next page) is active.

The so-called typical ovarian cycle repeats at intervals of 28 days, with *ovulation* occurring midcycle. However, only 10–15% of women naturally have 28-day cycles, and cycles as long as 40 days or as short as 21 days are fairly common. In such cases, the length of the follicular phase and timing of ovulation vary, but the luteal phase remains constant: It is always 14 days from the time of ovulation to the end of the cycle.

Follicular Phase of the Ovarian Cycle

The first phase is called the follicular phase because many large vesicular follicles are growing in the ovary during this phase. This cohort of vesicular follicles was rescued from atresia by rising levels of FSH near the end of the previous cycle. FSH is a survival factor for vesicular follicles, allowing them to continue to survive and grow. One of these growing vesicular follicles becomes more sensitive to FSH than the others. As FSH levels begin to drop in the middle of the follicular phase, that follicle outcompetes the other follicles for FSH, and so continues to escape from atresia. It becomes the *dominant follicle*. Multiple factors, including increased sensitivity to LH, allow it to continue to grow so that it is at its peak stage of maturation when the hormonal (LH) stimulus for ovulation is given. (The other stimulated follicles eventually undergo atresia.)

As one of the final events of follicle maturation, the primary oocyte of the dominant follicle completes meiosis I to form the secondary oocyte and first polar body (see Figure 27.22). Once this has occurred, the stage is set for ovulation. At this point, the granulosa cells send another important signal to the oocyte that says, in effect, "Wait, do not complete meiosis yet!"

Ovulation

Ovulation occurs when the ballooning ovary wall ruptures and expels the secondary oocyte, still surrounded by its corona radiata, into the peritoneal cavity (Figure 27.23 ⑤). Some women experience a twinge of pain in the lower abdomen when ovulation occurs. The precise cause of this pain, called *mittelschmerz* (mit′el-shmārts; German for "middle pain"), is not known, but possible reasons include intense stretching of the ovarian wall during ovulation and irritation of the peritoneum by blood or fluid released from the ruptured follicle.

In 1–2% of all ovulations, more than one oocyte is ovulated. This phenomenon, which increases with age, can result in multiple births. Since, in such cases, different oocytes are fertilized by different sperm, the siblings are *fraternal*, or nonidentical, *twins*. *Identical twins* result from the fertilization of a single oocyte by a single sperm, followed by separation of the fertilized egg's daughter cells during early development. Additionally, it now appears that in some women oocytes may be released at times unrelated to hormone levels. This timing may help to explain why a rhythm method of contraception sometimes fails and why some fraternal twins have different conception dates.

Luteal Phase of the Ovarian Cycle

After ovulation, the ruptured follicle collapses and the antrum fills with clotted blood. This *corpus hemorrhagicum* is eventually absorbed. The remaining granulosa cells enlarge, and along with the internal theca cells they form a new, quite different endocrine structure, the **corpus luteum** (Figure 27.23 ⑥). The corpus luteum supplies the high levels of progesterone and estrogens that characterize the luteal phase.

If pregnancy does not occur, the corpus luteum starts degenerating after about 10 days and its hormonal output ends. In this case, all that ultimately remains is a scar called the *corpus albicans* (al′bĭ-kans; "white body") as shown in Figure 27.23 ⑦. The last two or three days of the luteal phase, when the endometrium is just beginning to erode, is sometimes called the *luteolytic* or *ischemic phase*.

On the other hand, if the oocyte is fertilized and pregnancy ensues, the corpus luteum persists until the placenta is ready to take over its hormone-producing duties in about three months.

34. How do identical twins differ developmentally from fraternal twins?

35. What occurs in the luteal phase of the ovarian cycle?

For answers, see Answers Appendix.

27.15 Female reproductive function is regulated by hypothalamic, anterior pituitary, and ovarian hormones

Learning Outcomes

- **Describe the regulation of the ovarian and uterine cycles.**
- **Discuss the physiological effects of estrogens and progesterone.**

Female reproductive events are much more complicated than those occurring in males, but the hormonal controls involving the hypothalamic-pituitary-gonadal axis set into motion at puberty are similar in both sexes. Gonadotropin-releasing hormone (GnRH), pituitary gonadotropins, and, in this case, ovarian estrogens and progesterone interact to produce the cyclic events occurring in the ovaries and uterus.

However, in females another hormone plays an important role in allowing the hypothalamus to release GnRH. The onset of puberty in females is linked to the amount of adipose tissue, and the messenger from fatty tissue to the hypothalamus is *leptin* (better known for its role in appetite and energy storage, ◀ p. 634). If body levels of fat and leptin are low, puberty is delayed.

Hormonal Regulation of the Ovarian Cycle

Establishing the Ovarian Cycle

During childhood, the ovaries grow and continuously secrete small amounts of estrogens, which inhibit hypothalamic release of GnRH. Provided that leptin levels are adequate, the hypothalamus becomes less sensitive to estrogens as puberty nears and, as we described on p. 1043, this triggers the rising levels of hormones seen at puberty.

Gonadotropin (FSH and LH) levels increase for about four years. During this time, pubertal girls are still not ovulating and cannot become pregnant. Eventually, the adult cyclic pattern is achieved, and hormonal interactions stabilize. These events are heralded by the young woman's first menstrual period, referred to as **menarche** (mĕ-nar′ke; *men* = month, *arche* = first). Usually, it is not until the third year postmenarche that the cycles become regular and all are ovulatory.

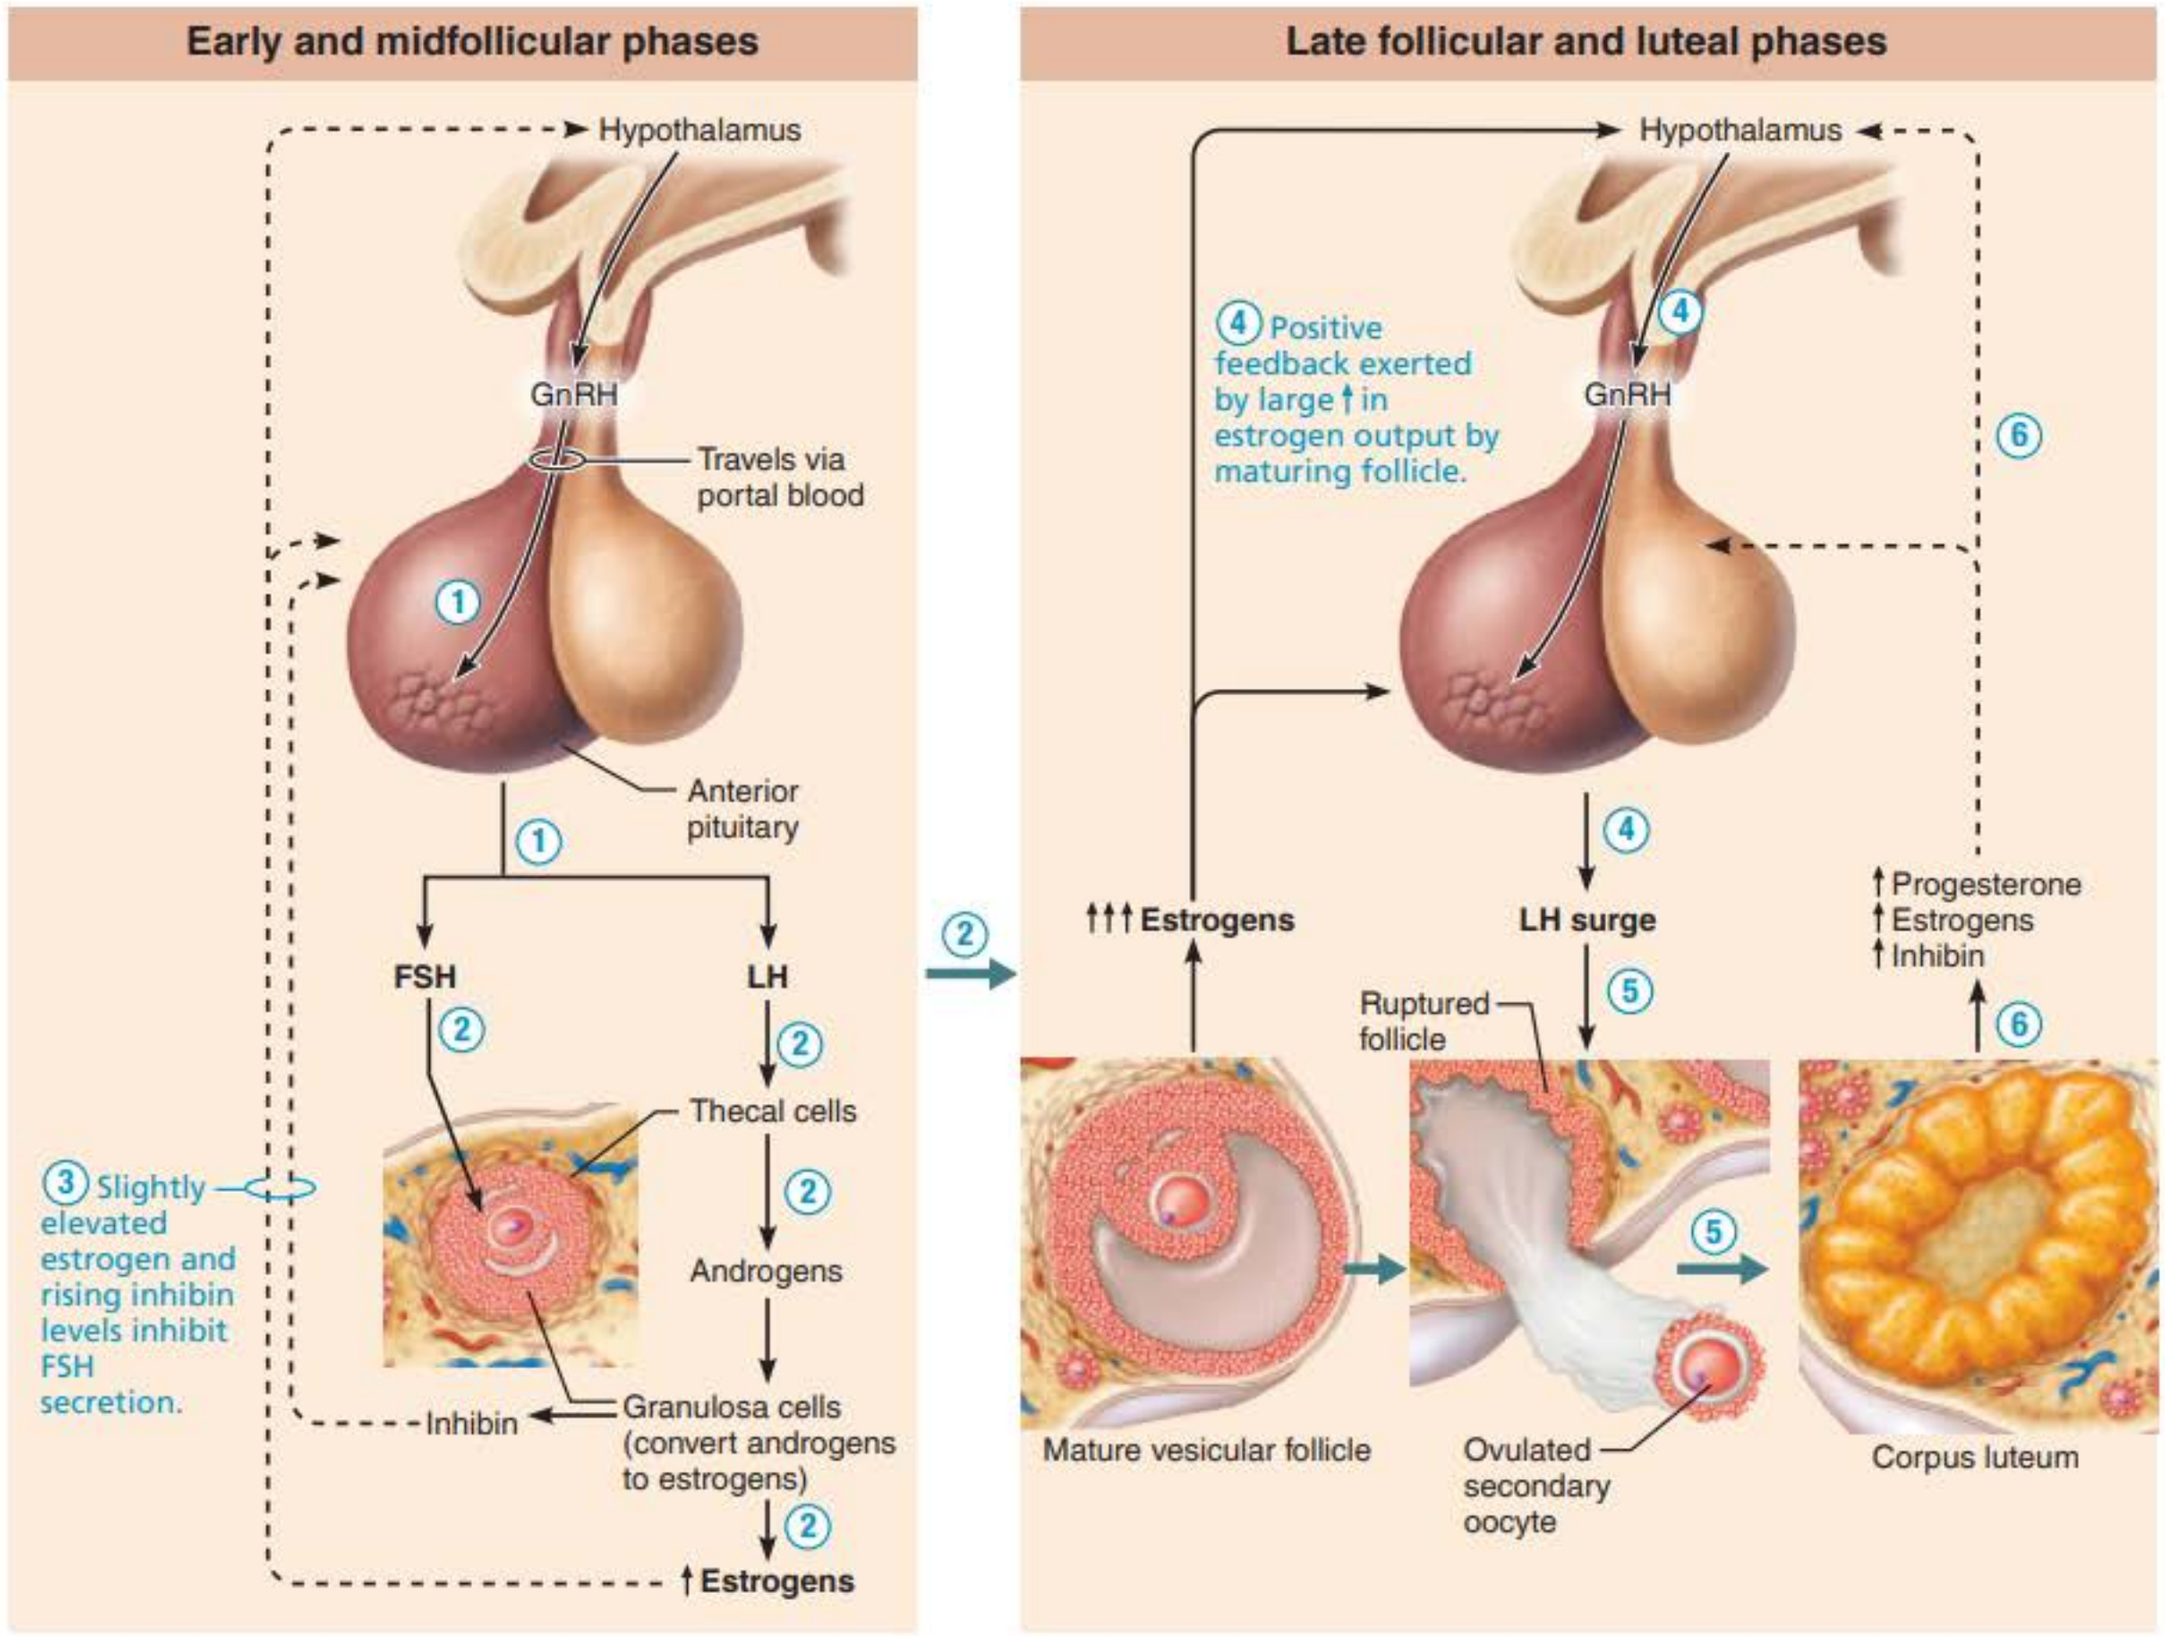

Figure 27.24 Regulation of the ovarian cycle. Events that follow step (6) are not depicted, but involve a gradual deterioration of the corpus luteum and, therefore, a decline in ovarian hormone production. Ovarian hormones reach their lowest blood levels at the end of the luteal phase. Note that inhibin only inhibits FSH release.

Hormonal Interactions during the Ovarian Cycle

Next, let's look at how the cyclic pattern of hormone release in females varies from the basic pattern (◀ p. 1042). In females, levels of anterior pituitary gonadotropins (FSH and LH) and ovarian hormones wax and wane, and there is both negative and positive feedback during each cycle. **Figure 27.24** shows these events.

(1) **GnRH stimulates FSH and LH secretion.**

(2) **FSH and LH stimulate follicles to grow, mature, and secrete sex hormones.** FSH exerts its main effects on the granulosa cells of vesicular follicles, causing them to release estrogens, whereas LH (at least initially) prods the thecal cells to release androgens, which the granulosa cells convert to estrogens. Only tiny amounts of ovarian androgens enter the blood, because they are almost completely converted to estrogens within the ovaries.

(3) **Negative feedback inhibits gonadotropin release.** As estrogen levels in the plasma rise, they exert *negative feedback* on the hypothalamus and anterior pituitary, inhibiting release of FSH. *Inhibin,* released by the granulosa cells, also exerts negative feedback controls on FSH release during this period. Only the dominant follicle survives the resulting dip in FSH—the other developing follicles fail to develop further.

(4) **Positive feedback stimulates gonadotropin release.** Although the initial small rise in bloodborne estrogens inhibits the hypothalamic-pituitary-gonadal axis, once the dominant follicle becomes a mature vesicular follicle just

before ovulation, the follicle produces high levels of estrogens. This has the opposite effect. When estrogens reach a critical blood concentration, they briefly exert *positive feedback* on the hypothalamus and anterior pituitary.

⑤ **LH surge triggers ovulation and formation of the corpus luteum.** The high estrogen level sets a cascade of events into motion. There is a sudden burst of LH (and, to a lesser extent, FSH) released by the anterior pituitary about midcycle (also see Figure 27.25a).

This **LH surge** rouses the primary oocyte of the mature vesicular follicle from its resting state and it completes its first meiotic division, forming a secondary oocyte that continues on to metaphase II. Around day 14, LH—aided by intraovarian paracrines—stimulates many events that lead to ovulation: It increases local vascular permeability and triggers an inflammatory response that promotes release of metalloproteinase enzymes that weaken the ovary wall. As a result, blood stops flowing through the protruding part of the follicle wall. Within minutes, that region of the follicle wall thins, bulges, and ruptures, forming a hole. The oocyte, still surrounded by its corona radiata, exits, accomplishing ovulation.

Shortly after ovulation, estrogen levels decline. This probably reflects the damage to the dominant estrogen-secreting follicle during ovulation.

The LH surge also transforms the ruptured follicle into a corpus luteum (which gives LH its name, "luteinizing" hormone). LH stimulates this newly formed endocrine structure to produce large amounts of progesterone and some estrogens almost immediately after it is formed (also see Figure 27.25c). Progesterone helps maintain the functional layer of the endometrium and is essential for maintaining pregnancy should conception occur.

⑥ **Negative feedback inhibits LH and FSH release.** Rising progesterone and estrogen blood levels exert a powerful negative feedback effect on the hypothalamus and the anterior pituitary release of LH and FSH. Inhibin is also released by the corpus luteum and enhances this inhibitory effect. Declining gonadotropin levels inhibit the maturation of new vesicular follicles and prevent additional LH surges that might cause additional oocytes to be ovulated.

When pregnancy does not occur, the stimulus for luteal activity ends when LH blood levels fall and the corpus luteum degenerates. Without the corpus luteum supplying ovarian hormones, blood estrogen and progesterone levels drop sharply. The marked decline in ovarian hormones at the end of the cycle (days 26–28) ends their blockade of FSH and LH secretion, and the cycle starts anew.

We have just described ovarian events through a 28-day cycle. Be aware, however, that the cohort of vesicular follicles that we followed from the beginning of this cycle were actually recruited to grow from primordial follicles about 290 days before one of them is ultimately ovulated. This is far longer than the 14 days you might expect from a casual look at the graph.

27

The Uterine (Menstrual) Cycle

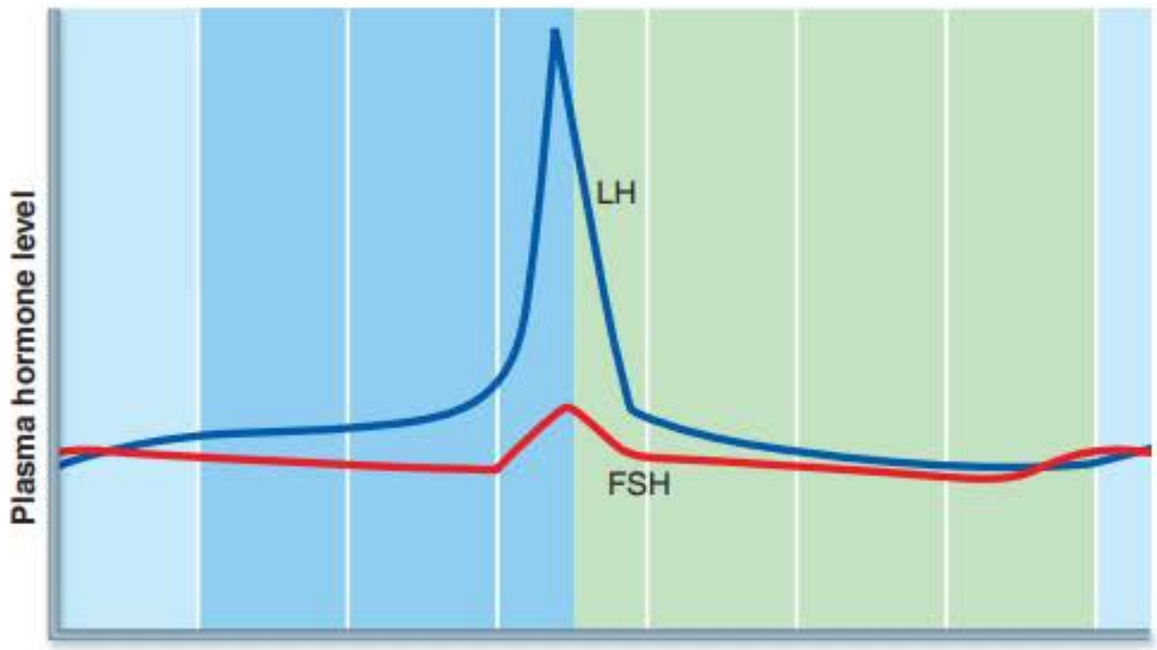
Although the uterus is where an embryo implants and develops, it is receptive to implantation for only a short period each month. Not surprisingly, this brief interval is exactly the time when a developing embryo would normally begin implanting, six to seven days after ovulation. The **uterine** or **menstrual cycle** (men′stroo-al) is a series of cyclic changes that the uterine endometrium goes through each month as it responds to the waxing and waning of ovarian hormones in the blood. These endometrial changes are coordinated with the phases of the ovarian cycle, which are dictated by gonadotropins released by the anterior pituitary.

Changes in ovarian steroid hormone levels drive the events of the uterine cycle (**Figure 27.25d**) as follows:

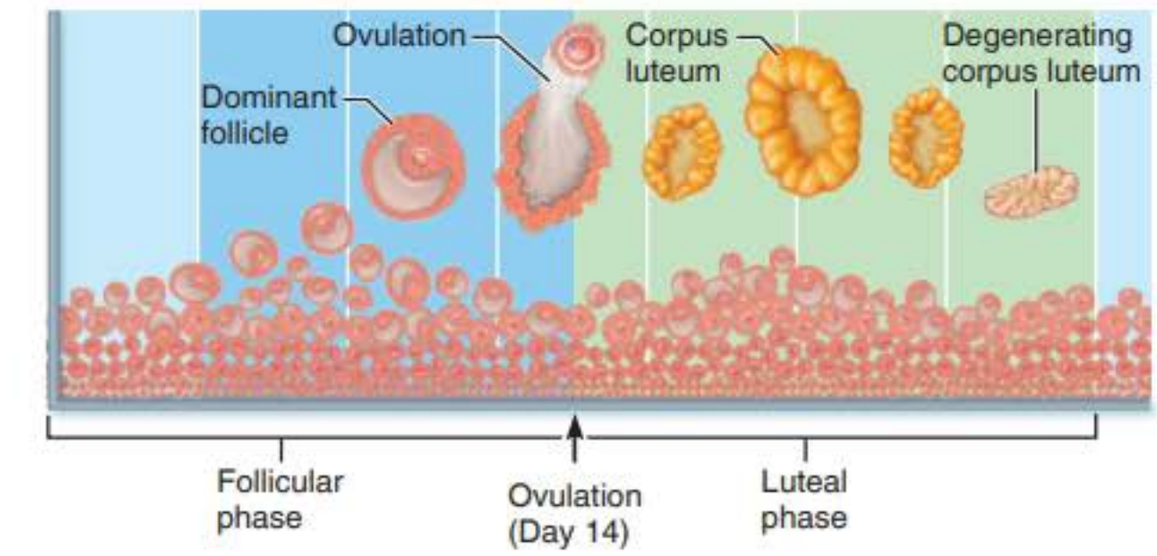
1. **Days 0–4: Menstrual phase.** In this phase, **menstruation** (men″stroo-a′shun) or **menses**, the uterus sheds all but the deepest part of its endometrium. (Note in Figure 27.25c that at the beginning of this stage, the ovarian hormones are at their lowest normal levels.) The thick, hormone-dependent functional layer of the endometrium detaches from the uterine wall, a process accompanied by bleeding for 3–5 days. The detached tissue and blood pass out through the vagina as the menstrual flow. By day 4, the growing ovarian follicles start to produce more estrogens (Figure 27.25c).
2. **Days 5–14: Proliferative (preovulatory) phase.** In this phase, the endometrium rebuilds itself: Under the influence of rising blood levels of estrogens, the basal layer of the endometrium generates a new functional layer. As this new layer thickens, its glands enlarge and its spiral arteries increase in number (also see Figure 27.18). Consequently, the endometrium once again becomes velvety, thick, and well vascularized. During this phase, estrogens also induce the endometrial cells to synthesize progesterone receptors, readying them for interaction with progesterone.

   Normally, cervical mucus is thick and sticky, but rising estrogen levels cause it to thin and form channels that facilitate sperm passage into the uterus. *Ovulation* occurs at the end of the proliferative stage (day 14) in response to the LH surge from the anterior pituitary.
3. **Days 15–28: Secretory (postovulatory) phase.** This 14-day phase is the most constant timewise. During the secretory phase the endometrium prepares for an embryo to implant. Rising levels of progesterone from the corpus luteum act on the estrogen-primed endometrium, causing the spiral arteries to elaborate and converting the functional layer to a secretory mucosa. The endometrial glands enlarge, coil, and begin secreting nutrients into the uterine cavity. These nutrients will sustain the embryo until it has implanted in the blood-rich endometrial lining.

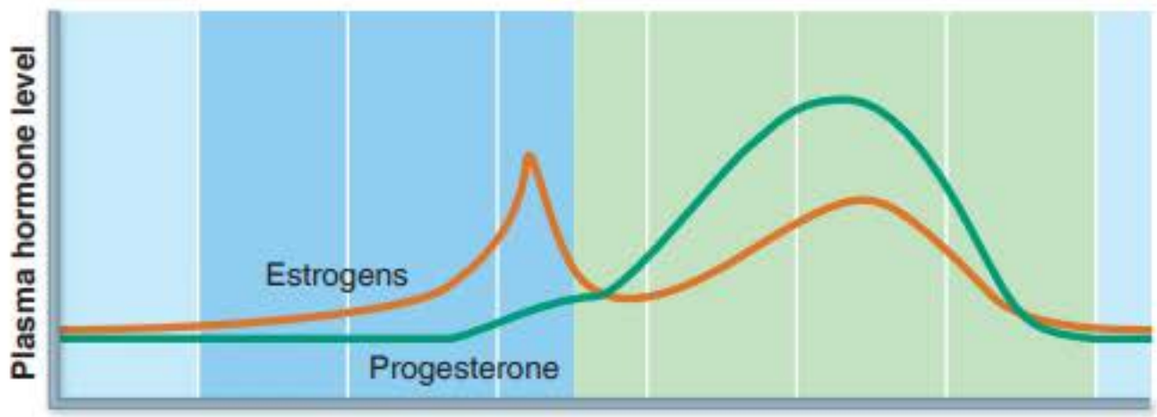
   As progesterone levels rise, the cervical mucus becomes viscous again, forming the *cervical plug*, which helps to block entry of sperm, pathogens, and other foreign materials. This protective role of the cervical plug is particularly important for sealing off the uterus in the event an embryo has begun to implant. Rising progesterone (and estrogen) levels inhibit LH release by the anterior pituitary.



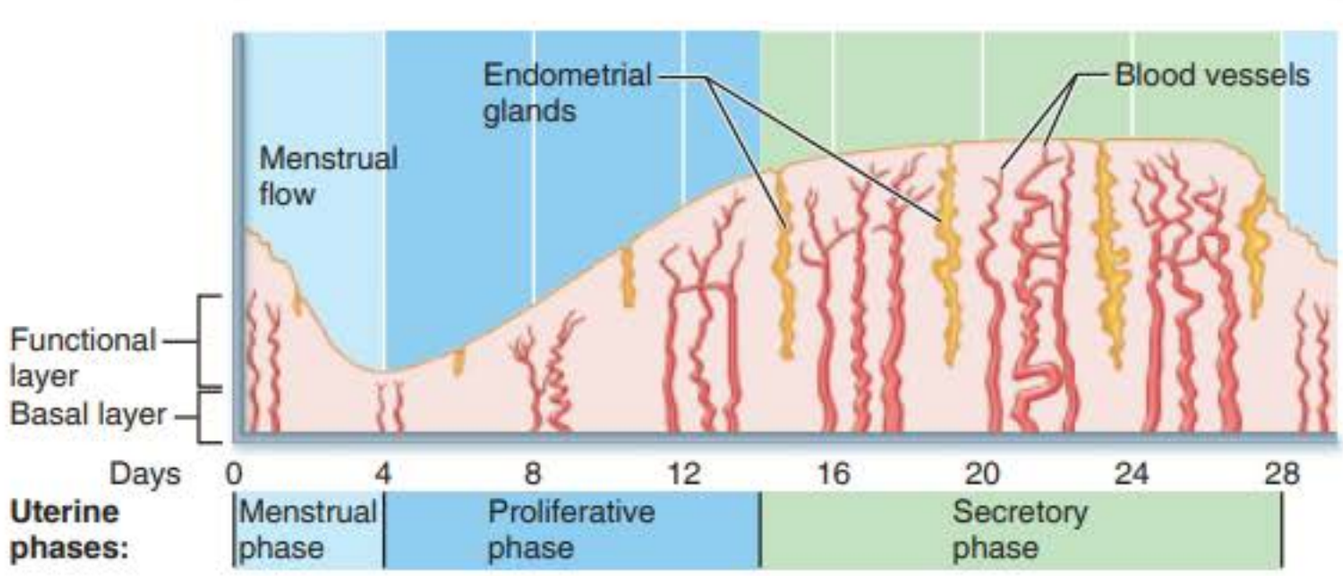
(a) Fluctuation of gonadotropin levels: Fluctuating levels of pituitary gonadotropins (follicle-stimulating hormone and luteinizing hormone) in the blood regulate the events of the ovarian cycle.



(b) Ovarian cycle: Structural changes in vesicular ovarian follicles and the corpus luteum are correlated with changes in the endometrium of the uterus during the uterine cycle (d). Recall that only vesicular follicles (in their antral phase) are hormone dependent. Primary and secondary follicles are not hormone dependent and develop in waves.



(c) Fluctuation of ovarian hormone levels: Fluctuating levels of ovarian hormones (estrogens and progesterone) cause the endometrial changes of the uterine cycle. The high estrogen levels are also responsible for the LH/FSH surge in (a).



(d) The three phases of the uterine cycle:

- Menstrual: The functional layer of the endometrium is shed.
- Proliferative: The functional layer of the endometrium is rebuilt.
- Secretory: Begins immediately after ovulation. Enrichment of the blood supply and glandular secretion of nutrients prepare the endometrium to receive an embryo.

Both the menstrual and proliferative phases occur before ovulation, and together they correspond to the follicular phase of the ovarian cycle. The secretory phase corresponds in time to the luteal phase of the ovarian cycle.

Figure 27.25 Correlation of anterior pituitary and ovarian hormones with structural changes of the ovary and uterus. Note that the end of day 28 of the current cycle marks the beginning (day 0) of the first day of the next cycle.

As noted earlier, if fertilization has not occurred, the corpus luteum degenerates toward the end of the secretory phase as LH blood levels decline. Progesterone levels fall, depriving the endometrium of hormonal support, and the spiral arteries kink and go into spasms. Denied oxygen and nutrients, the ischemic endometrial cells die and the glands regress, setting the stage for menstruation to begin again. The spiral arteries constrict one final time and then suddenly relax and open wide. As blood floods into the weakened capillary beds, they fragment, causing the functional layer to slough off. The uterine cycle starts over again on this first day of menstrual flow.

Figure 27.25b and d also illustrate how the ovarian and uterine cycles fit together. Notice that the menstrual and proliferative phases overlap the follicular phase and ovulation in the ovarian cycle, and that the uterine secretory phase corresponds to the ovarian luteal phase.

HOMEOSTATIC IMBALANCE 27.9 CLINICAL

Extremely strenuous physical activity can delay menarche in girls. Very low levels of body fat in female athletes can also cause *amenorrhea* (a-men″o-re′ah), cessation of menstruation. This is because adipose cells help convert adrenal androgens to estrogens and are the source of leptin which, as noted above, plays a critical permissive role in the onset of puberty in females. Leptin informs the hypothalamus whether energy stores are sufficient to support the high energy demands of reproduction. If not, the reproductive cycles are shut down.

Amenorrhea is usually reversible if the woman increases her body fat, but it has a worrisome consequence in young, healthy adult women: dramatic losses in bone mass normally seen only in osteoporosis of old age. Once estrogen levels drop and the menstrual cycle stops (regardless of cause), bone loss begins.

Effects of Estrogens and Progesterone

With a name meaning "generators of sexual activity," estrogens are analogous to testosterone, the male steroid. As estrogen levels rise during puberty, they:

- Promote oogenesis and follicle growth in the ovary
- Exert anabolic effects on the female reproductive tract (**Table 27.2**)

Consequently, the uterine tubes, uterus, and vagina enlarge and become functional—more ready to support a pregnancy. The uterine tubes and uterus exhibit enhanced motility; the vaginal mucosa thickens; and the external genitalia mature.

Estrogens also support the growth spurt at puberty that makes girls grow much more quickly than boys between the ages of 11 and 12. But this growth is short-lived because rising estrogen levels also cause the epiphyses of long bones to close (◀ p. 188), and so females reach their full height between the ages of 13 and 15. In contrast, the aggressive growth of males continues until ages 15 to 19, at which point rising estrogen levels cause epiphyseal closure.

The estrogen-induced secondary sex characteristics of females include:

- Breast development
- Increasing deposition of subcutaneous fat, especially in the hips and breasts
- Development of a wider and lighter pelvis (adaptations for childbirth)

Estrogens also have several metabolic effects, including maintaining low total blood cholesterol levels (and high HDL levels, ◀ p. 956) and facilitating calcium uptake, which helps sustain the density of the skeleton. These metabolic effects begin under estrogens' influence during puberty, but they are not true secondary sex characteristics.

Progesterone works with estrogens to establish and then help regulate the uterine cycle, and promotes changes in cervical mucus. Its other effects are exhibited largely during pregnancy, when it inhibits uterine motility and takes up where estrogens leave off in preparing the breasts for lactation. Indeed, progesterone is named for these important roles (*pro* = for, *gestation* = pregnancy). However, the source of progesterone and estrogens during most of pregnancy is the placenta, not the ovaries.

27.16 The female sexual response is more diverse and complex than that of males

Learning Outcome

▶ **Describe the phases of the female sexual response.**

The **female sexual response** is similar to that of males in many respects. During sexual excitement, the clitoris, vaginal mucosa, bulbs of the vestibule, and breasts engorge with blood and the nipples become erect. Increased activity of the greater vestibular glands and seepage from the vaginal walls lubricate the vestibule to facilitate entry of the penis. These events, though more widespread, are analogous to the *erection* phase in men. Touch

Table 27.2 Summary of Hormonal Effects of Gonadal Estrogens, Progesterone, and Testosterone

SOURCE, STIMULUS, EFFECTS	ESTROGENS (MOSTLY ESTRADIOL)	PROGESTERONE	TESTOSTERONE
Major source	Ovary: developing follicles and corpus luteum.	Ovary: mainly the corpus luteum.	Testes: interstitial endocrine cells.
Stimulus for release	FSH (and LH).	LH.	LH.
Feedback effects exerted	Both negative and positive feedback on gonadotropin release by the anterior pituitary and GnRH release by the hypothalamus.	Negative feedback on gonadotropin release by the anterior pituitary and GnRH release by the hypothalamus.	Negative feedback on gonadotropin release by the anterior pituitary and GnRH release by the hypothalamus.
Effects on reproductive organs	Stimulate growth and maturation of reproductive organs and breasts at puberty and maintain their adult size and function. Promote the proliferative phase of the uterine cycle. Stimulate production of watery cervical mucus and activity of fimbriae and uterine tube cilia. Promote oogenesis and ovulation. During pregnancy, stimulate growth of the uterus and enlargement of the external genitalia and mammary glands.	Cooperates with estrogens in stimulating growth of breasts. Promotes the secretory phase of the uterine cycle. Stimulates production of viscous cervical mucus. Progesterone surge after ovulation enhances beating of cilia in the uterine tube, promoting meeting of sperm and oocyte. During pregnancy, quiets the myometrium and acts with estrogens to cause mammary glands to achieve their mature milk-producing state.	Stimulates formation of male reproductive ducts, glands, and external genitalia. Promotes descent of the testes. Stimulates growth and maturation of the internal and external genitalia at puberty; maintains their adult size and function. Required for normal spermatogenesis; ABP keeps its concentration high near spermatogenic cells.
Promotion of secondary sex characteristics and somatic effects	Promote long bone growth followed by epiphyseal closure, and feminization of the skeleton (particularly the pelvis); inhibit bone reabsorption. Promote female pattern of fat deposit.		Promotes (after conversion to estrogens) long bone growth followed by epiphyseal closure; promotes increased skeletal and muscle mass during adolescence. Promotes growth of the larynx and vocal cords and deepening of the voice. Enhances sebum secretion and hair growth, especially on the face, axillae, genital region, and chest.
Metabolic effects	Generally anabolic. Stimulate Na^+ reabsorption by the renal tubules, which inhibits diuresis. Enhance HDL (and reduce LDL) blood levels (cardiovascular sparing effect).	Promotes diuresis (antiestrogenic effect). Increases body temperature.	Generally anabolic. Stimulates hematopoiesis. Enhances the basal metabolic rate.
Neural effects	Along with DHEA (an androgen produced by the adrenal cortex) are partially responsible for female libido (sex drive).		Responsible for libido in males; promotes aggressiveness.

and psychological stimuli promote sexual excitement, which is mediated along the same autonomic nerve pathways as in males.

The final phase of the female sexual response, *orgasm*, is not accompanied by ejaculation. However, muscle tension increases throughout the body, pulse rate and blood pressure rise, and the uterus contracts rhythmically. As in males, orgasm is accompanied by a sensation of intense pleasure followed by relaxation. But unlike what is seen in males, a refractory period does not follow orgasm, so females may experience multiple orgasms during a single sexual experience. Female orgasm is not required for conception. Indeed, some women never experience orgasm, yet are perfectly able to conceive.

It is unclear which hormones are most closely associated with sexual desire in females. Female libido seems to be driven by both estrogens and dehydroepiandrosterone (DHEA), an androgen produced by the adrenal cortex (see gonadocorticoids, ◀ p. 626).

PART 5

CLINICAL

SEXUALLY TRANSMITTED INFECTIONS

27.17 Sexually transmitted infections cause reproductive and other disorders

Learning Outcome

- **Indicate the infectious agents and modes of transmission of chlamydia, trichomoniasis, gonorrhea, syphilis, genital warts, and genital herpes.**

Sexually transmitted infections (STIs), also called *sexually transmitted diseases* (*STDs*), are infectious diseases spread through sexual contact. The United States has the highest rates of infection among developed countries. About 20 million people in the U.S. each year get STIs, which are the single most important cause of reproductive disorders. The first STI you might think of is HIV, which we discussed in Chapter 21 (◀ p. 811), but there are many more common ones. The last few years have seen a dramatic rise in STIs, particularly among 15- to 24-year-olds. Transmission of all STIs can be reduced through the consistent use of condoms.

Bacterial and Parasitic Sexually Transmitted Infections

Chlamydia

Chlamydia (klah-mid′e-ah; *chlamys* = cloak) is the most common bacterial STI in the U.S. *Chlamydia trachomatis* is a bacterium with a viruslike dependence on host cells. Its incubation period may be up to several weeks.

Most infections are silent (asymptomatic)—only about 20% of women and 10% of men have symptoms. These can include urethritis (painful, frequent urination); penile or vaginal discharge; abdominal, rectal, or testicular pain; painful intercourse; and irregular menses. In women, chlamydia is responsible for 25–50% of all cases of pelvic inflammatory disease and is a major cause of sterility. Newborns infected during birth tend to develop conjunctivitis, a painful eye infection that leads to corneal scarring if untreated, and respiratory tract inflammations including pneumonia. Chlamydia can easily be cured with antibiotics.

Trichomoniasis

Trichomoniasis is a parasitic infection that is more common in women than men. It is easily and inexpensively treated. While 70% of women have no symptoms, a characteristic yellow-green vaginal discharge with a strong odor is sometimes present.

Gonorrhea

The causative agent of **gonorrhea** (gon″o-re′ah) is *Neisseria gonorrhoeae*, which invades the mucosae of the reproductive and urinary tracts. Like chlamydia, most infections are asymptomatic.

In men, the most common symptom of gonorrhea is *urethritis*, inflammation of the urethra accompanied by painful urination and discharge of pus from the penis (penile "drip"). Symptoms vary in women, but can include abdominal discomfort, vaginal discharge, abnormal uterine bleeding, and occasionally, urethral symptoms similar to those seen in males.

In men, untreated gonorrhea can cause urethral constriction and inflammation of the entire duct system. In women, it causes pelvic inflammatory disease and sterility. Gonorrhea is becoming increasingly resistant to antibiotics and now requires treatment with at least two antibiotics simultaneously.

Syphilis

Syphilis (sif′ĭ-lis), caused by the corkscrew-shaped bacterium *Treponema pallidum*, is usually transmitted sexually, but it can be contracted congenitally from an infected mother. Fetuses infected with syphilis are usually stillborn or die shortly after birth.

The bacterium easily penetrates intact mucosae and abraded skin. Within a few hours of exposure, an asymptomatic body-wide infection is in progress. After an incubation period of about three weeks, a red, painless primary lesion called a *chancre* (shang′ker) appears at the site of bacterial invasion. In males, this is typically the penis, but in females the lesion often goes undetected within the vagina or on the cervix. The chancre ulcerates and becomes crusty, and then heals spontaneously and disappears within a few weeks.

Secondary signs of untreated syphilis appear several weeks later. A pink skin rash all over the body is one of the first symptoms. Fever and joint pain are common. These signs and symptoms disappear spontaneously in three to twelve weeks. Then the disease enters the *latent period* and is detectable only by a blood test. The latent stage may last a person's lifetime (or the immune system may kill the bacteria), or it may be followed by *tertiary syphilis*.

Tertiary syphilis is characterized by destructive lesions of the CNS, blood vessels, bones, and skin. Penicillin is still the treatment of choice for all stages of syphilis.

Viral Sexually Transmitted Infections

While a number of viruses (such as hepatitis, Ebola, and Zika) can be transmitted sexually, we limit our discussion here to those viruses that are *primarily* transmitted sexually.

Human Papillomavirus (HPV)

Infection by the **human papillomavirus (HPV)**—actually a group of about 40 viruses—is the most common STI in the United States. More than half of adults are infected during their lifetime. Although HPV causes **genital warts**, the long-term concern is that HPV causes cancers in infected body regions. The virus is linked not only to 80% of all cases of invasive cervical cancer (see Homeostatic Imbalance 27.6, p. 1064) but also to penile, anal, and oropharyngeal cancers.

Vaccination can guard against infection by the most common cancer-causing strains of HPV, and is recommended for both girls and boys before they become sexually active.

Genital Herpes

The cause of **genital herpes** is the *herpes simplex virus*, and these viruses are among the most difficult human pathogens to

control. In part, this is because most people who have genital herpes do not know they have it and can shed the virus while symptom free. Only about 15% of infected individuals display signs of infection.

Characteristic blisterlike lesions may flare up repeatedly over time. The painful lesions that appear on the reproductive organs of infected adults are usually more of a nuisance than a threat. However, congenital herpes infections can cause severe malformations of a fetus. The virus is transmitted via infectious secretions or direct skin-to-skin contact.

Antiviral drugs can reduce the duration and intensity of the flare-ups. However, once contracted, genital herpes never leaves. It just goes into periodic remissions.

42. Which pathogen is most associated with cervical cancer?

43. What is the most common bacterial STI in the United States?

For answers, see Answers Appendix.

Developmental Aspects of the Reproductive System

So far, we have described the reproductive organs as they exist and operate in adults. Now we are ready to look at events that cause us to become reproductive individuals. These events begin long before birth and end, at least in women, in late middle age.

Embryological and Fetal Events

Determination of Genetic Sex

Aristotle believed that the "heat" of lovemaking determined maleness of the offspring. Not so! Genetic sex is determined at the instant the genes of a sperm combine with those of an ovum, and the determining factor is the **sex chromosomes** each gamete contains. Of the 46 chromosomes in the fertilized egg, two (one pair) are sex chromosomes. The other 44 are called **autosomes**.

Two types of sex chromosomes, quite different in size, exist in humans: the large **X chromosome** and the much smaller **Y chromosome**. The body cells of females have two X chromosomes and are designated XX, and the ovum resulting from normal meiosis in a female always contains an X chromosome (**Figure 27.26**). Males have one X chromosome and one Y in each body cell (XY).

If the fertilizing sperm delivers an X chromosome, the fertilized egg and its daughter cells will contain the female (XX) composition, and the embryo will develop ovaries. If the sperm bears a Y chromosome, the offspring will be male (XY) and will develop testes. The presence of a single gene on the Y chromosome—the **SRY** (for **s**ex-determining **r**egion of the **Y** chromosome) **gene**—determines maleness by initiating testes development. In this way, the father's gamete determines the genetic sex of the offspring. All subsequent events of sexual differentiation depend on which gonads form during embryonic life.

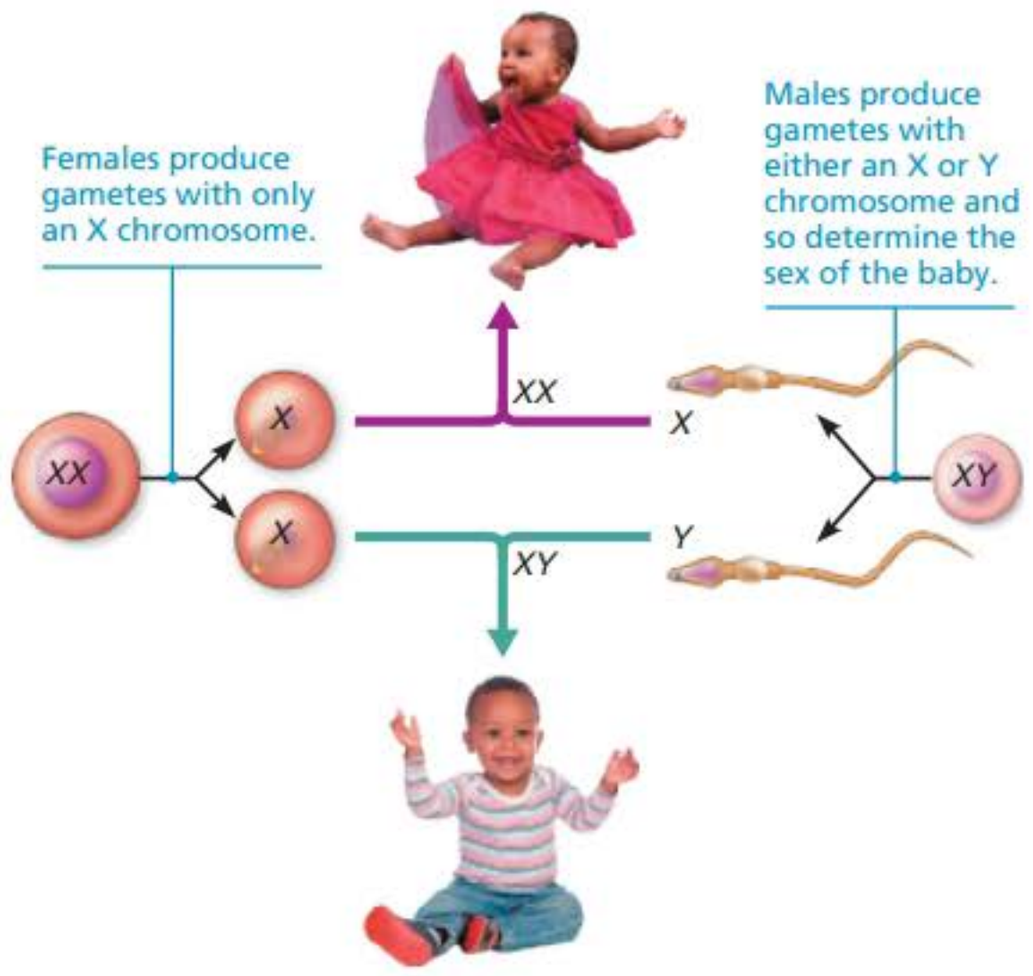

Figure 27.26 Genetic determination of sex. The male gamete determines the sex of the baby.

HOMEOSTATIC IMBALANCE 27.10 CLINICAL

When meiosis distributes the sex chromosomes to the gametes improperly (an event called **nondisjunction**, see Related Clinical Terms, p. 1135), abnormal combinations of sex chromosomes in the zygote (fertilized egg) result. If the sex chromosomes are involved, striking **disorders of sex development (DSD)** follow. These are named using the total number of chromosomes and the complement of X and Y chromosomes.

For example, females with a single X chromosome (XO), a condition called *Turner's syndrome* (45,XO DSD), never develop ovaries. Women with Turner's syndrome usually have short stature and are at risk for some heart defects and specific learning disabilities.

Klinefelter's syndrome (47,XXY DSD), which affects one out of 500 live male births, is the most common sex chromosome abnormality. Affected individuals usually have a single Y chromosome, two or more X chromosomes, and are sterile males. Although XXY males are normal (or only slightly below normal) intellectually, the incidence of intellectual disability increases as the number of X chromosomes rises.

Sexual Differentiation of the Reproductive System

Differentiation of accessory structures and the external genitalia into male or female structures depends on whether testosterone is present. When testes form in response to *SRY*, they release testosterone, which causes the development of male accessory ducts and external genitalia. In the absence of testosterone, the female ducts and external genitalia develop.

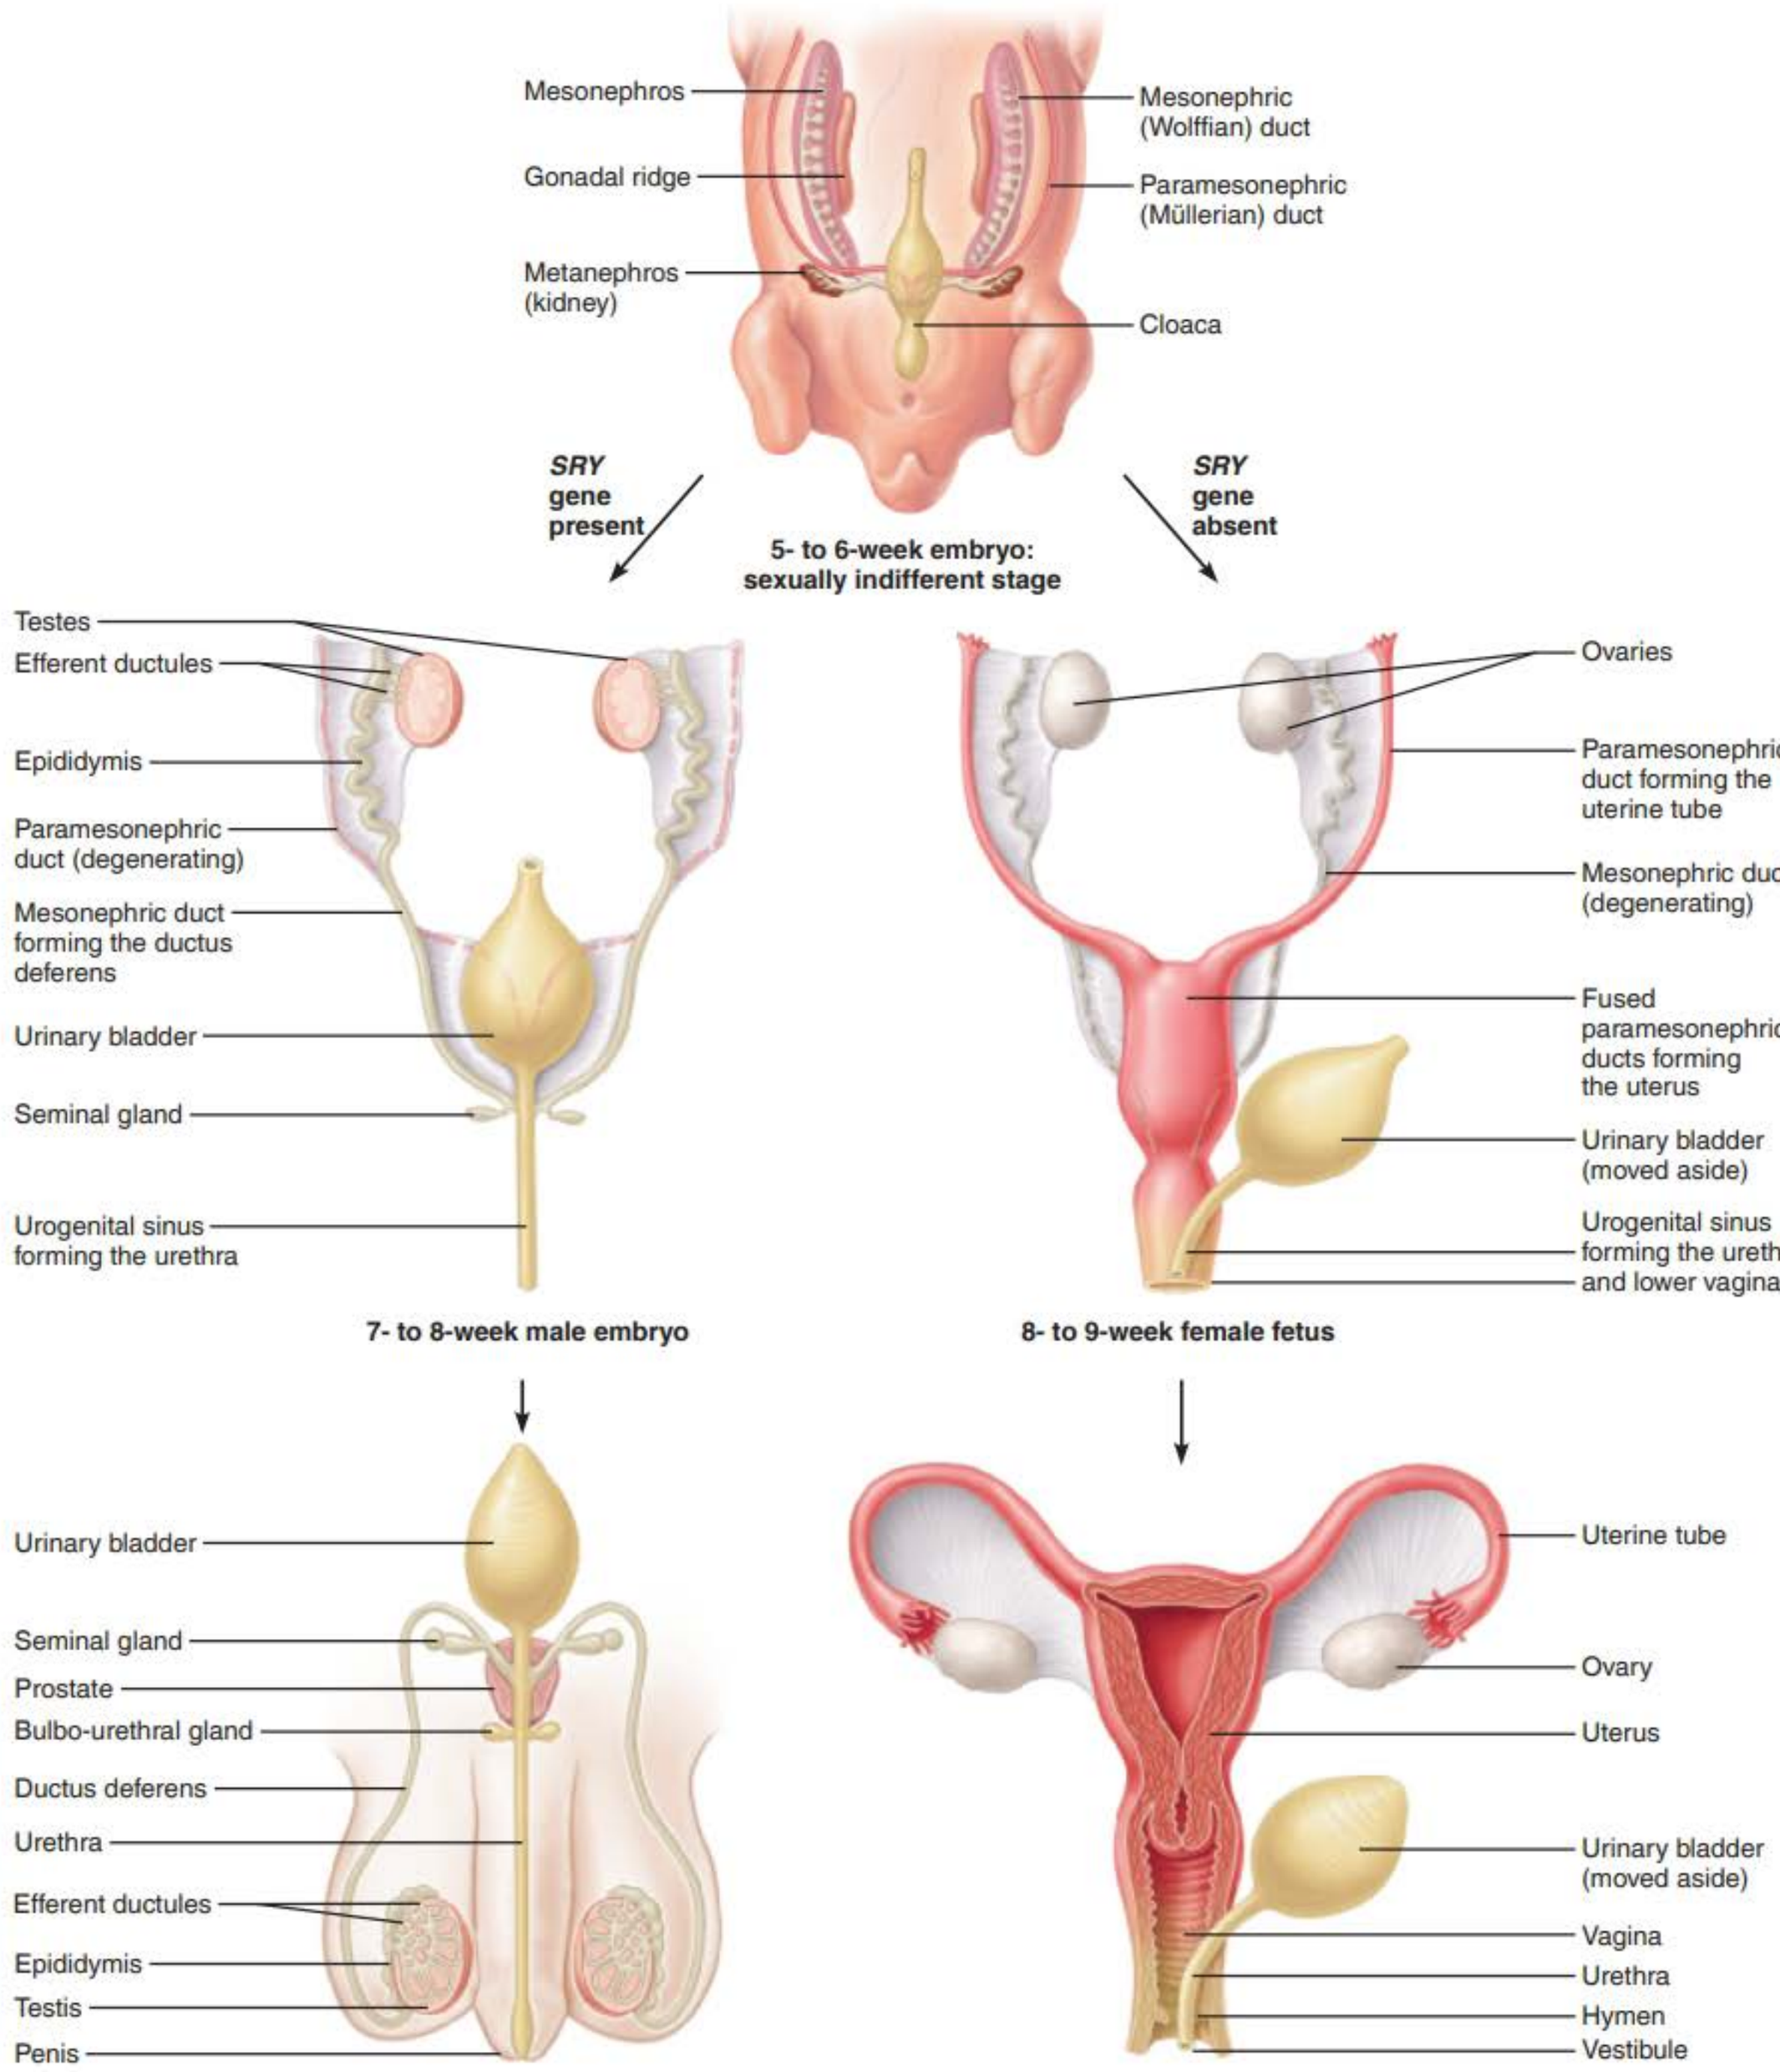

Figure 27.27 Development of the internal reproductive organs. (*SRY* = sex-determining region of the Y chromosome)

The gonads begin to develop during week 5 of gestation as masses of mesoderm called the **gonadal ridges** (**Figure 27.27**). These ridges bulge from the dorsal abdominal wall just medial to the mesonephros (a transient kidney system, ◀ p. 1006). The **paramesonephric**, or *Müllerian*, **ducts** (future female ducts) develop lateral to the **mesonephric** (*Wolffian*) **ducts** (future male ducts). Both sets of ducts empty into a common chamber called the *cloaca*. At this stage of development, the embryo is said to be in the **sexually indifferent stage**, because the gonadal ridge tissue can develop into either male or female gonads and both duct systems are present.

Shortly after the gonadal ridges appear, **primordial germ cells** migrate to them from the yolk sac (described in Chapter 28). There they seed the developing gonads with stem cells destined to become spermatogonia or oogonia. Once these cells are in residence, the gonadal ridges form testes or ovaries, depending on the genetic makeup of the embryo.

In male embryos, the process of forming the testes begins in week 7. (1) Seminiferous tubules form in the internal part of the gonadal ridges and join the mesonephric duct via the efferent ductules. (2) Further development of the mesonephric duct produces the duct system of the male. (3) The paramesonephric ducts degenerate.

In female embryos the process of gonad formation begins about a week later. (1) The cortical part of each immature ovary forms follicles. (2) The paramesonephric ducts differentiate into the structures of the female duct system. (3) The mesonephric ducts degenerate.

Like the gonads, the external genitalia arise from the same structures in both sexes (**Figure 27.28**). During the sexually

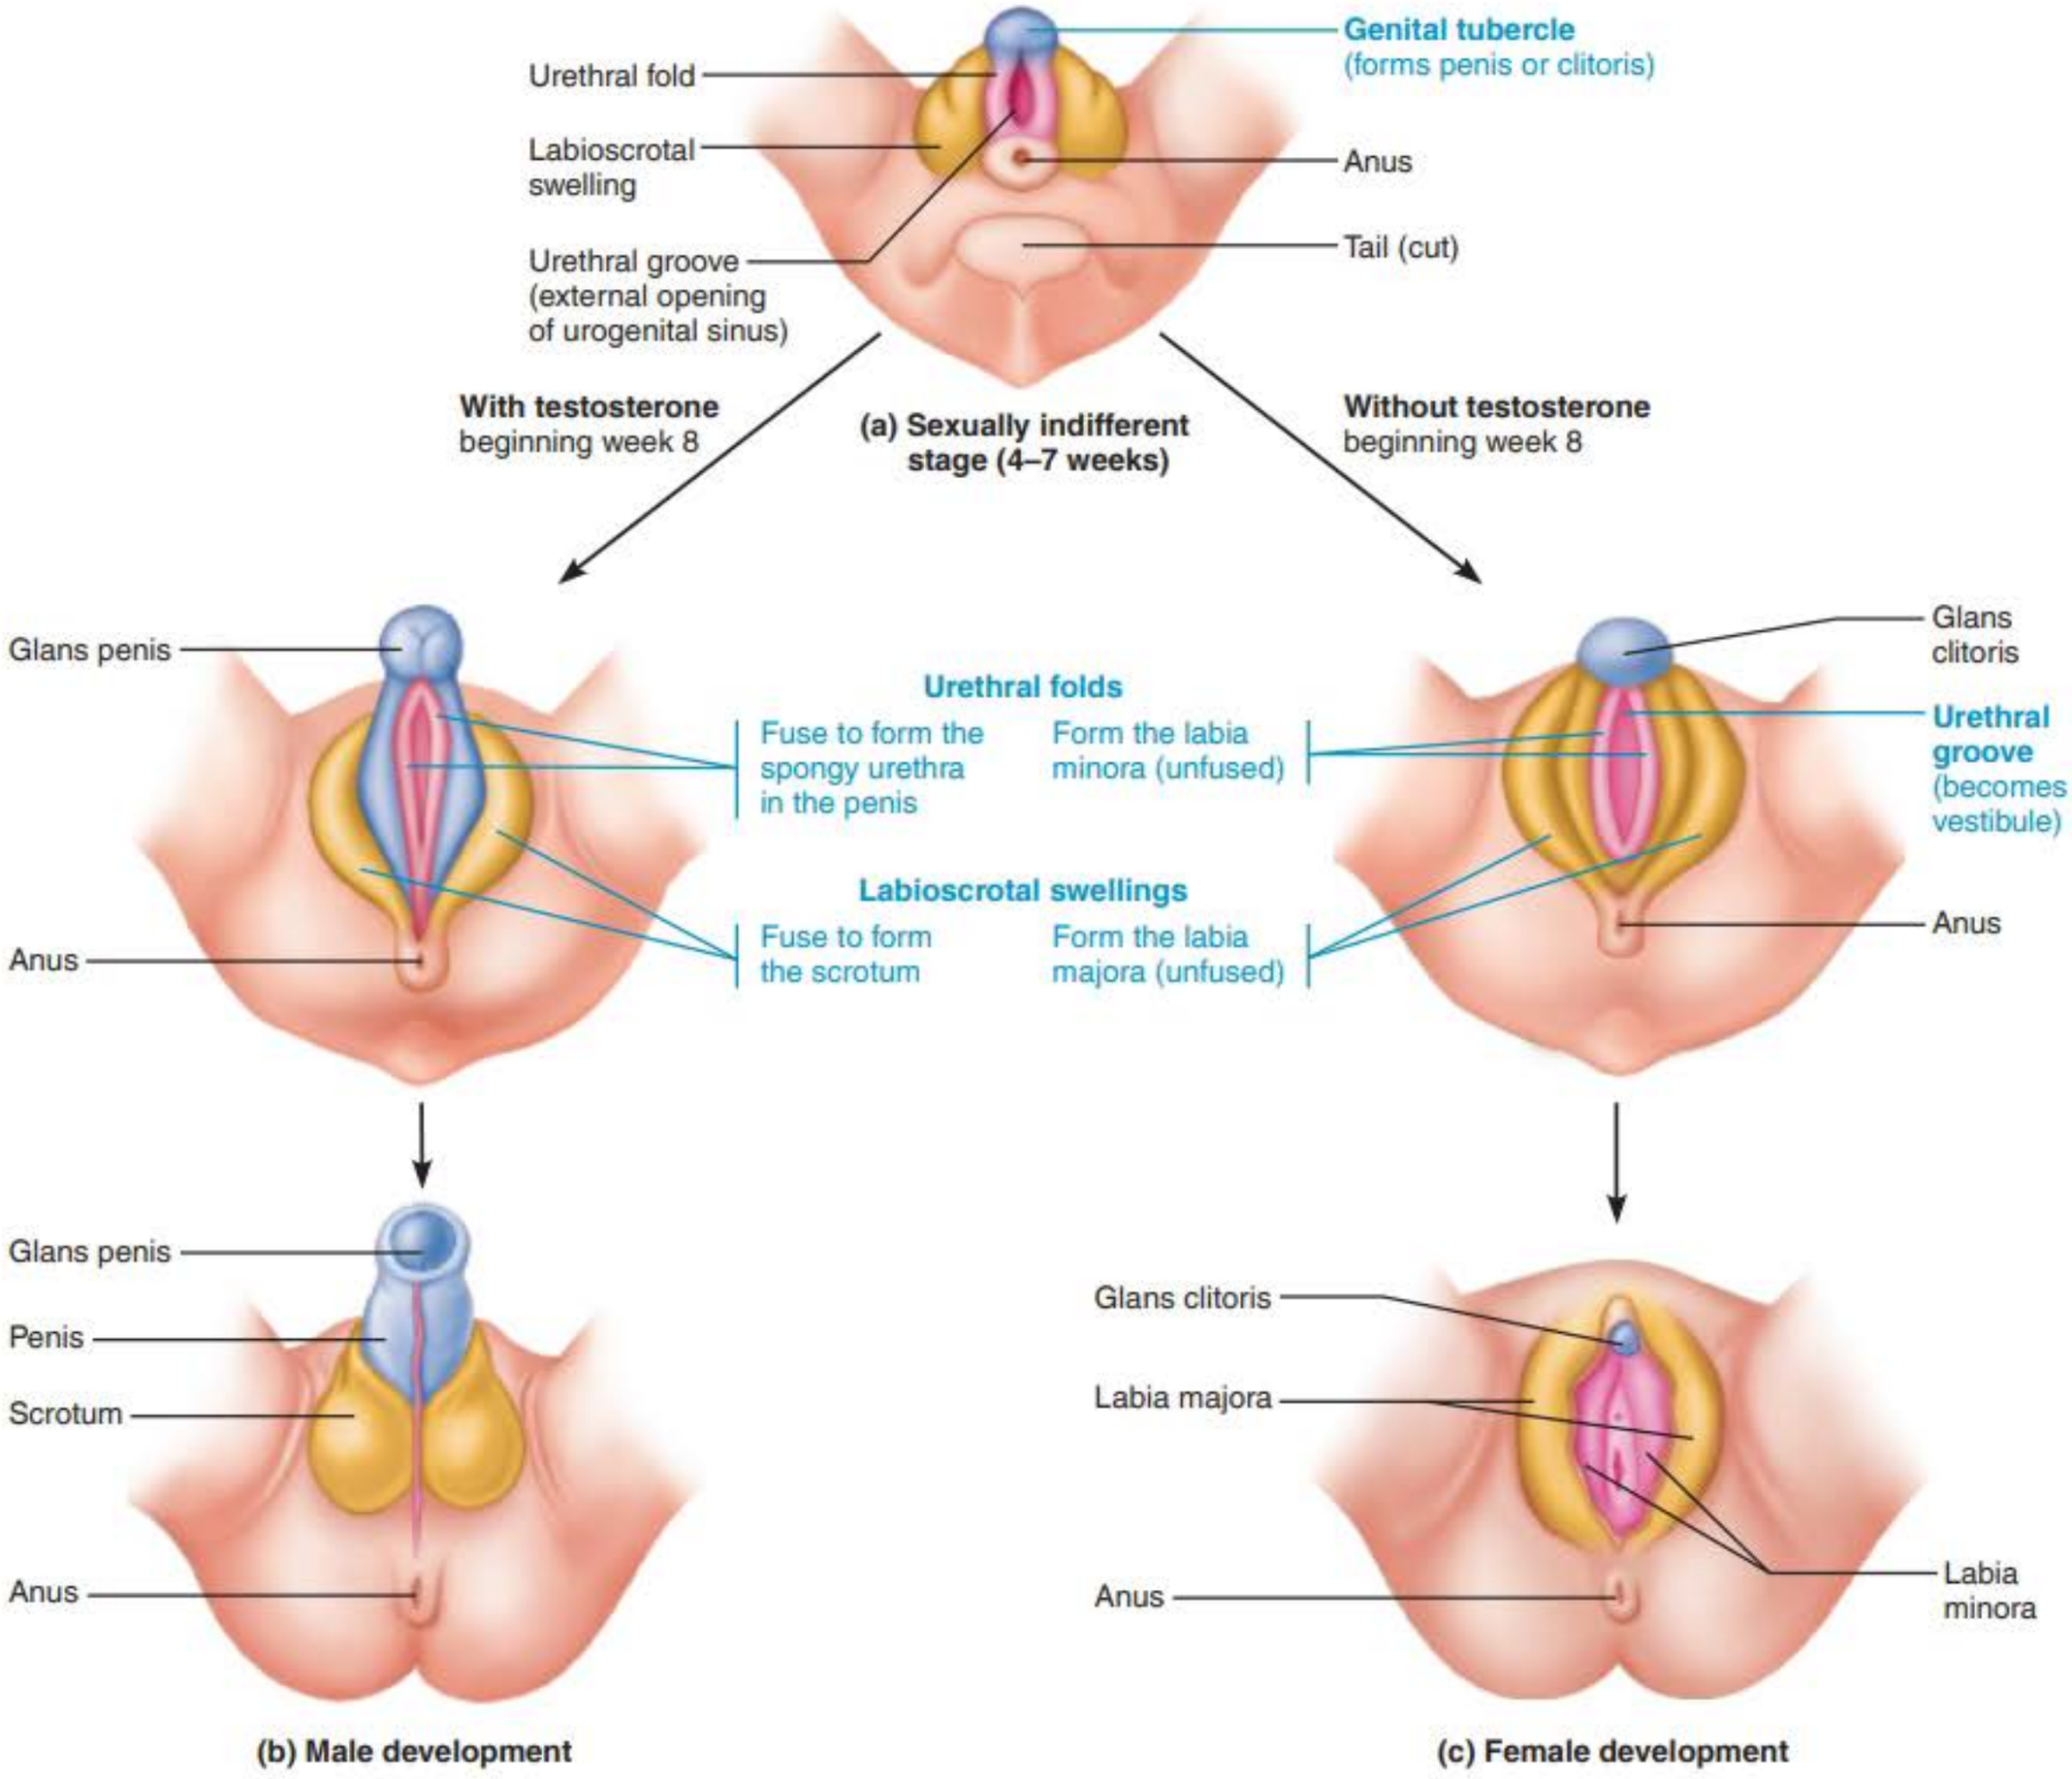

Figure 27.28 Development of homologous structures of the external genitalia in both sexes. The two pictures at the bottom of the figure show the fully developed perineum.

indifferent stage, all embryos exhibit a small external projection called the **genital tubercle**. The urogenital sinus (future bladder and urethra), which develops by subdivision of the cloaca, lies deep to the tubercle. The **urethral groove**, the external opening of the urogenital sinus, is on the tubercle's inferior surface and is flanked laterally by the **urethral folds** and then the **labioscrotal swellings**. Figure 27.28 shows the sequence of events in males and females.

HOMEOSTATIC IMBALANCE 27.11 CLINICAL

Any interference with the normal pattern of sex hormone production in the embryo results in abnormalities. For example:

- If the embryonic testes do not produce testosterone, a genetic male develops female accessory structures and external genitalia.
- If a genetic female is exposed to testosterone (as might happen if the mother has an androgen-producing tumor of her adrenal gland), the embryo has ovaries but develops the male ducts and glands, as well as a penis and an empty scrotum.

The female pattern of reproductive structures has an intrinsic ability to develop. In the absence of testosterone it proceeds to do so, regardless of the embryo's genetic makeup. In many cases, however, the external genitalia are ambiguous (neither fully male nor female).

Individuals with external genitalia that do not "match" their gonads are *intersex*. Intersex individuals sometimes have surgery to match their outer selves (external genitalia) with their inner selves (gonads).

Descent of the Gonads

About two months before birth, the testes begin their descent toward the scrotum, dragging their supplying blood vessels and nerves along behind them. They finally exit from the pelvic cavity via the inguinal canals and enter the scrotum. Testosterone made by the fetus's testes stimulates this migration. The migration is mechanically guided by a strong fibrous cord called the **gubernaculum** ("governor"), which extends from the testis to the floor of the scrotal sac.

Initially the gubernaculum is a column of soft connective tissue, but it becomes increasingly fibrous as it continues to grow. By the seventh month of fetal development, it stops growing. The gubernaculum's cessation of growth, coupled with rapid growth of the fetal body, helps to pull the testes into the scrotum.

The *tunica vaginalis* covering of the testis is derived from a fingerlike outpocketing of the parietal peritoneum, the *vaginal process*. The accompanying blood vessels, nerves, and fascial layers form part of the *spermatic cord*, which helps suspend the testis within the scrotum.

Like the testes, the ovaries descend during fetal development, but in this case only to the pelvic brim, where the tentlike broad ligament stops their progress. Each ovary is guided in its descent by a gubernaculum that later divides, becoming the ovarian and round ligaments that help support the internal genitalia in the pelvis.

HOMEOSTATIC IMBALANCE 27.12 CLINICAL

Failure of the testes to make their normal descent leads to *cryptorchidism* (*crypt* = hidden, concealed; *orchi* = testicle). Because cryptorchidism causes sterility and increases the risk of testicular cancer, surgery is usually performed during early childhood to rectify this problem.

Puberty

The events of puberty occur in the same sequence in all individuals, but the age at which they occur varies widely. Puberty usually occurs between the ages of 10 and 15 as a consequence of the maturation of the hypothalamic-pituitary-gonadal axis (◀ p. 1043).

In males, secretion of adrenal androgens, particularly dehydroepiandrosterone (DHEA; ◀ p. 626), begins to rise several years before the testosterone surge of puberty and initiates facial, pubic, and axillary hair growth and other pubertal events. The major event that signals puberty's onset in males is enlargement of the testes and scrotum between the ages of 8 and 14. The penis grows over the next two years, and sexual maturation is evidenced by the presence of mature sperm in the semen (see Figure 27.14). In the meantime, the young man has unexpected erections and occasional nocturnal emissions ("wet dreams") as his hormones surge and the hormonal control axis struggles to achieve a normal balance.

In females, the first sign of puberty is budding breasts between the ages of 8 and 13, followed by the appearance of axillary and pubic hair. Menarche usually occurs about two years later, but dependable ovulation and fertility takes nearly two more years.

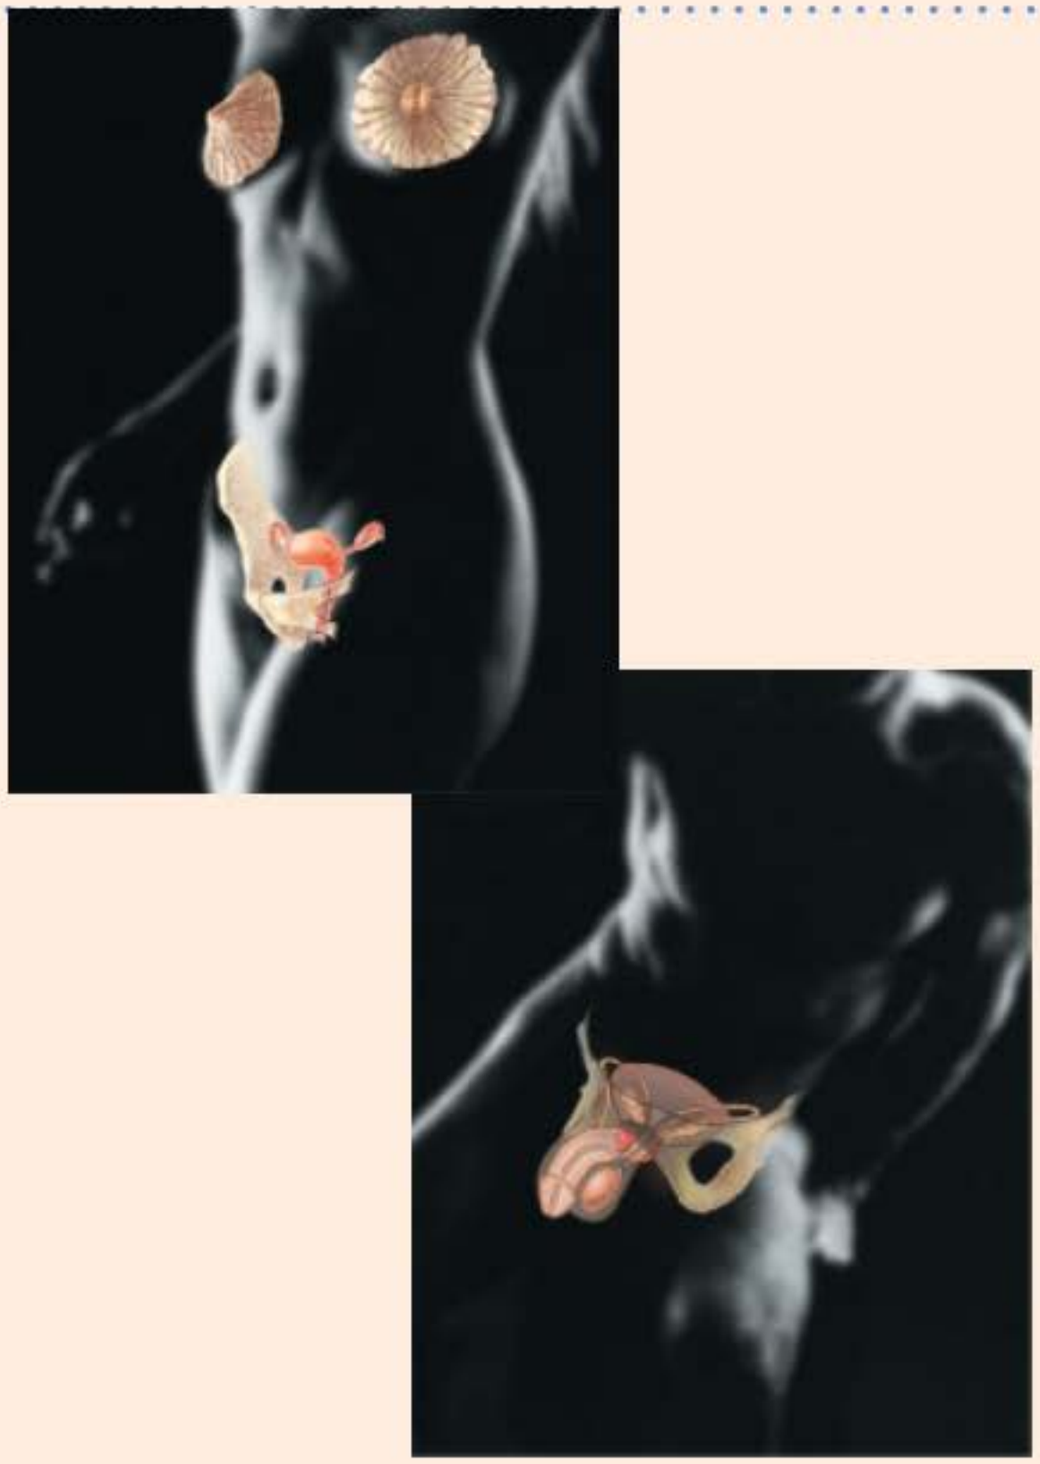
Menopause

Most women reach the peak of their reproductive abilities in their late 20s. At age 30, there are still some 100,000 oocytes in the ovaries but their quality (fertility) has begun to decline. By age 50, there are about 1000 eggs left. As the number of follicles decreases, the total amount of estrogen produced also decreases until at last the feedback loop with the anterior pituitary and hypothalamus fails. As a result, cyclical hormone changes no longer occur.

As estrogen production declines, many ovarian cycles become anovulatory, while in others 2 to 4 oocytes per month are ovulated. This sign of declining control explains why twins and triplets are more common in older women. In the perimenopausal period, menstrual periods become erratic and shorter. Eventually, ovulation and menstruation cease entirely. This normally occurs between the ages of 46 and 54, an event called *menopause*. **Menopause** is considered to have occurred when a year has passed without menstruation.

Although the ovaries continue to produce estrogens for a while after menopause, they finally stop producing hormones. Without sufficient estrogens the reproductive organs and breasts begin to atrophy, the vagina becomes dry, and vaginal

Homeostatic Interrelationships between the Reproductive System and Other Body Systems



Integumentary System Chapter 5

- Androgens activate oil glands that lubricate skin and hair; gonadal hormones stimulate characteristic fat distribution and appearance of pubic and axillary hair; estrogens increase skin hydration, and during pregnancy they enhance facial skin pigmentation
- Skin protects all body organs by external enclosure; mammary gland secretions (milk) nourish the infant

Skeletal System Chapters 6–8

- Androgens masculinize the skeleton and increase bone density; estrogens feminize the skeleton and maintain bone mass in females
- The pelvis encloses some reproductive organs; if narrow, the pelvis may hinder vaginal delivery of an infant

Muscular System Chapters 9–10

- Androgens promote increased muscle mass
- Abdominal muscles active during childbirth; muscles of the pelvic floor support reproductive organs and aid erection of penis/clitoris

Nervous System Chapters 11–15

- Sex hormones masculinize or feminize the brain and influence sex drive
- Hypothalamus regulates timing of puberty; neural reflexes regulate events of sexual response

Endocrine System Chapter 16

- Gonadal hormones exert feedback effects on hypothalamic-pituitary axis
- Gonadotropins (and GnRH) help regulate function of gonads; leptin signals the hypothalamus about the body's state of energy availability (in fat stores)

Cardiovascular System Chapters 17–19

- Estrogens lower blood cholesterol levels and promote cardiovascular health in premenopausal women; pregnancy increases workload of the cardiovascular system
- Cardiovascular system transports needed substances to organs of reproductive system; local vasodilation involved in erection; blood transports sex hormones

Lymphatic System/Immunity Chapters 20–21

- Developing embryo/fetus escapes immune surveillance (not rejected)
- Lymphatic vessels drain leaked tissue fluids; transport sex hormones; immune cells protect reproductive organs from disease; IgA is present in breast milk

Respiratory System Chapter 22

- Pregnancy impairs descent of the diaphragm, promotes dyspnea
- Respiratory system provides oxygen; disposes of carbon dioxide; tidal volume increases during pregnancy while residual volume declines

Digestive System Chapter 23

- Developing fetus crowds digestive organs; heartburn, constipation common during pregnancy
- Digestive system provides nutrients needed for health

Urinary System Chapters 25–26

- Hypertrophy of the prostate inhibits urination; compression of bladder during pregnancy leads to urinary frequency and urgency
- Kidneys maintain acid-base balance of blood of mother and fetus and dispose of nitrogenous wastes; semen discharged through the urethra of the male

infections become increasingly common. Other sequels due to lack of estrogens include:

- Intense vasodilation of the skin's blood vessels, which causes uncomfortable, sweat-drenching "hot flashes"
- Gradually thinning skin
- Loss of bone mass

Slowly rising total blood cholesterol levels and falling HDL levels place postmenopausal women at risk for cardiovascular disorders. Irritability and depression occurs in some women.

Estrogen-containing hormone replacement therapy (HRT) is sometimes used to help women with severe menopausal symptoms through this period. Clinical trials have shown that HRT can increase the quality of life, decrease loss of bone mass, and decrease the risk for colon cancer. Surprisingly, despite its beneficial effects on blood lipids, HRT increases the risk for heart disease. HRT also increases the risk of breast cancer because many breast cancers are sensitive to estrogens.

Nonetheless, for women who do not have existing breast cancer, the risks may be outweighed by the benefits of taking the smallest dose of HRT needed to reduce symptoms for the shortest period of time.

There is no equivalent of menopause in males, and healthy men are able to father offspring well into their eighth decade of life. However, aging men do exhibit a steady decline in testosterone secretion and experience a longer latent period after orgasm, a condition sometimes called *andropause*. Additionally, there is a noticeable difference in sperm quality and motility with aging.

RELATED CLINICAL TERMS

Dysmenorrhea (dis″men-ŏ-re′ah; *dys* = bad, *meno* = menses, a month) Painful menstruation; may reflect abnormally high prostaglandin activity during menses.

Endometrial cancer Cancer that arises from the uterine endometrium (usually from uterine glands). Most important sign is vaginal bleeding, which allows early detection. Risk factors include obesity and hormone replacement therapy.

Endometriosis (en″do-me″tre-o′sis) An inflammatory condition in which endometrial tissue occurs and grows atypically in the pelvic cavity. Characterized by abnormal uterine or rectal bleeding, dysmenorrhea, and pelvic pain. May cause sterility.

Gynecology (gi″nĕ-kol′o-je; *gyneco* = woman, *ology* = study of) Specialized branch of medicine that deals with the diagnosis and treatment of female reproductive system disorders.

Gynecomastia (gi″nĕ-ko-mas′te-ah) Development of breast tissue in the male; a consequence of adrenal cortex hypersecretion of estrogens, or certain drugs (cimetidine, spironolactone, and some chemotherapeutic agents).

Hysterectomy (his″tĕ-rek′to-me; *hyster* = uterus, *ectomy* = cut out) Surgical removal of the uterus.

Inguinal hernia Protrusion of part of the intestine into the scrotum or through a separation in the abdominal muscles in the groin region. Since the inguinal canals represent weak points in the abdominal wall, inguinal hernia may be caused by heavy lifting or other activities that increase intra-abdominal pressure.

Laparoscopy (lap″ah-ros′ko-pe; *lapar* = the flank, *scopy* = observation) Examination of the abdominopelvic cavity with a laparoscope, a viewing device at the end of a thin tube inserted through the anterior abdominal wall. Laparoscopy is often used to assess the condition of a woman's pelvic reproductive organs.

Oophorectomy (o″of-o-rek′to-me; *oophor* = ovary) Surgical removal of the ovary.

Orchitis (or-ki′tis; *orcho* = testis) Inflammation of the testes, sometimes caused by the mumps virus.

Ovarian cancer Malignancy that typically arises from the cells in the epithelial covering of the ovary. The fifth most common reproductive system cancer, its incidence increases with age. Early symptoms are nondescript and easily mistaken for other disorders (back pain, abdominal discomfort, nausea, bloating, and flatulence). Diagnosis may involve palpating a mass during a physical exam, visualizing it with ultrasound imaging, or conducting blood tests for a protein marker for ovarian cancer (CA-125). However, medical assessment is often delayed until after metastasis has occurred.

Ovarian cysts Ovarian cysts are nonovulatory, fluid-filled sacs larger than normal follicles in the ovaries. They are extremely common, and the vast majority of these cysts are benign and asymptomatic. They are usually discovered by routine palpation during a pelvic exam or by ultrasound. Some cause abdominal pain or discomfort due to their size. Twisting or rupture may lead to more severe pain. For persistent follicles of more than 5–10 cm, surgery may be required.

Polycystic ovary syndrome The most common endocrinopathy in women and the most common cause of anovulatory infertility. Affects 5–10% of women; characterized by signs of androgen excess, increased cardiovascular risk (evidenced by high blood pressure, decreased HDL cholesterol levels, and high triglycerides); and linked to obesity and some degree of insulin resistance. Treated with insulin-sensitizing drugs.

Prostatitis An acute or chronic inflammatory condition of the prostate that may (or may not) be associated with infection. Acute or chronic bacterial prostatitis is usually caused by *E. coli*.

Salpingitis (sal″pin-ji′tis; *salpingo* = uterine tube) Inflammation of the uterine tubes.

CHAPTER SUMMARY

1. The function of the reproductive system is to produce offspring. The gonads produce gametes (sperm or ova) and sex hormones. All other reproductive organs are accessory organs.

27.1 The male and female reproductive systems share common features (pp. 1042–1047)

1. The gonads (testes or ovaries) are the primary sex organs. They produce gametes (sperm or eggs) and sex hormones. The gonads (and many other reproductive structures) are homologous structures.
2. In both males and females, secretion of reproductive hormones is regulated by interactions along the hypothalamic-pituitary-gonadal (HPG) axis. GnRH, produced by the hypothalamus, stimulates the anterior pituitary gland to release FSH and LH. These, in turn, stimulate the secretion of steroid hormones from the gonads. Beginning at puberty, the HPG axis becomes established.
3. Meiosis, the basis of gamete production, consists of two consecutive nuclear divisions without DNA replication in between. Meiosis reduces the chromosomal number by half and introduces genetic variability. Events unique to meiosis include synapsis and crossing over of homologous chromosomes.

PART 1
ANATOMY OF THE MALE REPRODUCTIVE SYSTEM

27.2 The testes are enclosed and protected by the scrotum (pp. 1048–1049)

1. The scrotum contains the testes. It provides a temperature slightly lower than body temperature, as required to produce viable sperm.
2. Each testis is covered externally by a tunica albuginea that extends internally to divide the testis into many lobules. Each lobule contains sperm-producing seminiferous tubules.

27.3 Sperm travel from the testes to the body exterior through a system of ducts (p. 1050)

1. The epididymis hugs the external surface of the testis and serves as a site for sperm maturation and storage.
2. The ductus (vas) deferens, extending from the epididymis to the ejaculatory duct, propels sperm into the urethra by peristalsis during ejaculation. Its terminus fuses with the duct of the seminal gland, forming the ejaculatory duct, which empties into the urethra within the prostate.
3. The urethra extends from the urinary bladder to the tip of the penis. It conducts semen and urine to the body exterior.

27.4 The penis is the copulatory organ of the male (pp. 1050–1052)

1. The penis is largely erectile tissue (corpus spongiosum and corpora cavernosa). Engorgement of the erectile tissue with blood causes the penis to become rigid, an event called erection.
2. The male perineum, which suspends the scrotum and penis, is the region encompassed by the pubic symphysis, ischial tuberosities, and coccyx.

27.5 The male accessory glands produce the bulk of semen (pp. 1052–1053)

1. The accessory glands include the seminal glands, the prostate, and the bulbo-urethral glands. Semen contains fructose from the seminal glands, an activating fluid from the prostate, and mucus from the bulbo-urethral glands.
2. Semen is an alkaline fluid that dilutes and transports sperm. Important chemicals in semen are nutrients, prostaglandins, and antibiotic chemicals.

PART 2
PHYSIOLOGY OF THE MALE REPRODUCTIVE SYSTEM

27.6 The male sexual response includes erection and ejaculation (pp. 1053–1054)

1. Parasympathetic reflexes control erection.
2. Ejaculation is expulsion of semen from the male duct system, promoted by the sympathetic nervous system. Ejaculation is part of male orgasm, which also includes pleasurable sensations and increased pulse and blood pressure.

27.7 Spermatogenesis is the sequence of events that leads to formation of sperm (pp. 1054–1058)

1. Spermatogenesis, the production of male gametes in the seminiferous tubules, begins at puberty.
2. Interstitial endocrine cells, located in connective tissue between seminiferous tubules, secrete testosterone.
3. Spermatogonia divide by mitosis to maintain the germ cell line. Some of their progeny become primary spermatocytes, which undergo meiosis I to produce secondary spermatocytes. Secondary spermatocytes undergo meiosis II, each producing two haploid (n) spermatids.
4. Spermiogenesis converts spermatids to functional sperm, stripping away superfluous cytoplasm and producing an acrosome and a flagellum (tail).
5. Sustentocytes form the blood testis barrier, nourish spermatogenic cells, move them toward the lumen of the tubules, and secrete fluid for sperm transport.

27.8 Male reproductive function is regulated by hypothalamic, anterior pituitary, and testicular hormones (pp. 1059–1060)

1. FSH causes sustentocytes to produce androgen-binding protein (ABP). LH stimulates interstitial endocrine cells to release testosterone, which binds to ABP, stimulating spermatogenesis. Testosterone feeds back to inhibit the hypothalamus and anterior pituitary. Inhibin, released by sustentocytes, inhibits FSH release.
2. Maturation of hormonal controls occurs during puberty and takes about three years.
3. Testosterone stimulates maturation of the male reproductive organs and triggers the development of the secondary sex characteristics of the male. It exerts anabolic effects on the skeleton and skeletal muscles, stimulates spermatogenesis, and is responsible for male sex drive.

PART 3
ANATOMY OF THE FEMALE REPRODUCTIVE SYSTEM

1. The female reproductive system produces gametes and sex hormones and houses a developing infant until birth.

27.9 Immature eggs develop in follicles in the ovaries (pp. 1061–1062)

1. The ovaries flank the uterus laterally and are held in position by the ovarian and suspensory ligaments and mesovaria.
2. Within each ovary are oocyte-containing follicles at different stages of development.

27.10 The female duct system includes the uterine tubes, uterus, and vagina (pp. 1062–1067)

1. The uterine tube, supported by the mesosalpinx, extends from near the ovary to the uterus. Movements of its ciliated distal projections, called fimbriae, along with peristalsis, create currents that help move an ovulated oocyte into the uterine tube.
2. The uterus has fundus, body, and cervical regions. It is supported by the broad, cardinal, uterosacral, and round ligaments.
3. The uterine wall is composed of the outer perimetrium, the myometrium, and the inner endometrium. The endometrium consists of a functional layer (stratum functionalis), which sloughs off periodically unless an embryo has implanted, and an underlying basal layer (stratum basalis), which rebuilds the functional layer.
4. The vagina extends from the uterus to the exterior. It is the copulatory organ and allows passage of the menstrual flow or a baby.

27.11 The external genitalia of the female include those structures that lie external to the vagina (p. 1067)

1. The female external genitalia (vulva) include the mons pubis, labia majora and minora, clitoris, and the urethral and vaginal orifices. The mucus-secreting greater vestibular glands flank the vaginal opening.

27.12 The mammary glands produce milk (pp. 1068–1069)

1. The mammary glands lie over the pectoral muscles of the chest and are surrounded by adipose and fibrous connective tissue. Each mammary gland consists of many lobules, which contain milk-producing alveoli.

PART 4
PHYSIOLOGY OF THE FEMALE REPRODUCTIVE SYSTEM

27.13 Oogenesis is the sequence of events that leads to the formation of ova (pp. 1069–1073)

1. Oogenesis, the production of eggs, begins in the fetus. Oogonia, diploid stem cells that give rise to female gametes, are converted to primary oocytes before birth. The infant female's ovaries contain about 2 million primary oocytes arrested in prophase of meiosis I.
2. At puberty, meiosis resumes. Each month, one primary oocyte completes meiosis I, producing a large secondary oocyte and a tiny first polar body. Meiosis II of the secondary oocyte produces a functional ovum and a second polar body, but does not occur unless a sperm penetrates the secondary oocyte.
3. The ovum contains most of the primary oocyte's cytoplasm. The polar bodies are nonfunctional and degenerate.

27.14 The ovarian cycle consists of the follicular phase and the luteal phase (pp. 1073–1074)

1. During the follicular phase (days 1–14), several vesicular follicles are rescued from atresia and continue to grow. Generally, only one follicle per month is selected to become the dominant follicle and completes the maturation process. Late in this phase, the oocyte in the dominant follicle completes meiosis I. Ovulation occurs about day 14, releasing the secondary oocyte into the peritoneal cavity. Other developing follicles deteriorate.
2. In the luteal phase (days 15–28), the ruptured follicle is converted to a corpus luteum, which produces progesterone and estrogens for the remainder of the cycle. If fertilization does not occur, the corpus luteum degenerates after about 10 days.

27.15 Female reproductive function is regulated by hypothalamic, anterior pituitary, and ovarian hormones (pp. 1074–1078)

Hormonal Regulation of the Ovarian Cycle (pp. 1074–1076)

1. Establishment of the mature cyclic pattern of hormone secretion, indicated by menarche, takes about four years. Leptin serves a permissive role in puberty's onset, stimulating the hypothalamus when adipose tissue is sufficient for the energy requirements of reproduction.
2. The hormonal events of each ovarian cycle are as follows: (1) GnRH stimulates the anterior pituitary to release FSH and LH, which stimulate follicle maturation and estrogen production. (2) When blood estrogens reach a certain level, positive feedback exerted on the hypothalamic-pituitary-gonadal axis causes a sudden release of LH that stimulates the primary oocyte to continue meiosis and triggers ovulation. LH then causes conversion of the ruptured follicle to a corpus luteum and stimulates its secretory activity. (3) Rising levels of progesterone and estrogens inhibit the hypothalamic-pituitary-gonadal (HPG) axis, the corpus luteum deteriorates, ovarian hormones drop to their lowest levels, and the cycle begins anew.
3. While the ovarian cycle is about 28 days, maturation of a primordial follicle from its recruitment until it is ready to be ovulated takes about 290 days.

The Uterine (Menstrual) Cycle (pp. 1076–1078)

4. Varying levels of ovarian hormones in the blood trigger events of the uterine cycle.
5. During the menstrual phase of the uterine cycle (days 0–4), the functional layer sloughs off in menses. During the proliferative phase (days 5–14), rising estrogen levels stimulate its regeneration. Under the influence of both estrogens and progesterone during the secretory phase (days 15–28), the uterine glands secrete nutrients, and endometrial vascularity increases further. This makes the uterus receptive to implantation about one week after ovulation.
6. Falling levels of ovarian hormones during the last few days of the ovarian cycle cause the spiral arteries to become spastic and cut off the blood supply of the functional layer. The uterine cycle begins again with menstruation.

Effects of Estrogens and Progesterone (p. 1078)

7. Estrogens promote oogenesis. At puberty, they stimulate the growth of the reproductive organs and the growth spurt and promote the appearance of the secondary sex characteristics.
8. Progesterone cooperates with estrogens in breast maturation and regulation of the uterine cycle.

27.16 The female sexual response is more diverse and complex than that of males (pp. 1078–1079)

1. The female sexual response is similar to that of males. Orgasm in females is not accompanied by ejaculation.

PART 5

SEXUALLY TRANSMITTED INFECTIONS

27.17 Sexually transmitted infections cause reproductive and other disorders (pp. 1080–1081)

1. Sexually transmitted infections (STIs) are infectious diseases spread via sexual contact. Gonorrhea, syphilis, and chlamydia are bacterial diseases. Syphilis has broader consequences than most other sexually transmitted bacterial diseases since it can infect organs throughout the body. Trichomoniasis is a parasitic infection. Genital herpes and genital warts are viral infections; genital warts, caused by the HPV virus, are implicated in cervical cancer.

Developmental Aspects of the Reproductive System (pp. 1081–1086)

Embryological and Fetal Events (pp. 1081–1084)

1. Genetic sex is determined by the sex chromosomes: an X from the mother, an X or a Y from the father. If the fertilized egg contains XX, it is a female and develops ovaries; if it contains XY, it is a male and develops testes.
2. Gonads of both sexes arise from the mesodermal gonadal ridges. The mesonephric ducts produce the male accessory ducts and glands. The paramesonephric ducts produce the female duct system.
3. The external genitalia arise from the genital tubercle and associated structures. The development of male accessory structures and external genitalia depends on the presence of testosterone produced by the embryonic testes. In its absence, female structures develop.
4. The testes descend into the scrotum from the abdominal cavity.

Puberty (p. 1084)

5. Puberty is the interval when reproductive organs mature and become functional. It begins in males with penile and scrotal growth and in females with breast development.

Menopause (pp. 1084, 1086)

6. During menopause, ovulation and menstruation cease. Hot flashes and mood changes may occur. Postmenopausal events include atrophy of the reproductive organs, bone mass loss, and increasing risk for cardiovascular disease. Men experience andropause with milder signs and symptoms of testosterone deficit.

REVIEW QUESTIONS

To access additional practice questions using your smartphone, tablet, or computer: MasteringA&P® > Study Area > Practice Tests & Quizzes

Level 1 Remember/Understand

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. The normal diploid number of human chromosomes is **(a)** 48, **(b)** 47, **(c)** 46, **(d)** 23, **(e)** 24.
2. Relative to differences between mitosis and meiosis, choose the statements that apply *only* to events of meiosis. **(a)** tetrads present, **(b)** produces two daughter cells, **(c)** produces four daughter cells, **(d)** occurs throughout life, **(e)** reduces the chromosomal number by half, **(f)** synapsis and crossing over of homologues occur.
3. The structures that draw an ovulated oocyte into the female duct system are **(a)** cilia, **(b)** fimbriae, **(c)** microvilli, **(d)** stereocilia.
4. The usual site of embryo implantation is **(a)** the uterine tube, **(b)** the peritoneal cavity, **(c)** the vagina, **(d)** the uterus.
5. Which of the following is correct relative to female anatomy? **(a)** the vaginal orifice is the most dorsal of the three openings in the perineum, **(b)** the urethra is between the vaginal orifice and the anus, **(c)** the anus is between the vaginal orifice and the urethra, **(d)** the urethra is the more ventral of the two orifices in the vulva.
6. Secondary sex characteristics are **(a)** present in the embryo, **(b)** a result of male or female sex hormones increasing in amount at puberty, **(c)** the testis in the male and the ovary in the female, **(d)** development of male and female external genitalia.
7. Which of the following produces the male sex hormones? **(a)** seminal glands, **(b)** corpus luteum, **(c)** developing follicles in the testes, **(d)** interstitial endocrine cells.
8. Which will occur as a result of nondescent of the testes? **(a)** male sex hormones will not be circulated in the body, **(b)** sperm will have no means of exit from the body, **(c)** inadequate blood supply will retard the development of the testes, **(d)** viable sperm will not be produced.
9. Match the key choices with the descriptive phrases below.

   Key:

   (a) androgen-binding protein
   (b) estrogens
   (c) FSH
   (d) GnRH
   (e) inhibin
   (f) LH
   (g) progesterone
   (h) testosterone

   ____ **(1)** Hormones that directly regulate the ovarian cycle
   ____ **(2)** Chemicals in males that inhibit the hypothalamic-pituitary-testicular axis
   ____ **(3)** Hormone that makes the cervical mucus viscous
   ____ **(4)** Potentiates the activity of testosterone on spermatogenic cells
   ____ **(5)** Chemicals in females that inhibit the hypothalamic-pituitary-ovarian axis
   ____ **(6)** Stimulates the secretion of testosterone
10. Which of the following does not add a secretion that makes a major contribution to semen? **(a)** prostate, **(b)** bulbo-urethral glands, **(c)** testes, **(d)** ductus deferens.
11. The corpus luteum is formed at the site of **(a)** fertilization, **(b)** ovulation, **(c)** menstruation, **(d)** implantation.

Level 2 Apply/Analyze

12. Sperm are to seminiferous tubules as oocytes are to **(a)** fimbriae, **(b)** corpus albicans, **(c)** ovarian follicles, **(d)** corpora lutea.
13. FSH is to estrogens as high levels of estrogens are to **(a)** progesterone, **(b)** LH, **(c)** FSH, **(d)** testosterone.
14. Why is the term *urogenital system* more applicable to males than to females?
15. Describe the major structural (and functional) regions of a sperm.
16. Describe the events and possible consequences of menopause.
17. Define menarche. What does it indicate?

18. Trace the pathway of a sperm from the male testes to the uterine tube of a female.
19. In menstruation, the functional layer is shed from the endometrium. Explain the hormonal and physical factors responsible for this shedding. (Hint: See Figure 27.25.)
20. Both the epithelium of the vagina and the cervical glands of the uterus help prevent the invasion and spread of vaginal pathogens. Explain how each of these mechanisms works.

Level 3 Evaluate/Synthesize

21. Oogenesis in the female results in one functional gamete—the egg, or ovum. What other cells are produced? What is the significance of this rather wasteful type of gamete production—that is, production of a single functional gamete instead of four, as seen in males?
22. Gina Marciano, a 44-year-old mother of eight children, visited her physician complaining of a "bearing down" sensation in her pelvis, low backache, and urinary incontinence. A vaginal examination showed that the external os of her cervix was just inside the vaginal orifice and her perineum exhibited large keloids (masses of scar tissue). What do you think Gina's problem is and what caused it? (Be anatomically specific.)
23. Grant, a sexually active adolescent, visited his doctor complaining of a red, painless swelling on his penis. He has no penile discharge or pain on urination. An account of his recent sexual behavior was requested and recorded. **(a)** What do you think Grant's problem is? **(b)** What is the causative agent of this disorder? **(c)** How is the condition treated, and what may happen if it isn't treated?
24. A 36-year-old mother of four is considering tubal ligation to ensure that her family gets no larger. She asks the physician if she will become "menopausal" after the surgery. **(a)** How would you answer her question and explain away her concerns? **(b)** Explain what a tubal ligation is.
25. Mr. Scanlon, a 76-year-old man, is interested in a much younger woman. Concerned because of his age, he asks his urologist if he will be able to father a child. What questions would a physician ask of this man, and what diagnostic tests might be ordered?
26. Erin had both her left ovary and her right uterine tube removed surgically at age 17 because of a cyst and a tumor in these organs. Now, at age 32, she remains healthy and is expecting her second child. How could Erin conceive a child with just one ovary and one uterine tube, widely separated on opposite sides of the pelvis like this?

CLINICAL CASE STUDY

23-Year-Old Female with Menstrual Irregularity

Jasmine Herrera, 23, has been referred to the endocrinology clinic. She is very overweight, with obvious acne and facial hair. She complains of irregular menstrual cycles. "My husband and I want to use the rhythm method," she says, "but I don't have any rhythm!"

1. A change in the levels of which hormone triggers ovulation? What triggers the onset of menstruation?
2. ✚ NCLEX-STYLE Jasmine's doctor has ordered measurement of her androgen levels. Which of the following statements is most accurate about this test?
   - **a.** It should come back negative, because women do not produce any androgens.
   - **b.** It depends on the phase of her cycle; androgens are only synthesized during the luteal phase of the ovarian cycle.
   - **c.** It depends on her muscle mass; androgens are anabolic steroids and cause muscle growth, so more muscle means more androgens.
   - **d.** Levels should be low but not absent, because the ovaries produce androgens but convert most of them into estrogens.
3. Transvaginal ultrasound reveals more than 30 enlarged vesicular follicles in Jasmine's left ovary. What are vesicular follicles?
4. Jasmine thinks that having so many follicles means she is extremely fertile. Is her assumption correct?
5. Jasmine's blood tests reveal very high levels of androgens. She is diagnosed with polycystic ovary syndrome (PCOS). In this syndrome, the woman develops high levels of androgens and many vesicular follicles, but has reduced fertility because few follicles are ovulated and the timing of their release is unpredictable. Part of the profile of PCOS is that LH levels are high. How would this lead to androgen excess, and what clinical evidence of androgen excess does Jasmine have?
6. ✚ NCLEX-STYLE Jasmine is started on oral contraceptives containing a combination of an estrogen and progesterone. These will regulate her menstrual cycles and decrease her androgen level. They will also act to prevent pregnancy by preventing ovulation. What phase of the uterine cycle is caused by sustained elevation of both estrogen and progesterone levels?
   - **a.** Proliferative phase
   - **b.** Follicular phase
   - **c.** Secretory phase
   - **d.** Menstrual phase

28 Pregnancy and Human Development

In this chapter, you will learn that

Pregnancy and development are an intricate series of events that allow a single cell to become a fully formed human being

by asking

- **28.1** How does fertilization occur?
  - and
- **28.2** What happens between fertilization and implantation?
  - and
- **28.3** How does the embryo implant into the uterus wall and trigger development of the placenta?
  - and
- **28.4** How does the embryo become a fetus?

- **28.5** How does pregnancy affect the mother?
  - and
- **28.6** How is a baby born?
  - and
- **28.7** How does the infant adjust to extrauterine life?

- **28.8** Lactation (then examining)

- **28.9** How can infertile couples be helped?

The birth of a baby is such a familiar event that we tend to lose sight of the wonder of this accomplishment: How does a single cell, the fertilized egg, grow to become a complex human being consisting of trillions of cells? The details of this process can fill a good-sized book. Our intention here is simply to outline the important events of gestation and to consider briefly the events occurring immediately after birth.

Let's get started by defining some terms.

- **Conceptus** (kon-sep′tus; "that which is conceived"): The pregnant woman's developing offspring (embryo or fetus).
- **Pregnancy**: The state of carrying a developing conceptus.
- **Gestation period** (*gestare* = to carry): The time during which the development of the conceptus occurs. By convention, this extends from the last menstrual period (a date the woman is likely to remember) until birth, approximately 280 days. So, at the moment of fertilization, the mother is officially (but illogically) two weeks pregnant!

From fertilization through week 8, the *embryonic period*, the conceptus is called an **embryo**, and from week 9 through birth, the *fetal period*, the conceptus is called a **fetus** ("the young in the womb"). At birth, it is an infant. **Figure 28.1** shows the changing size and shape of the conceptus as it progresses from fertilization to the early fetal stage.

28.1 Fertilization combines the sperm and egg chromosomes, forming a zygote

Learning Outcomes

- **Describe the importance of sperm capacitation.**
- **Explain the mechanisms behind the blocks to polyspermy.**
- **Define fertilization.**

Before fertilization can occur, sperm must reach the ovulated secondary oocyte. The oocyte is viable for 12 to 24 hours after it is ejected from the ovary. The chance of pregnancy drops to almost zero the next day. Although sperm may survive in the female reproductive tract for up to a week, fertilization is most likely to occur within 24 to 48 hours after ejaculation. Consequently, for successful fertilization to occur, intercourse must occur no more than two days before ovulation and no later than 24 hours after, at which point the oocyte has traveled approximately one-third of the way down the uterine tube.

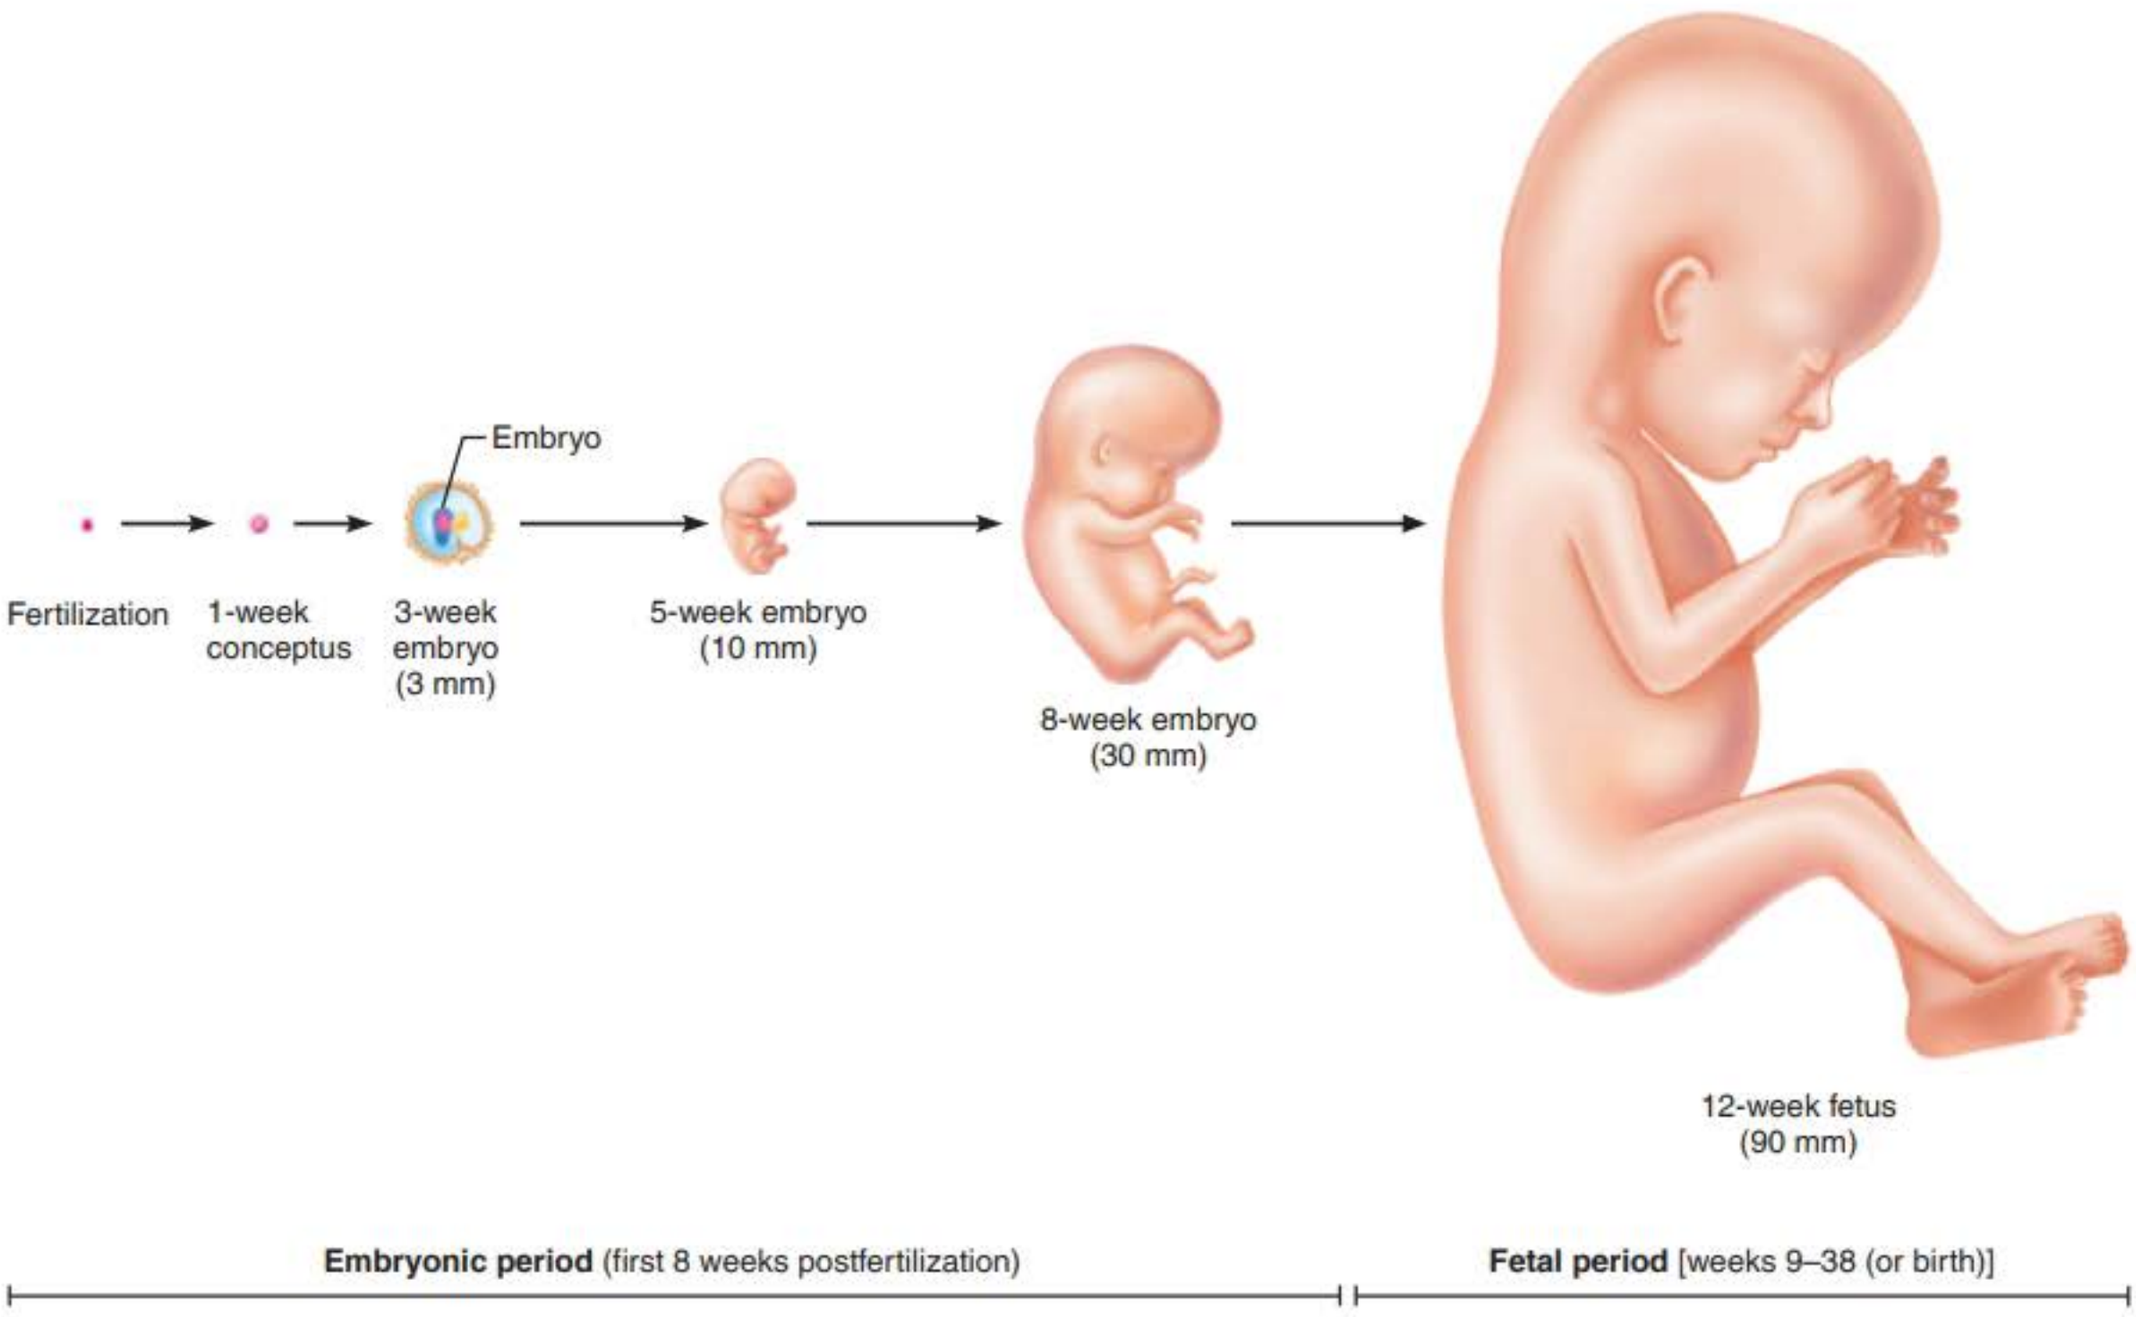

Figure 28.1 Size of the conceptus up to the early fetal stage. Embryos and fetus are shown approximately life size. (Measurements are crown-to-rump length.)

Fertilization occurs when a sperm's chromosomes combine with those of an egg to form a fertilized egg, or **zygote** (zi′gōt; "yoked together"), the first cell of the new individual. Let's look at the events leading to fertilization.

Sperm Transport and Capacitation

During ejaculation, a man expels millions of sperm into his partner's vagina. Despite these vast numbers, most sperm don't reach the oocyte, even though it is only about 12 cm (5 inches) away. Millions of sperm leak from the vagina almost immediately. Of those remaining, millions more are destroyed by the vagina's acidic environment. Only a small fraction of sperm make it through the cervix and gain access to the uterus.

Sperm that do reach the uterus, propelled by their whiplike tail movements, are subjected to forceful uterine contractions that tumble them throughout the uterine cavity, where thousands more are destroyed by resident phagocytes. Only a few thousand sperm, out of the millions in the male ejaculate, are conducted by reverse peristalsis into the uterine tube, where the oocyte may be moving leisurely toward the uterus.

These difficulties aside, there is still another hurdle to overcome. Sperm freshly deposited in the vagina are incapable of penetrating an oocyte. They must first undergo **capacitation**, a biochemically delicate process that can take 2 to 10 hours. Specifically, their motility must be enhanced and their membranes must become fragile so that the hydrolytic enzymes in their acrosomes (◀ p. 1058) can be released. How does this happen? As sperm move through the cervical mucus, uterus, and uterine tubes, secretions of the female tract remove some of their protective membrane proteins, as well as the cholesterol that keeps their acrosomal membranes "tough" and stable. Even if the sperm reach the oocyte within a few minutes, they must "wait around" (so to speak) for capacitation to occur.

This elaborate mechanism prevents the spilling of acrosomal enzymes. Consider the alternative: Fragile acrosomal membranes could rupture prematurely in the male reproductive tract, causing some degree of autolysis (self-digestion) of the male reproductive organs.

How do sperm find their way to a released oocyte in the uterine tube? Sperm have receptors that sense the direction of fluid flow, temperature, and certain chemicals. These cues guide sperm "upstream" through the uterine tubes. For example, they swim toward warmer temperatures at the far end of the tube, and, like a dog following a scent trail, sperm use olfactory receptor proteins to "sniff" chemicals released by the ooctye and its surrounding cells.

Acrosomal Reaction and Sperm Penetration

Recall from Chapter 27 that the ovulated oocyte is encapsulated by the corona radiata and by the deeper zona pellucida (◀ p. 1073). Both must be breached before the oocyte can be penetrated by a sperm from the cloud of sperm that surrounds it (**Figure 28.2**). Central to this process is the sperm's **acrosomal reaction**, the release of acrosomal enzymes. *Focus on Sperm Penetration and the Blocks to Polyspermy* (**Focus Figure 28.1**, pp. 1094–1095) describes the acrosomal reaction and sperm penetration.

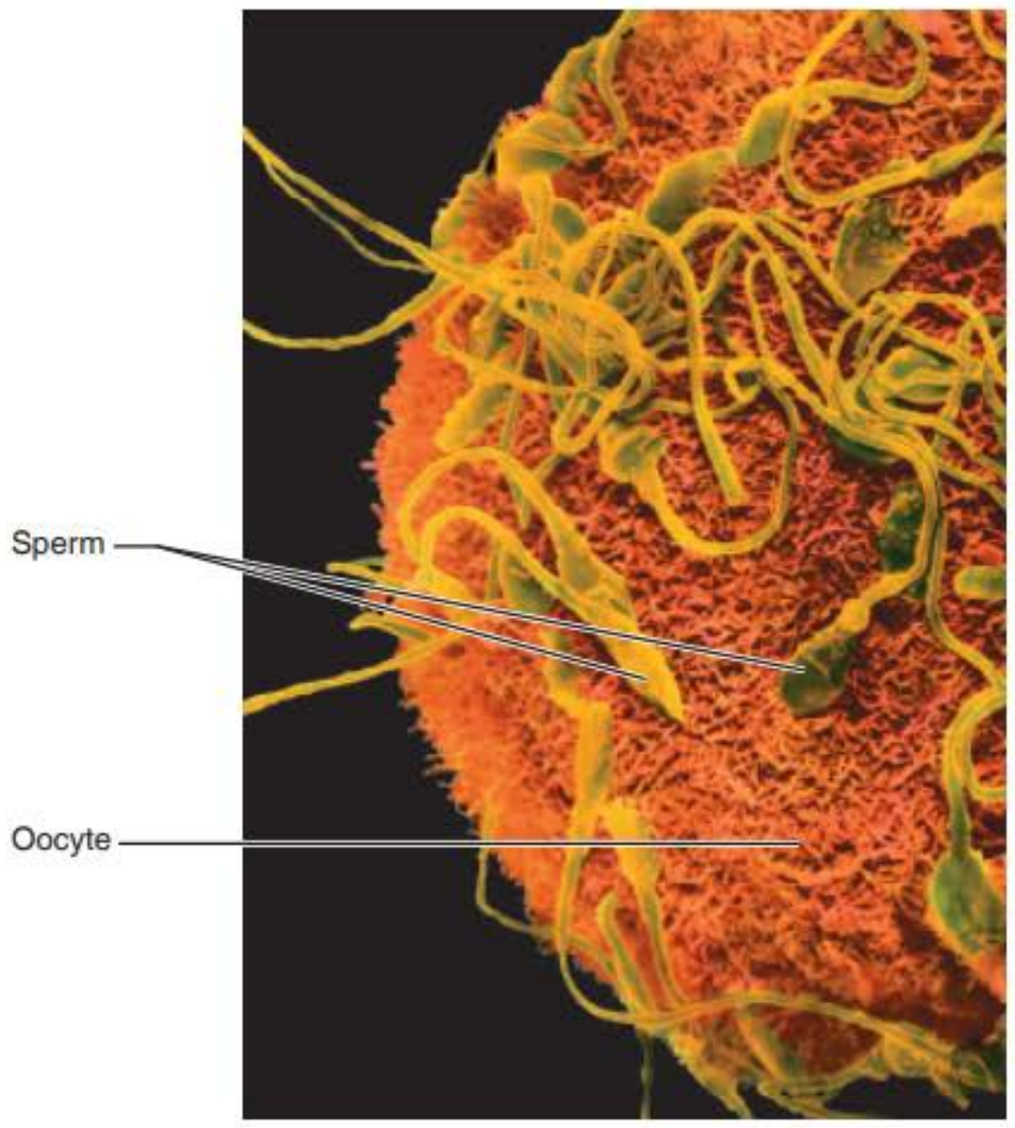

Figure 28.2 Sperm surrounding an oocyte. (SEM, 2240×)

Blocks to Polyspermy

Polyspermy (entry of several sperm into an egg) occurs in some animals, but in humans only one sperm is allowed to penetrate the oocyte, ensuring **monospermy**, the one-sperm-per-oocyte condition. In the rare cases of polyspermy that do occur, the embryos contain too much genetic material and die because they cannot successfully complete mitosis. At least two mechanisms help ensure monospermy: the *oocyte membrane block* and the *cortical reaction.*

When a sperm binds to the oocyte's sperm-binding membrane receptors, it triggers the **oocyte membrane block**. The oocyte sheds the remaining sperm-binding receptors on vesicles made from the plasma membrane. In the absence of sperm receptors, additional sperm are unable to bind to the oocyte. The released vesicles, studded with sperm-binding receptors, may act as "decoys" that attract and bind any other sperm that make it through the zona pellucida.

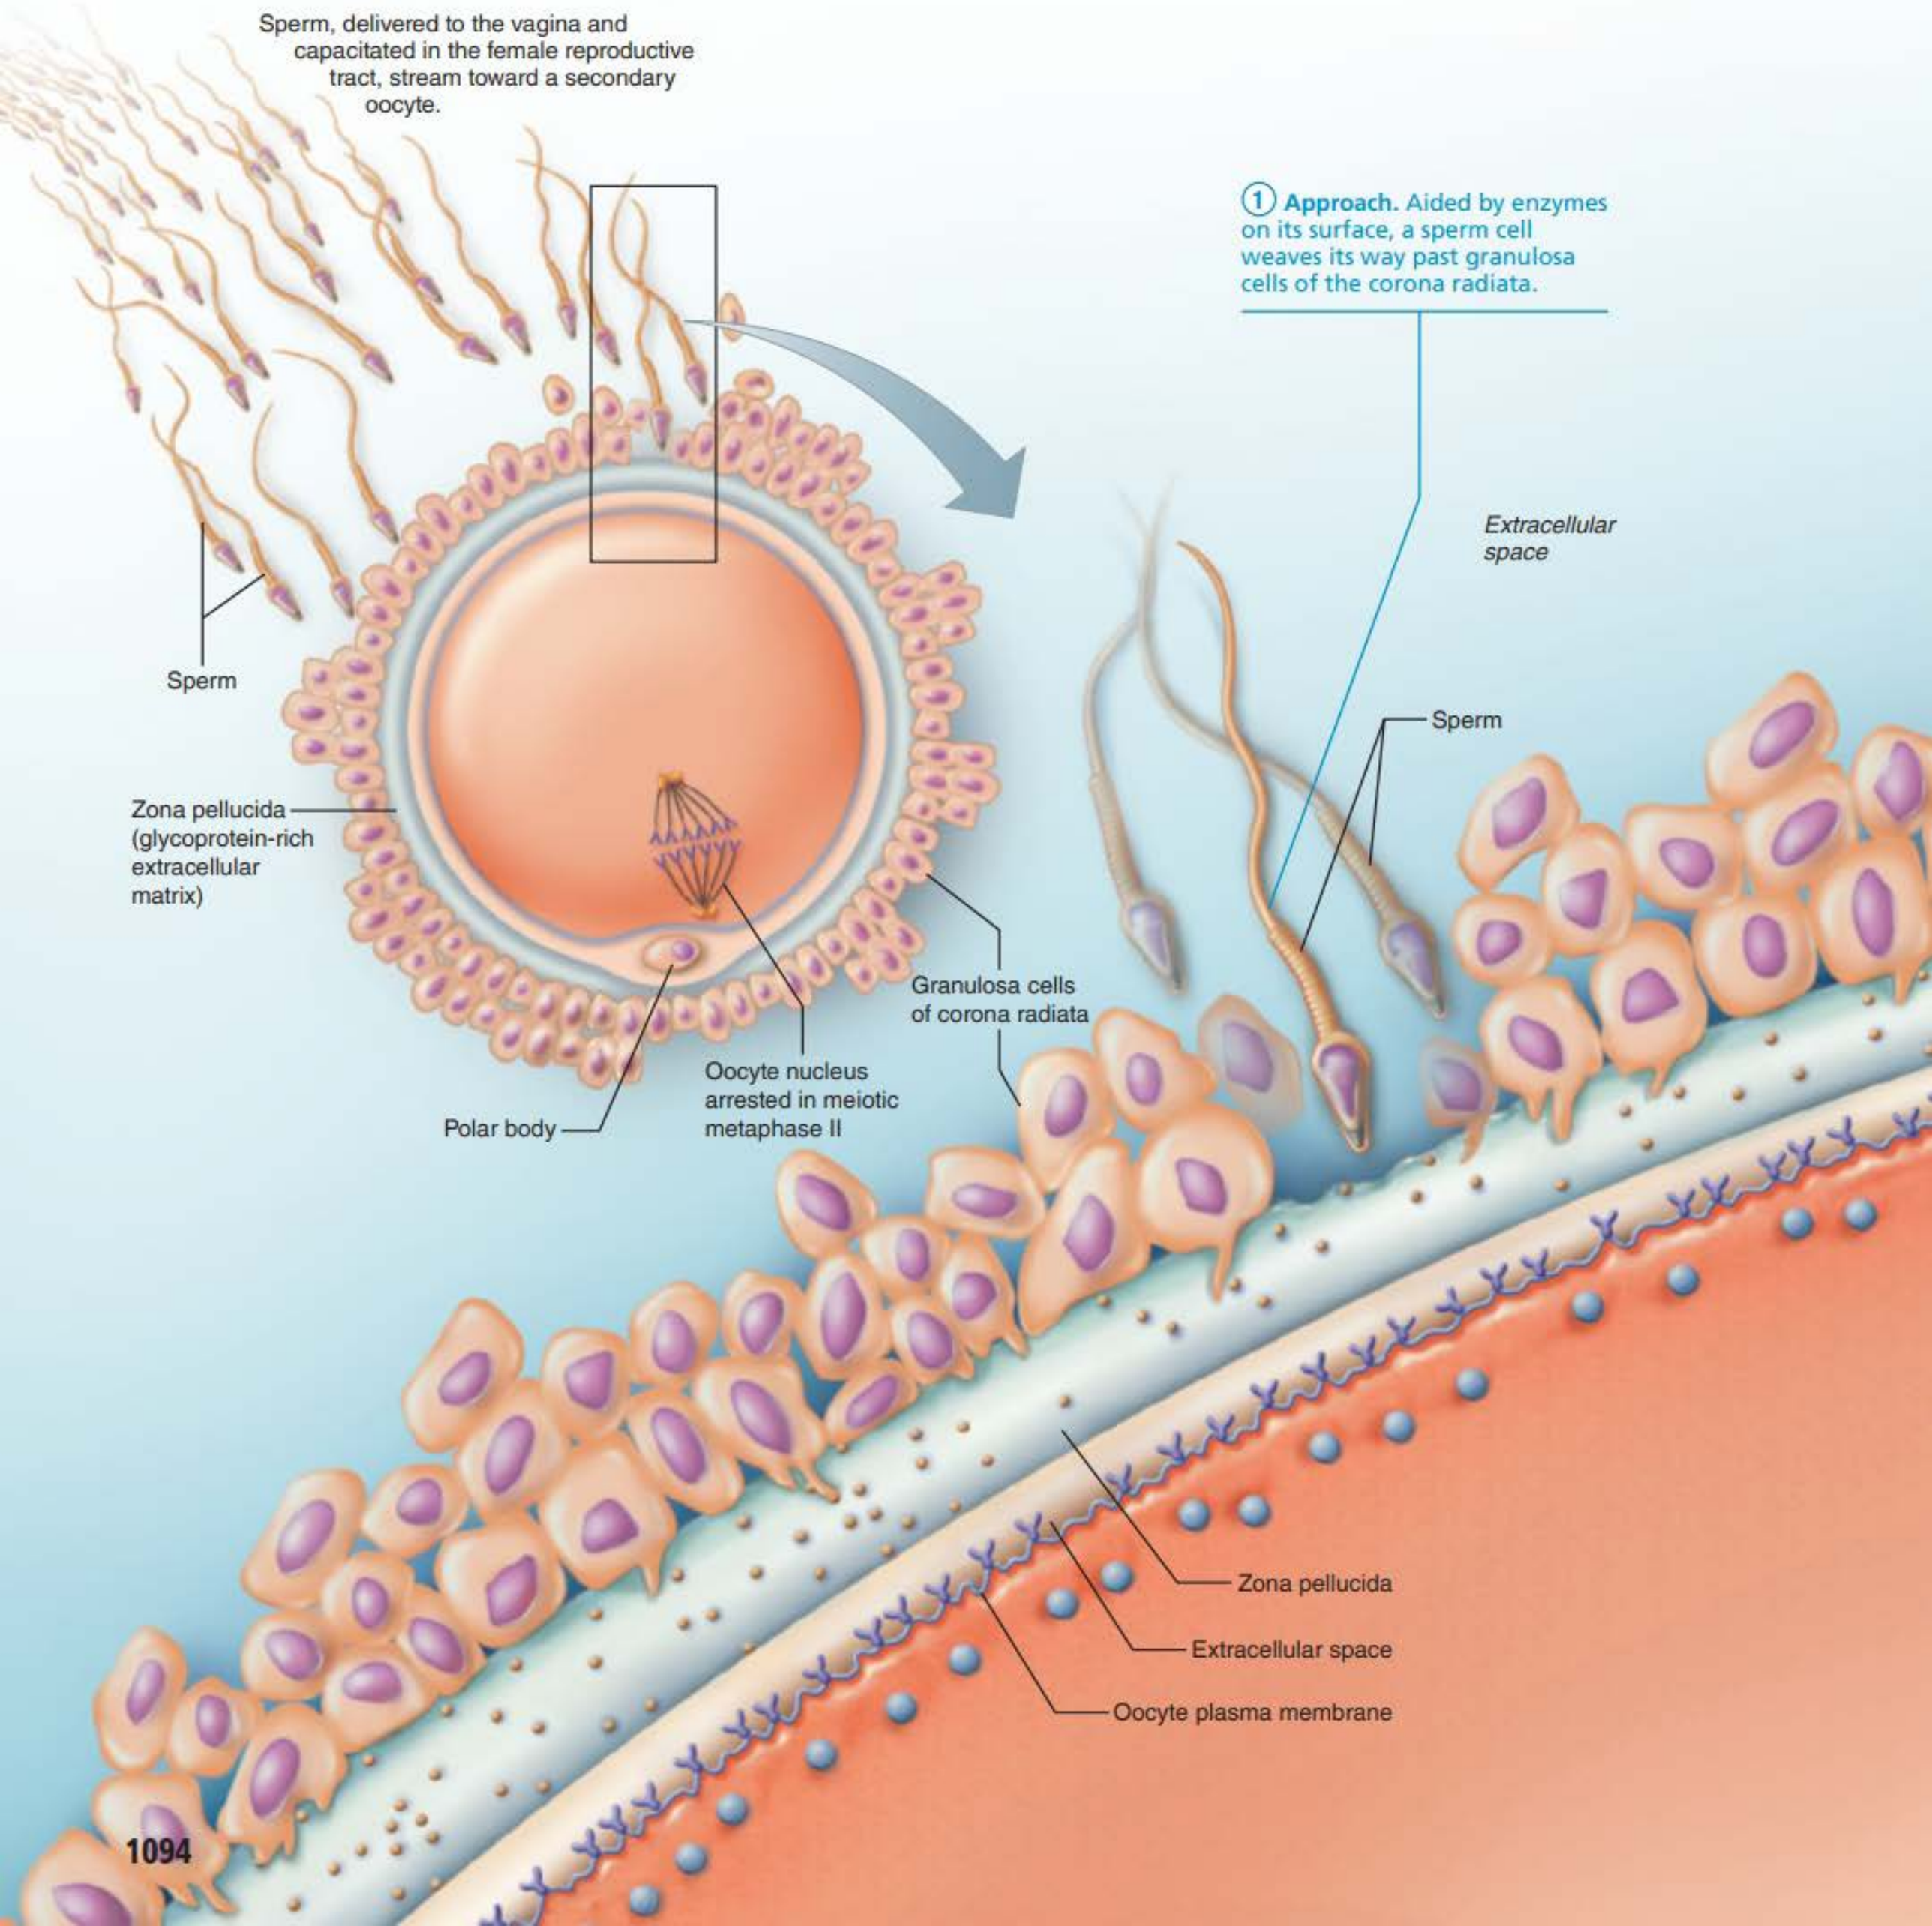
Once the plasma membranes of the sperm and oocyte have fused, waves of Ca^{2+} are released from the oocyte's endoplasmic reticulum into its cytoplasm. These calcium surges trigger the **cortical reaction*** (Focus Figure 28.1 ⑤)—exocytosis of

* The oocyte membrane block is analogous to the fast block to polyspermy seen in invertebrates. The cortical and zona reactions together are equivalent to the slow block to polyspermy of invertebrates.

(Text continues on p. 1096.)

FOCUS FIGURE 28.1 Sperm Penetration and the Blocks to Polyspermy

Sperm use acrosomal enzymes and receptors to approach, bind, and enter the oocyte. Blocks to polyspermy prevent further sperm entry, ensuring that only two copies of each chromosome are present in the fertilized ovum.



(2) **Acrosomal reaction.**
- Binding of the sperm to receptors in the zona pellucida causes Ca^{2+} levels within the sperm to rise, triggering the release of acrosomal enzymes.
- Acrosomal enzymes from many sperm digest holes through the zona pellucida, clearing a path to the oocyte plasma membrane.

(3) **Binding.** The sperm's membrane binds to the oocyte's sperm-binding receptors. This allows the next step (fusion) to proceed.

(4) **Fusion.** Sperm and oocyte plasma membranes fuse. Sperm contents enter the oocyte.

(5) **Blocks to polyspermy.**
- **Oocyte membrane block**: Oocyte sperm-binding membrane receptors are shed.
- **Cortical reaction**: Increased Ca^{2+} levels trigger exocytosis of cortical granules. This hardens the zona pellucida and destroys its sperm-binding receptors (*zona reaction*).

Zona pellucida sperm-binding receptors

Oocyte sperm-binding membrane receptors

Cortical granules

Microtubules from sperm flagellum

Mitochondria

Sperm nucleus

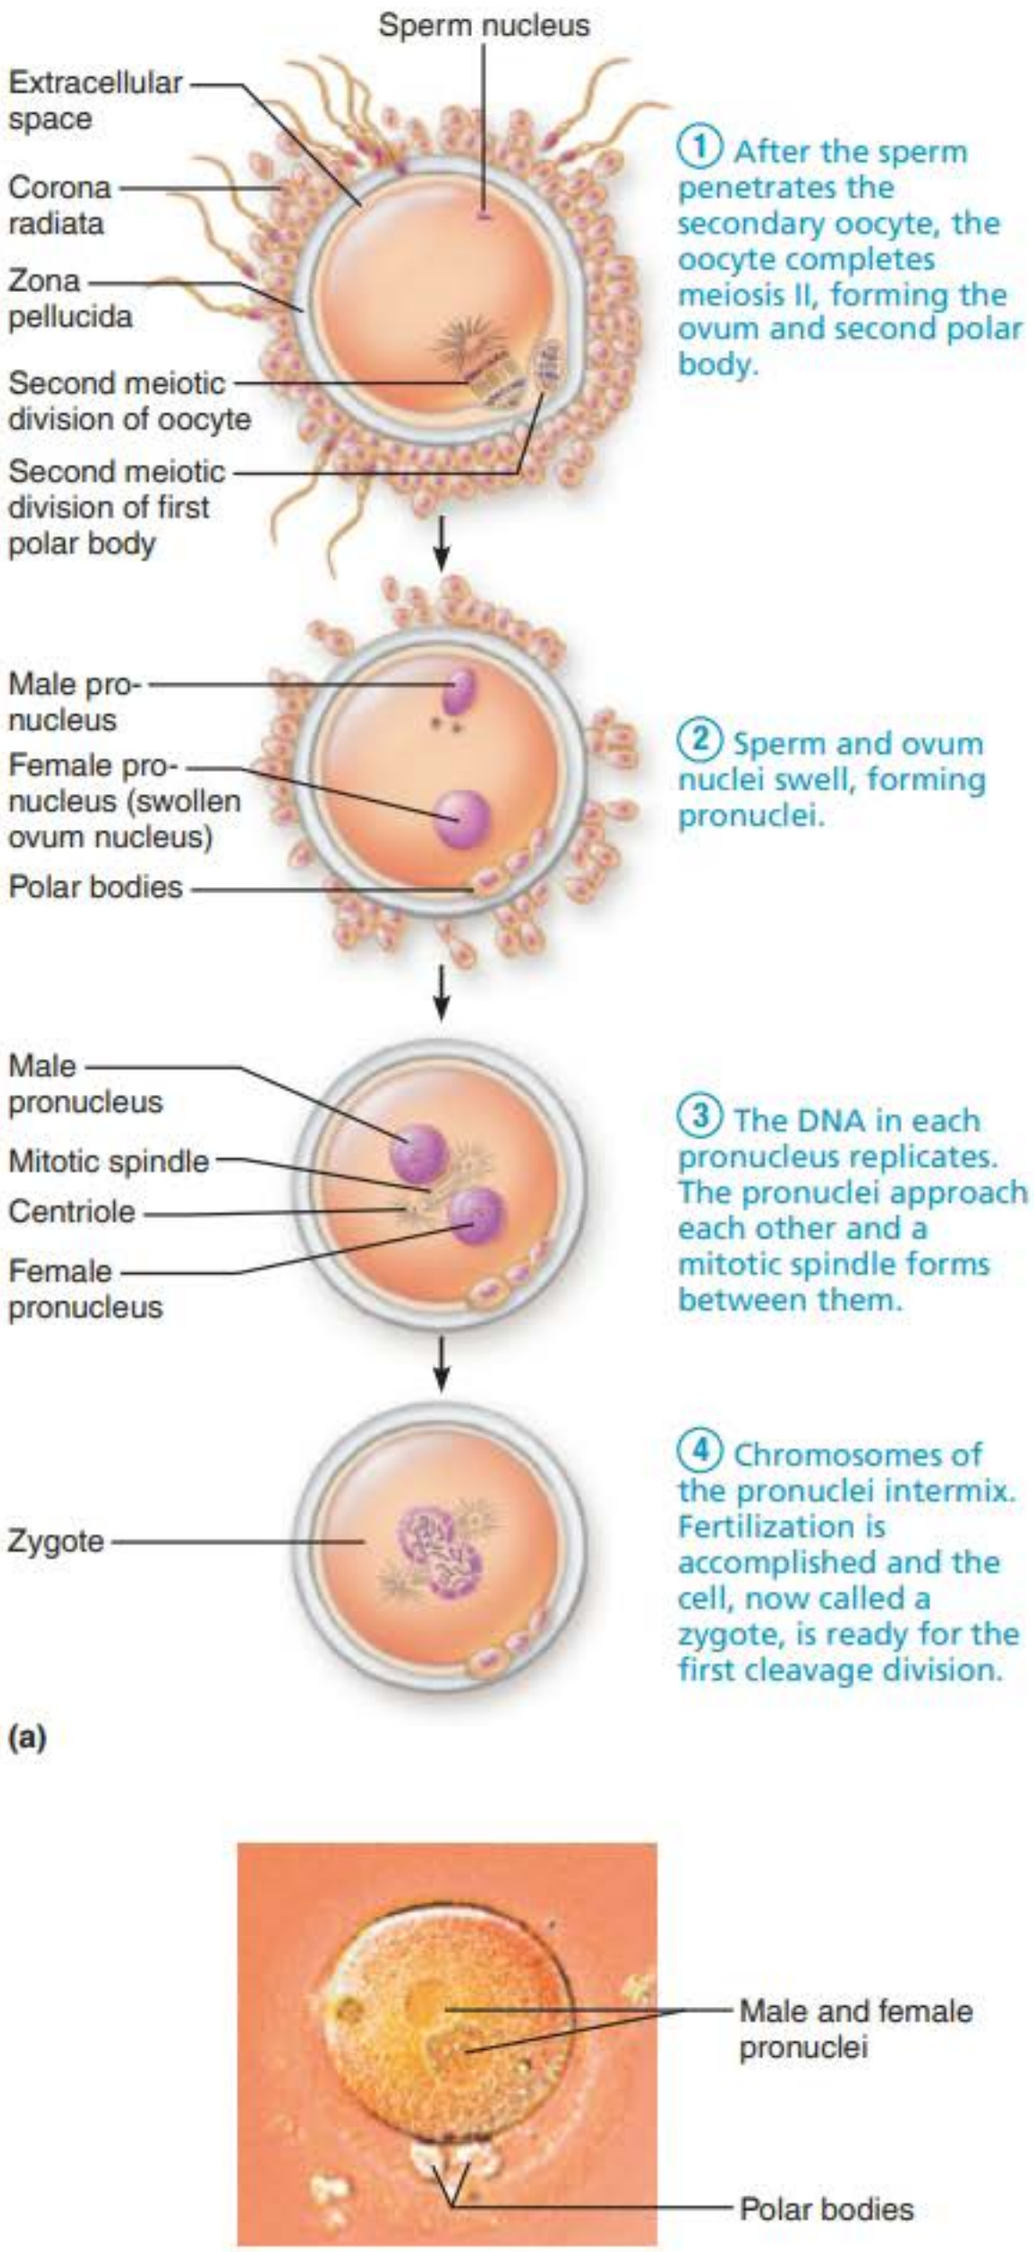


Figure 28.3 Fertilization. (a) Events from sperm penetration to zygote formation. **(b)** Micrograph of an oocyte in the time between steps (3) and (4) of (a).

granules located just inside the plasma membrane. These granules contain enzymes that destroy the zona pellucida's sperm-binding receptors and harden the zona pellucida. These changes in the zona pellucida are called the **zona reaction** and they effectively clear sperm out of the zona pellucida.

Completion of Meiosis II and Fertilization

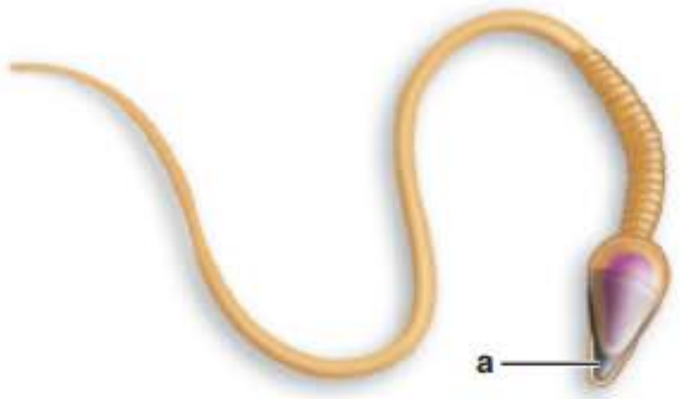
As the sperm's cytoplasmic contents enter the oocyte, the sperm loses its plasma membrane. The centrosome from its midpiece assembles microtubules which the sperm uses to propel its DNA-rich nucleus toward the oocyte nucleus. On the way, its nucleus swells to about five times its previous size to form the **male pronucleus** (pro-nu′kle-us; *pro* = before). Meanwhile the secondary oocyte is activated from its semidormant state by the same calcium surges that trigger the cortical reaction. Following the fluctuations in calcium levels, a shower of zinc ions bursts from the egg (zinc "sparks"). This efflux of zinc allows the oocyte to complete meiosis II, forming the ovum nucleus and the second polar body (**Figure 28.3a** (1) and (2)).

This accomplished, the ovum nucleus swells, becoming the **female pronucleus**, and the two pronuclei replicate their DNA as they approach each other. As a mitotic spindle develops between them (Figure 28.3a (3)), the pronuclei membranes rupture, releasing their chromosomes together into the immediate vicinity of the newly formed spindle.

The true moment of fertilization occurs as the maternal and paternal chromosomes combine and produce the diploid *zygote*, or fertilized egg (Figure 28.3a (4)). Some sources define the term fertilization simply as the act of oocyte penetration by the sperm. However, unless the chromosomes in the male and female pronuclei actually combine, the zygote is never formed in humans. The zygote, the first cell of a new individual, is now ready to undergo the first mitotic division of the conceptus.

Check Your Understanding

1. What is the cortical reaction and what does it accomplish?
2. WHAT IF? Suppose a sperm has penetrated a polar body (◀ p. 1071), and their nuclei fuse. Would it be likely that the resulting cell would develop into a healthy embryo? Explain.
3. MAKE CONNECTIONS In the diagram below, what is region **a** called and what does it contain? (Hint: See Chapter 27.) What triggers release of the contents of **a**? What process must the sperm complete before this can happen?



For answers, see Answers Appendix.

28.2 Embryonic development begins as the zygote undergoes cleavage and forms a blastocyst en route to the uterus

Learning Outcome

▶ **Describe the process and product of cleavage.**

Early embryonic development begins with fertilization and continues as the embryo travels through the uterine tube, floats free in the cavity of the uterus, and finally implants in the uterine wall. Significant events of this early embryonic period are *cleavage*, which produces a structure called a blastocyst, and *implantation* of the blastocyst.

Cleavage

Cleavage is a period of fairly rapid mitotic divisions of the zygote without intervening growth (**Figure 28.4**). The goal of this first phase of development is to produce small cells with a high surface-to-volume ratio, which enhances their uptake of nutrients and oxygen and the disposal of wastes. It also provides a large number of cells to serve as building blocks for constructing the embryo. Consider the difficulty of trying to construct a building from one huge block of granite. If you now consider how much easier it would be if instead you could use hundreds of bricks, you will quickly grasp the importance of cleavage.

Some 36 hours after fertilization, the first cleavage division of the zygote has produced two identical cells (called *blastomeres*). These divide to produce four cells (Figure 28.4b), then eight, and so on. By 72 hours after fertilization, a loose collection of cells that form a berry-shaped cluster of 16 or more cells called the **morula** (mor′u-lah; "little mulberry") has been formed (Figure 28.4c). All the while, transport of the embryo (still contained within the zona pellucida) toward the uterus continues.

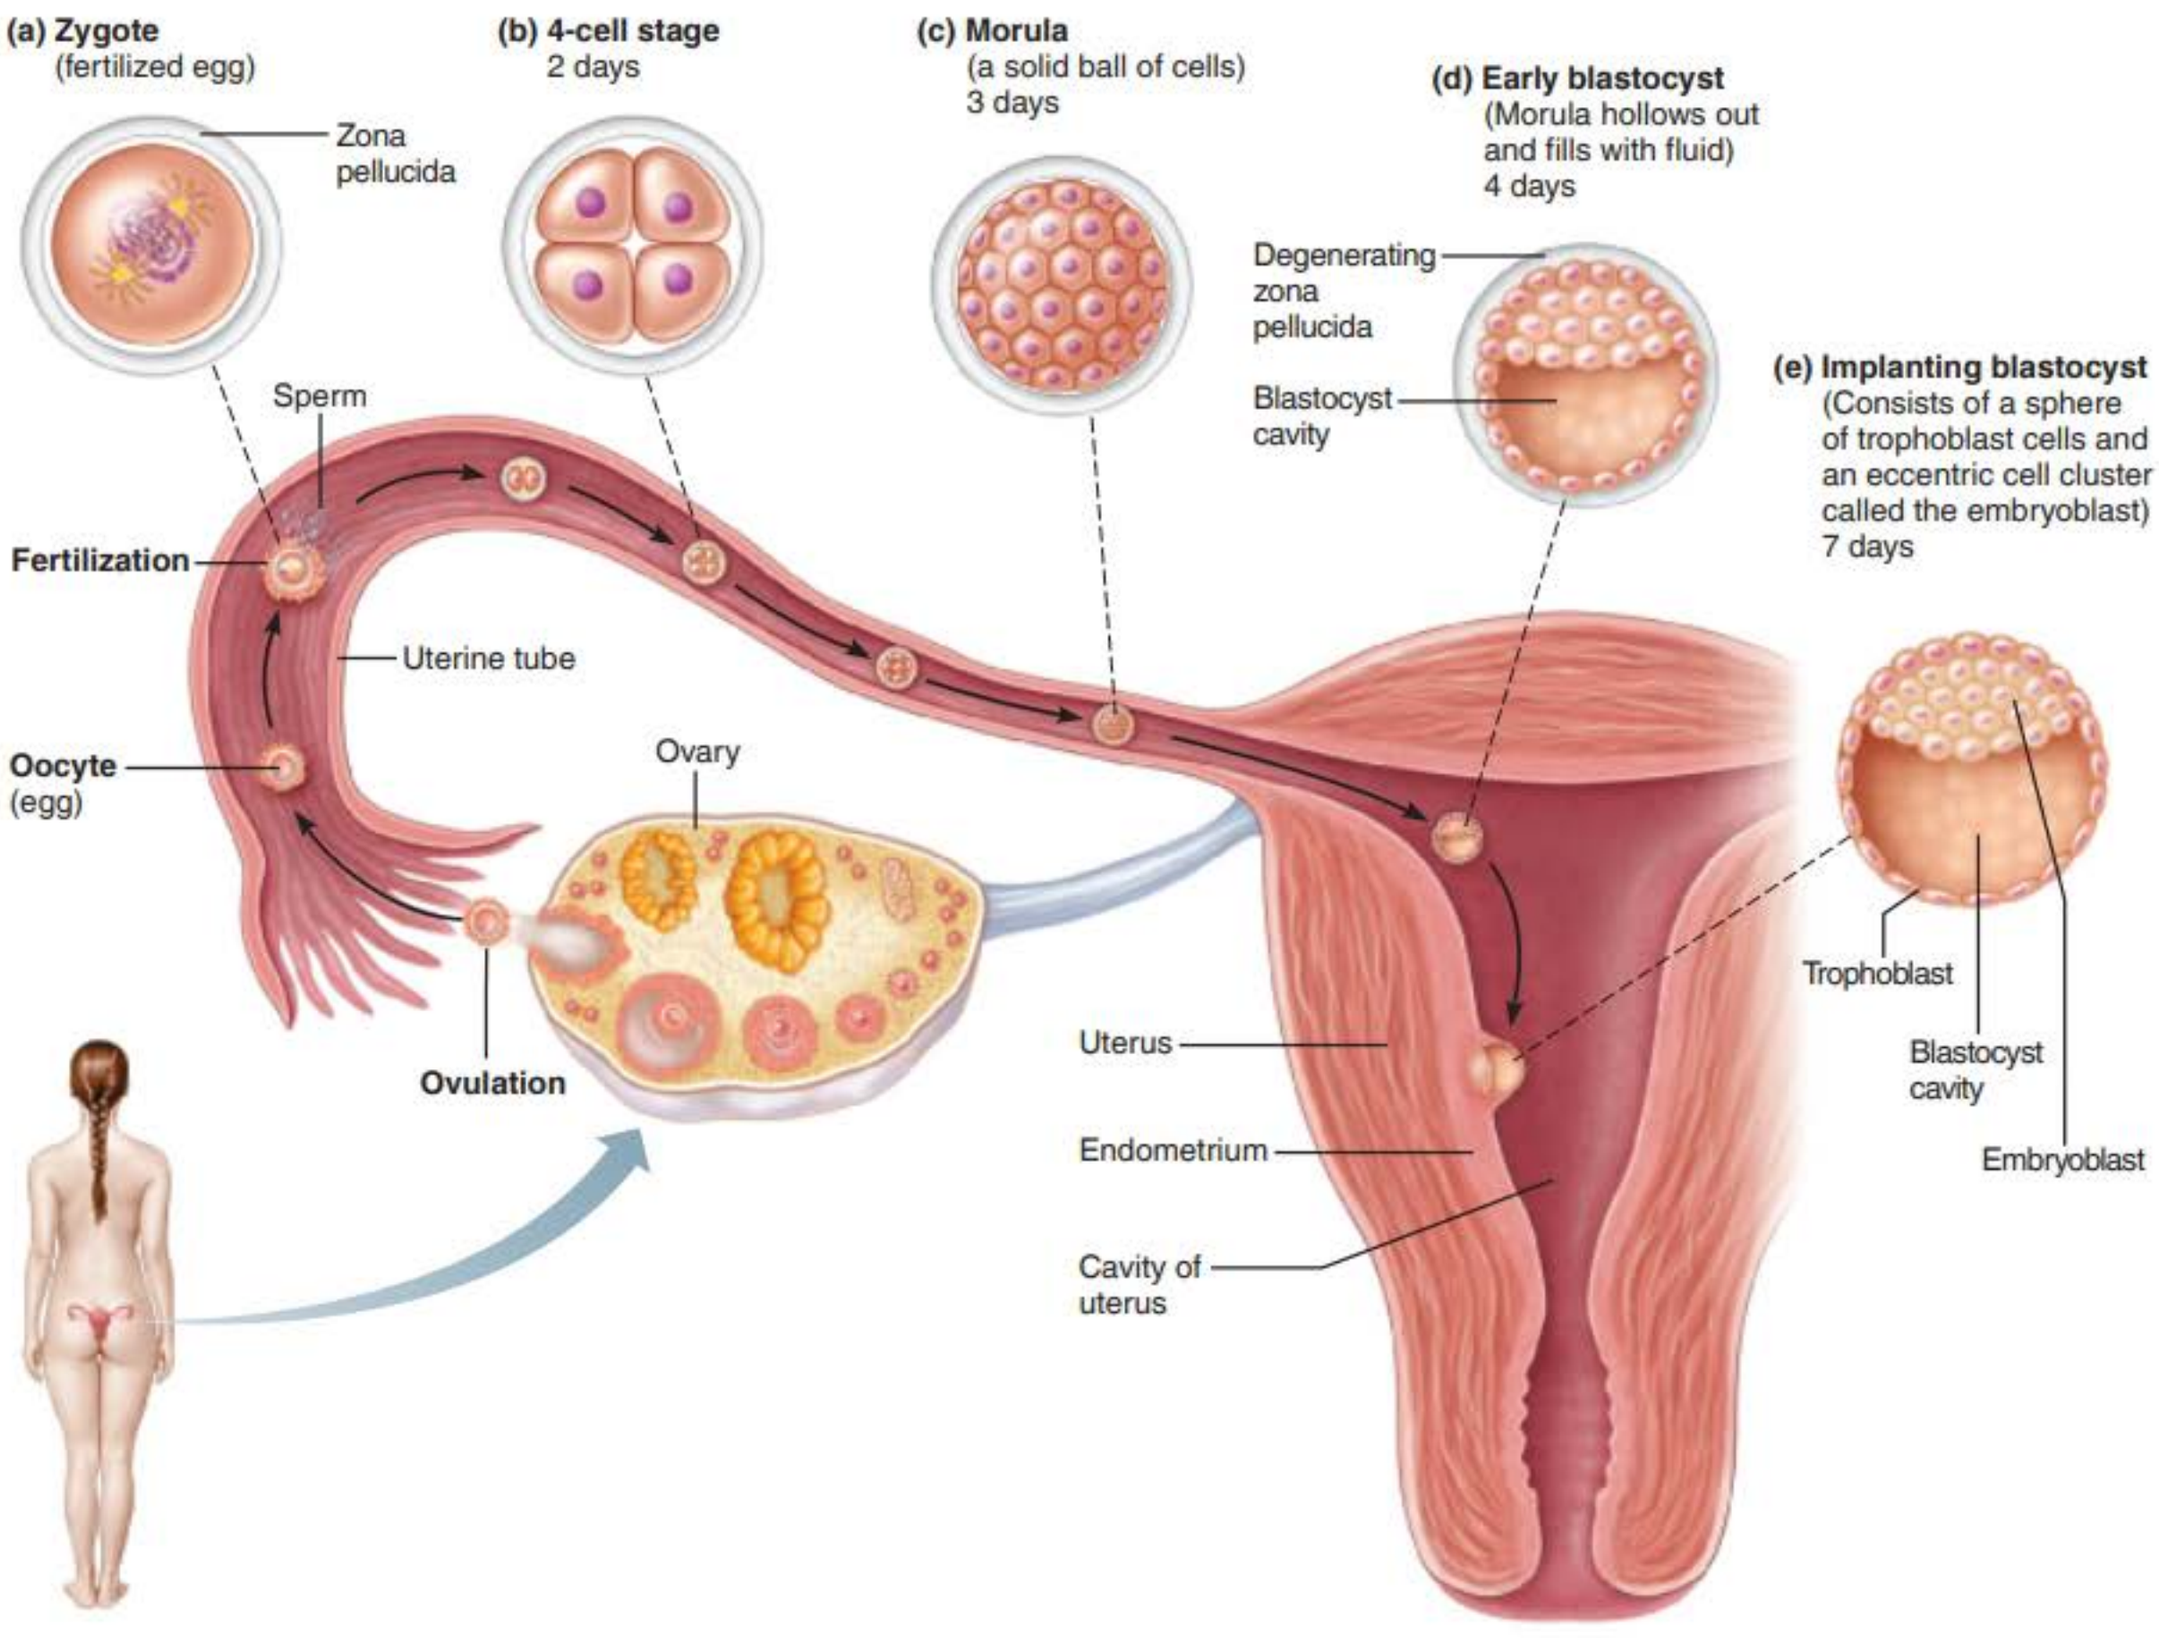


Figure 28.4 Cleavage: From zygote to blastocyst.

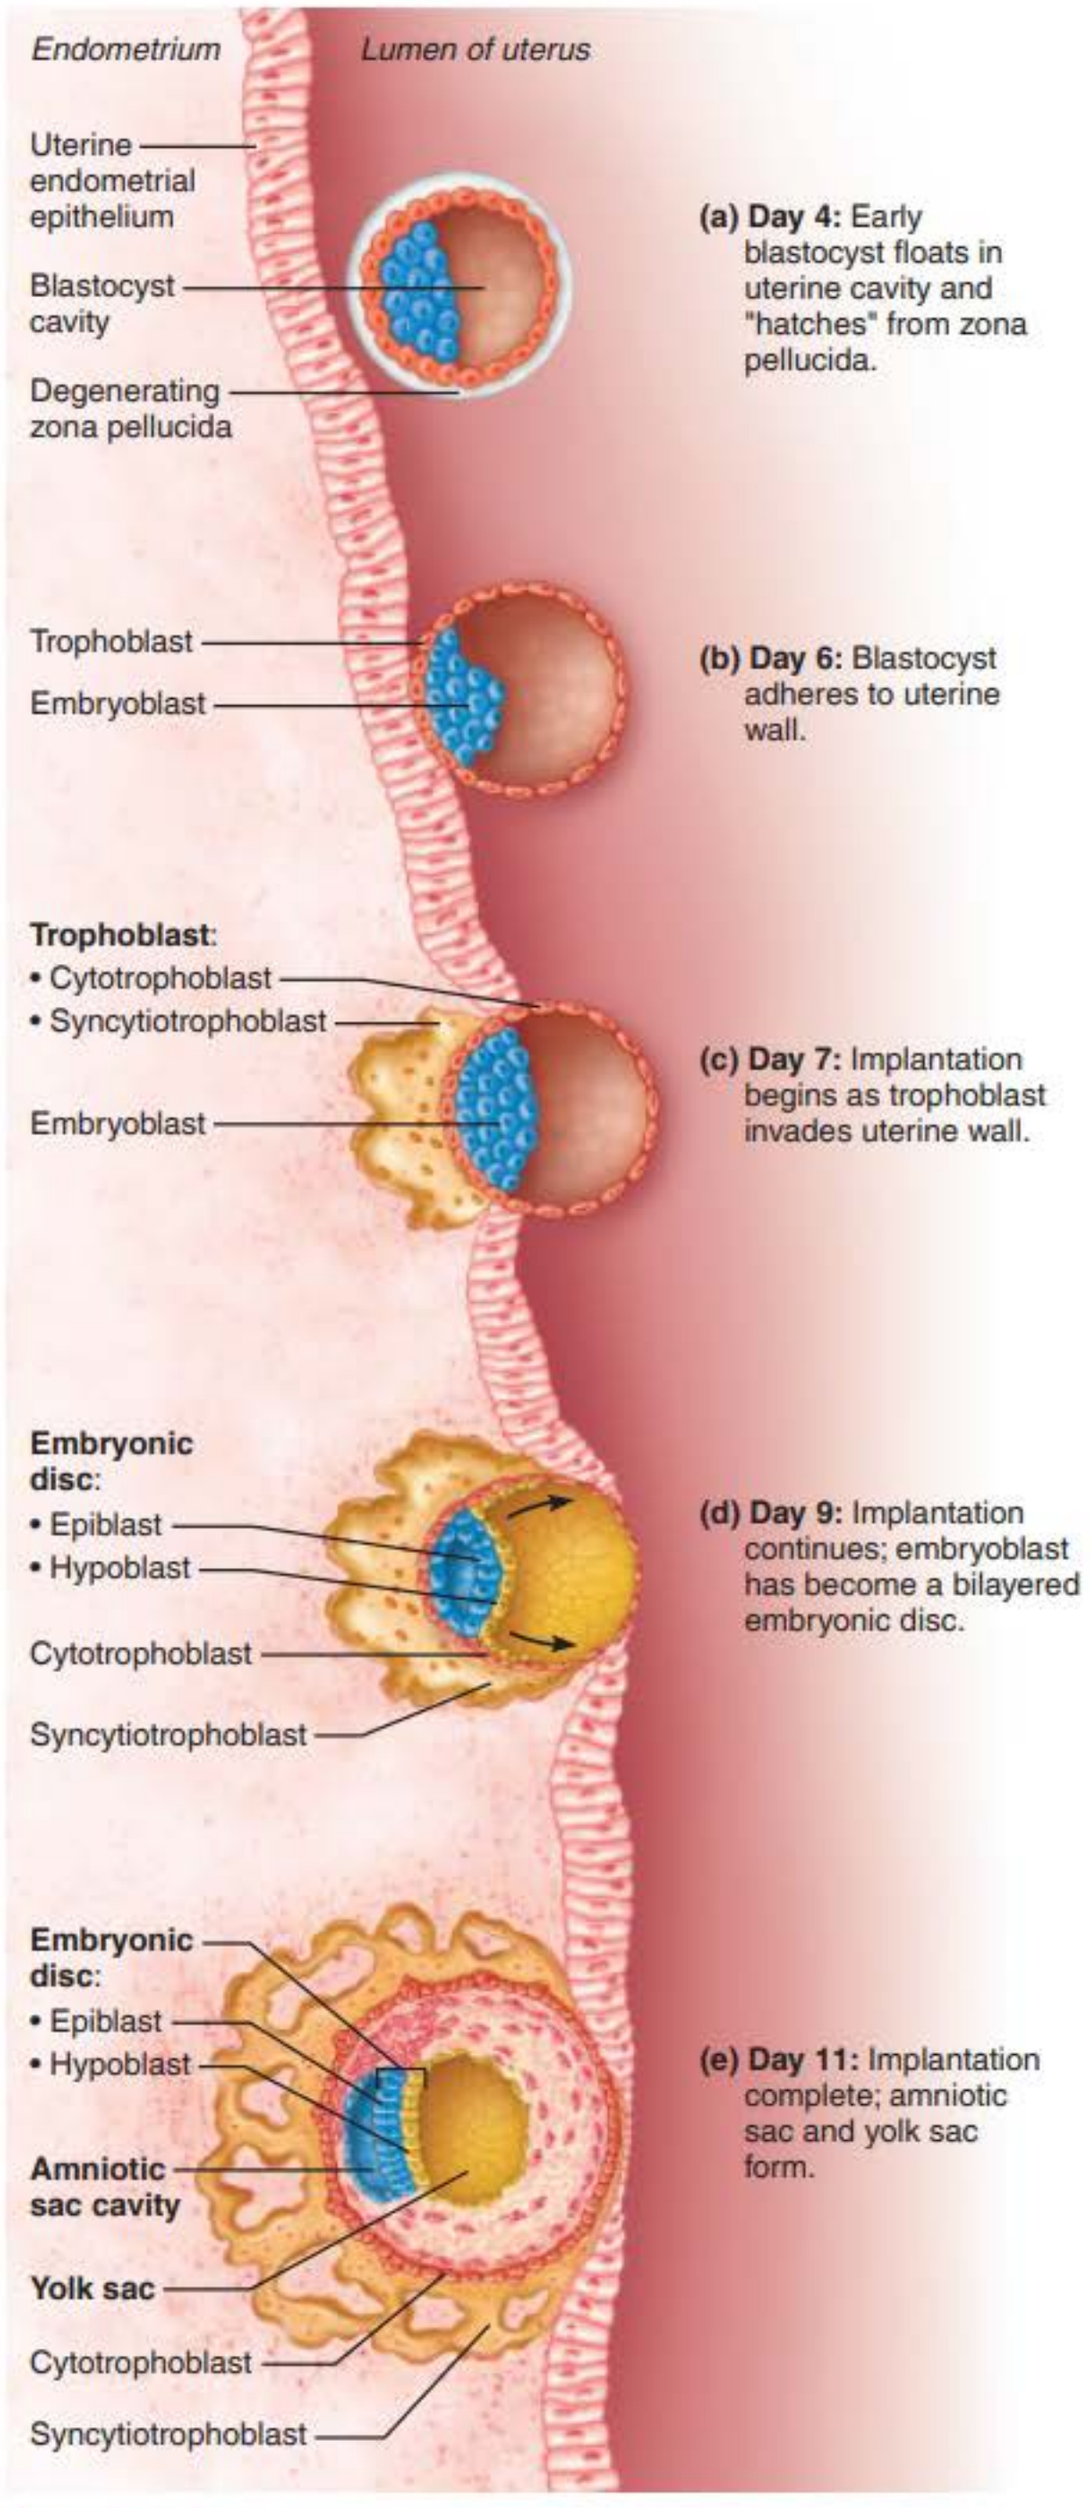

Figure 28.5 Implantation of the blastocyst. The embryos are shown in section (cut in half).

Blastocyst Formation

By day 4 or 5 after fertilization, the embryo consists of about 100 cells. It floats free in the uterus and has begun accumulating fluid within an internal cavity (Figure 28.4d and **Figure 28.5a**). The zona pellucida starts to break down and the inner structure, now called a blastocyst, "hatches" from it. The **blastocyst** (blas′to-sist) is a fluid-filled hollow sphere composed of a single layer of large, flattened cells called **trophoblast cells** (tro′fo-blast) and a small cluster of 20 to 30 rounded cells, called the **embryoblast** (or *inner cell mass*), clinging to the inside (Figure 28.5b, c).

The trophoblast has several key roles during development:

- As we will see in the next section, trophoblast cells play an important role in implanting the embryo in the wall of the uterus.
- As suggested by the literal translation of trophoblast ("nourishment generator"), it makes a major contribution to the *chorion*, the embryo's portion of the placenta.
- It protects the conceptus from attack by the mother's immune cells by producing several factors with immunosuppressive effects.

The embryoblast becomes the two-layered *embryonic disc* (Figure 28.5d, e), which forms the embryo proper and the extraembryonic membranes (except the chorion).

Check Your Understanding

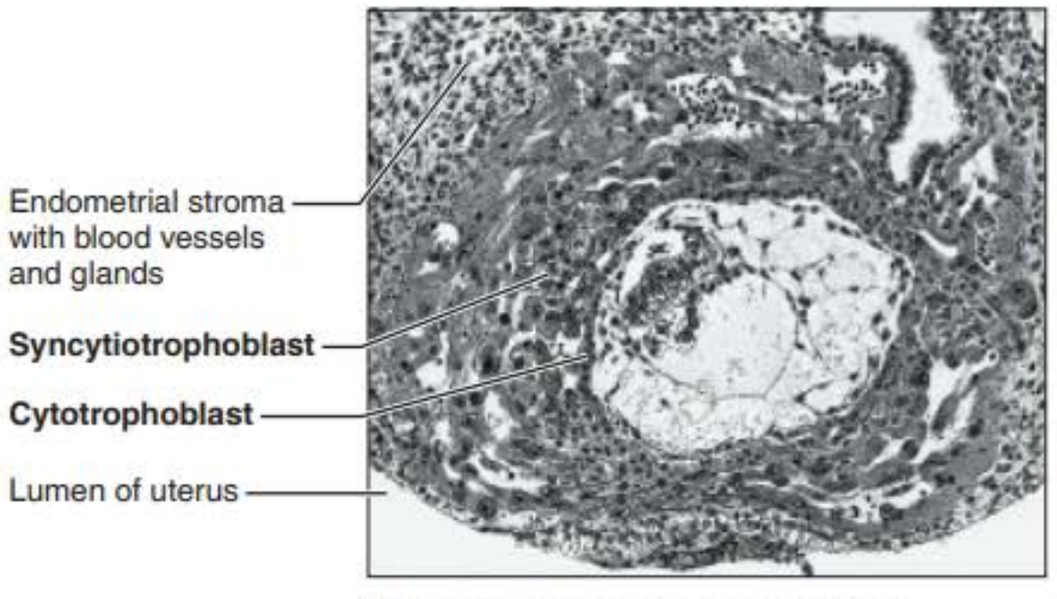
4. Why is the multicellular blastocyst only slightly larger than the single-celled zygote?
5. Trophoblasts contribute to a structure that lasts throughout pregnancy. What is this structure called?

For answers, see Answers Appendix.

28.3 Implantation occurs when the embryo burrows into the uterine wall, triggering placenta formation

Learning Outcomes

- **Describe implantation.**
- **Describe placenta formation, and list placental functions.**



(f) Day 12: Photomicrograph (150×)

Implantation

While the blastocyst floats in the uterine cavity for two to three days, it is nourished by the glycoprotein-rich uterine secretions. Then, six to seven days after ovulation, **implantation** begins. The receptivity of the endometrium to implantation—the so-called *window of implantation*—is opened by the surging levels of ovarian hormones (estrogens and progesterone) in the blood. If the mucosa is receptive, cell adhesion molecules (◀ p. 81) bind the trophoblast to the endometrial epithelium, and the blastocyst implants high in the uterus. If the endometrium is not yet optimally mature, the blastocyst fails to attach and drifts to a lower level, implanting when it finds a site with the proper receptors and chemical signals.

The trophoblast cells overlying the embryoblast adhere to the endometrium (Figure 28.5b) and secrete digestive enzymes and growth factors onto the endometrial surface. The endometrium quickly thickens at the point of contact and takes on characteristics of an acute inflammatory response—the uterine blood vessels become more permeable and leaky, and inflammatory cells including lymphocytes, natural killer cells, and macrophages invade the area.

The trophoblast then proliferates and forms two distinct layers (Figure 28.5c, d):

- The **cytotrophoblast** (si″to-tro′fo-blast; "cellular part of the trophoblast") forms the innermost layer of cells.
- The **syncytiotrophoblast** (sin-sit″e-o-tro′fo-blast; *syn* = together, *cyt* = cell) forms the outermost layer. Here the cells have fused together to form a single multinuclear cytoplasmic mass, or *syncytium*. This syncytium sends out long protrusions that invade the endometrium and rapidly digest the uterine cells it contacts.

As the endometrium is eroded, the blastocyst burrows into this thick, velvety lining and is surrounded by a pool of blood leaked from degraded endometrial blood vessels. Proliferation of the endometrial cells then covers and seals off the implanted blastocyst from the uterine cavity (Figure 28.5e).

In cases where implantation fails to occur, a receptive uterus becomes nonreceptive once again. At least two-thirds of all zygotes formed fail to implant by the end of the first week or spontaneously abort. Moreover, about 30% of implanted embryos later miscarry due to genetic defects of the embryo, uterine malformation, or other problems.

Successful implantation takes about five days. It is usually completed by day 12, which is day 26 of a woman's menstrual cycle—just before the endometrium normally begins to slough off. Menstruation would flush away the newly implanted embryo, so the embryo takes steps to prevent this by rescuing the corpus luteum. [Remember that menstruation occurs because the corpus luteum degenerates and stops releasing progesterone and estrogens required to maintain the uterine lining (◀ p. 1078).]

How does the embryo rescue the corpus luteum? Its syncytiotrophoblast secretes **human chorionic gonadotropin (hCG)** (ko″re-on′ik go-nad″o-trōp′in), which acts like LH but bypasses the usual hypothalamus-pituitary-ovarian controls. Just like LH, hCG prompts the corpus luteum to continue secreting

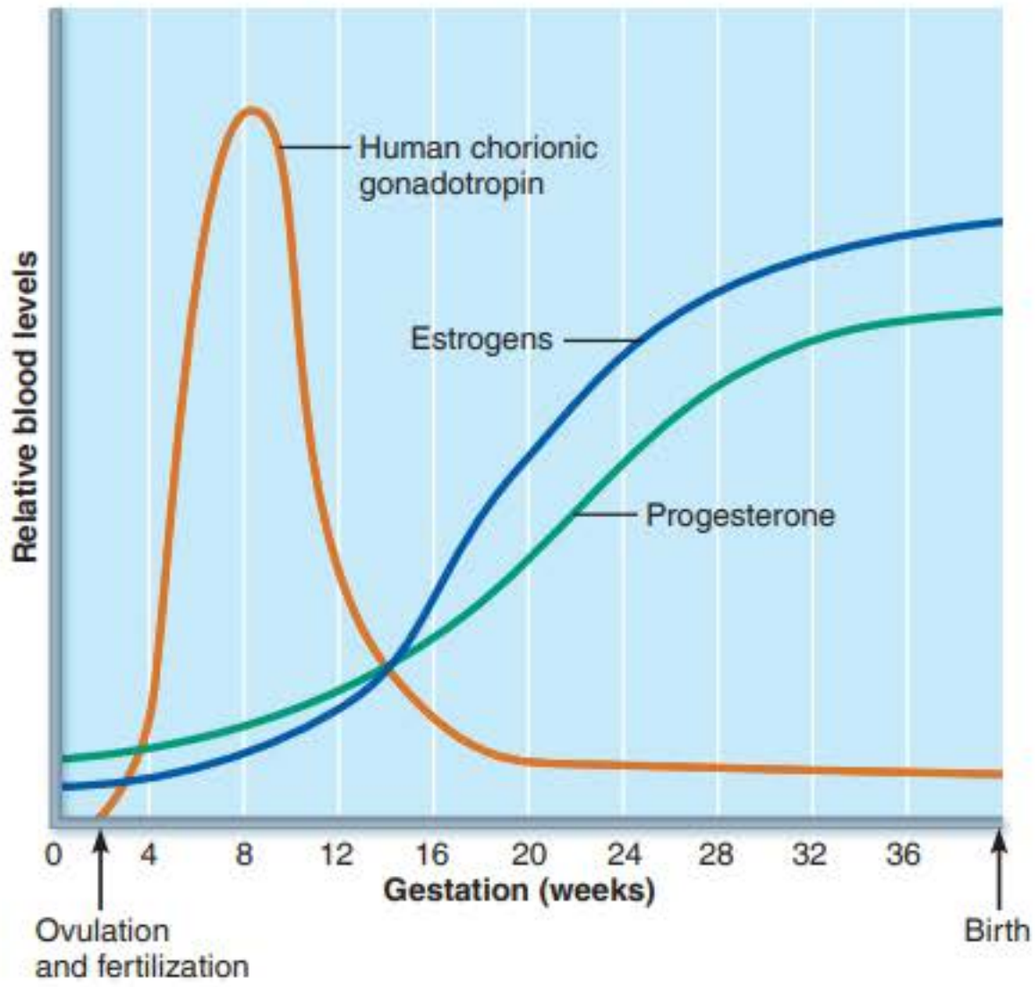


Figure 28.6 Hormonal changes during pregnancy. The relative changes in maternal blood levels of three hormones that maintain pregnancy are depicted, rather than actual blood concentrations.

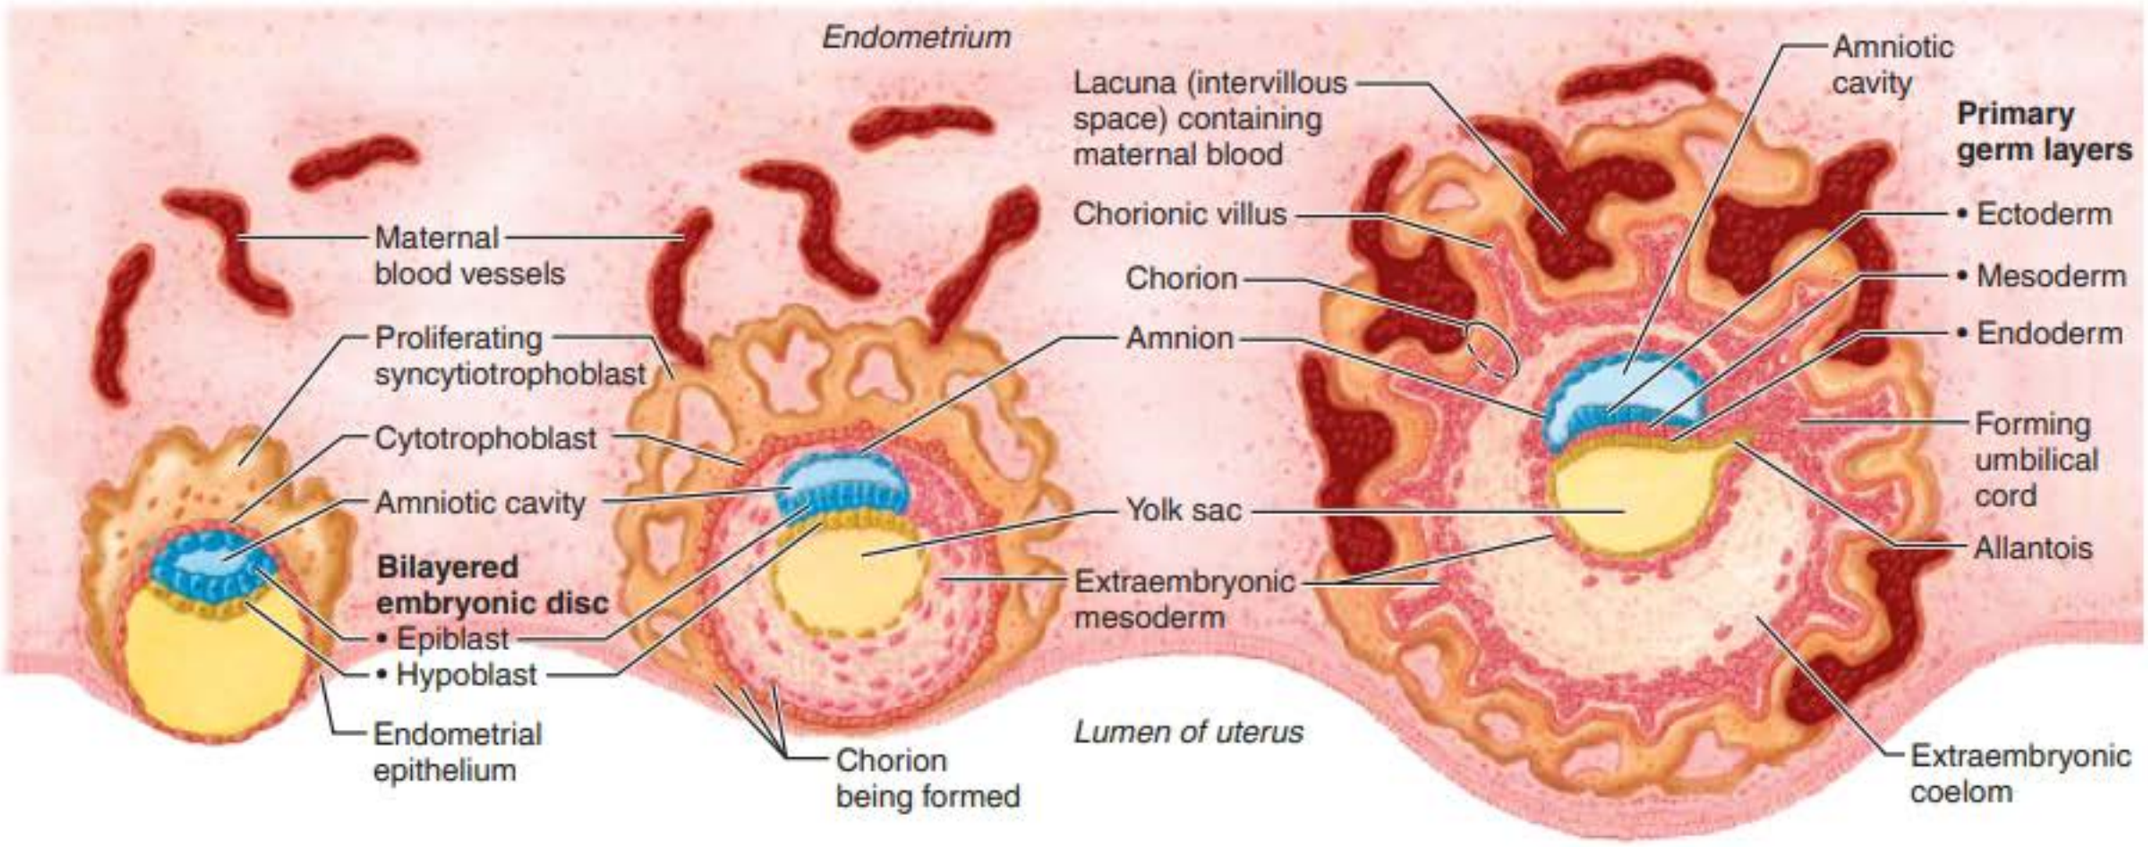
progesterone and estrogens. The syncytiotrophoblast, which becomes part of the *chorion* (a major part of the embryo's contribution to the placenta) continues to make hCG throughout pregnancy. Besides rescuing the corpus luteum, hCG also helps prevent the mother's immune system from rejecting the implanted embryo.

All pregnancy tests used today are antibody tests that detect hCG in a woman's blood or urine. hCG is usually detectable in the mother's blood two days after implantation. Blood levels of hCG continue to rise until the end of the second month. Then, blood levels decline sharply to reach a low value by 4 months, a situation that persists for the remainder of gestation (**Figure 28.6**). Between the second and third month, the placenta assumes the role of progesterone and estrogen production for the remainder of the pregnancy. The corpus luteum then degenerates and the ovaries remain inactive until after birth.

Initially, the implanted embryo acts like a parasite that obtains its nutrition by digesting the endometrial cells. By the second month, the placenta is providing nutrients and oxygen to the embryo and carrying away embryonic metabolic wastes. Since placenta formation is a continuation of the events of implantation, we will consider it next.

Formation of the Placenta

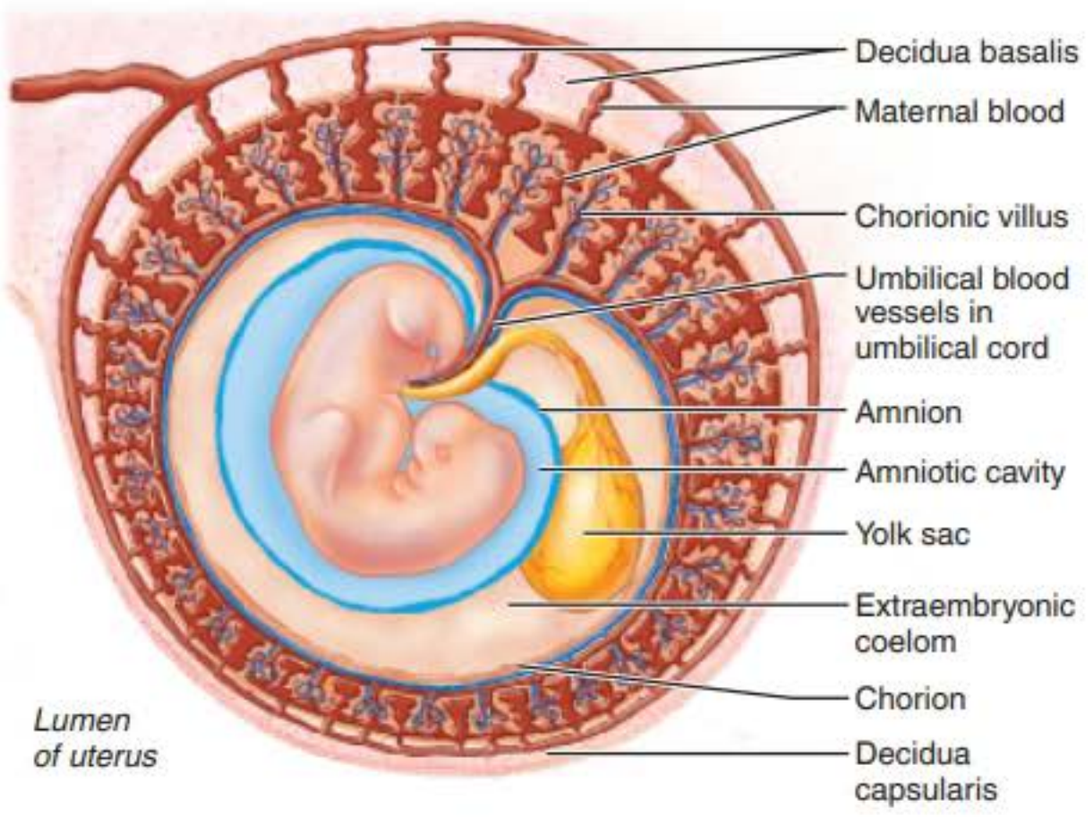
Formation of the **placenta** ("flat cake") is called **placentation** (plas″en-ta′shun). The placenta is a pancake-shaped temporary organ that originates from both embryonic and maternal (endometrial) tissues. Cells from the original embryoblast give rise to a layer of extraembryonic mesoderm that lines the inner surface



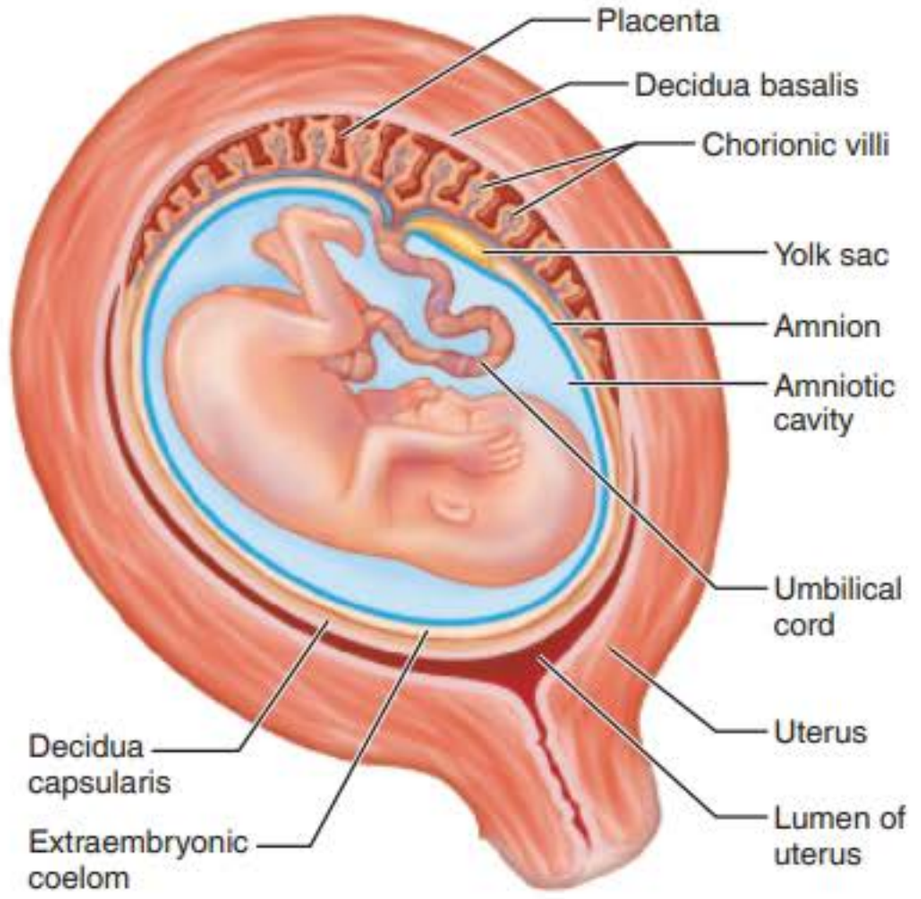
(a) Implanting 8-day blastocyst.
- The syncytiotrophoblast erodes the endometrium.
- The embryonic disc is now separated from the amnion by a fluid-filled space.

(b) 12-day blastocyst.
- Implantation is complete.
- Extraembryonic mesoderm is forming a discrete layer beneath the cytotrophoblast.

(c) 16-day embryo.
- Trophoblast and associated mesoderm have become the chorion.
- Chorionic villi are forming.
- The embryo exhibits all three germ layers, a yolk sac, and an allantois.



(d) 4½ -week embryo.
- The decidua capsularis, decidua basalis, amnion, and yolk sac are well formed.
- The chorionic villi lie in blood-filled intervillous spaces within the endometrium.
- The embryo is nourished via the umbilical vessels that connect it (through the umbilical cord) to the placenta.



(e) 13-week fetus.

Figure 28.7 Early embryonic development and formation of the placenta and extraembryonic membranes.

of the trophoblast (**Figure 28.7b**). Together these become the **chorion**. The chorion develops fingerlike **chorionic villi**, which become especially elaborate where they are in contact with maternal blood (Figure 28.7c).

Soon the mesodermal cores of the chorionic villi are invaded by newly forming blood vessels, which extend to the embryo as the umbilical arteries and vein. The continuing erosion of the endometrium produces large, blood-filled **lacunae**, or

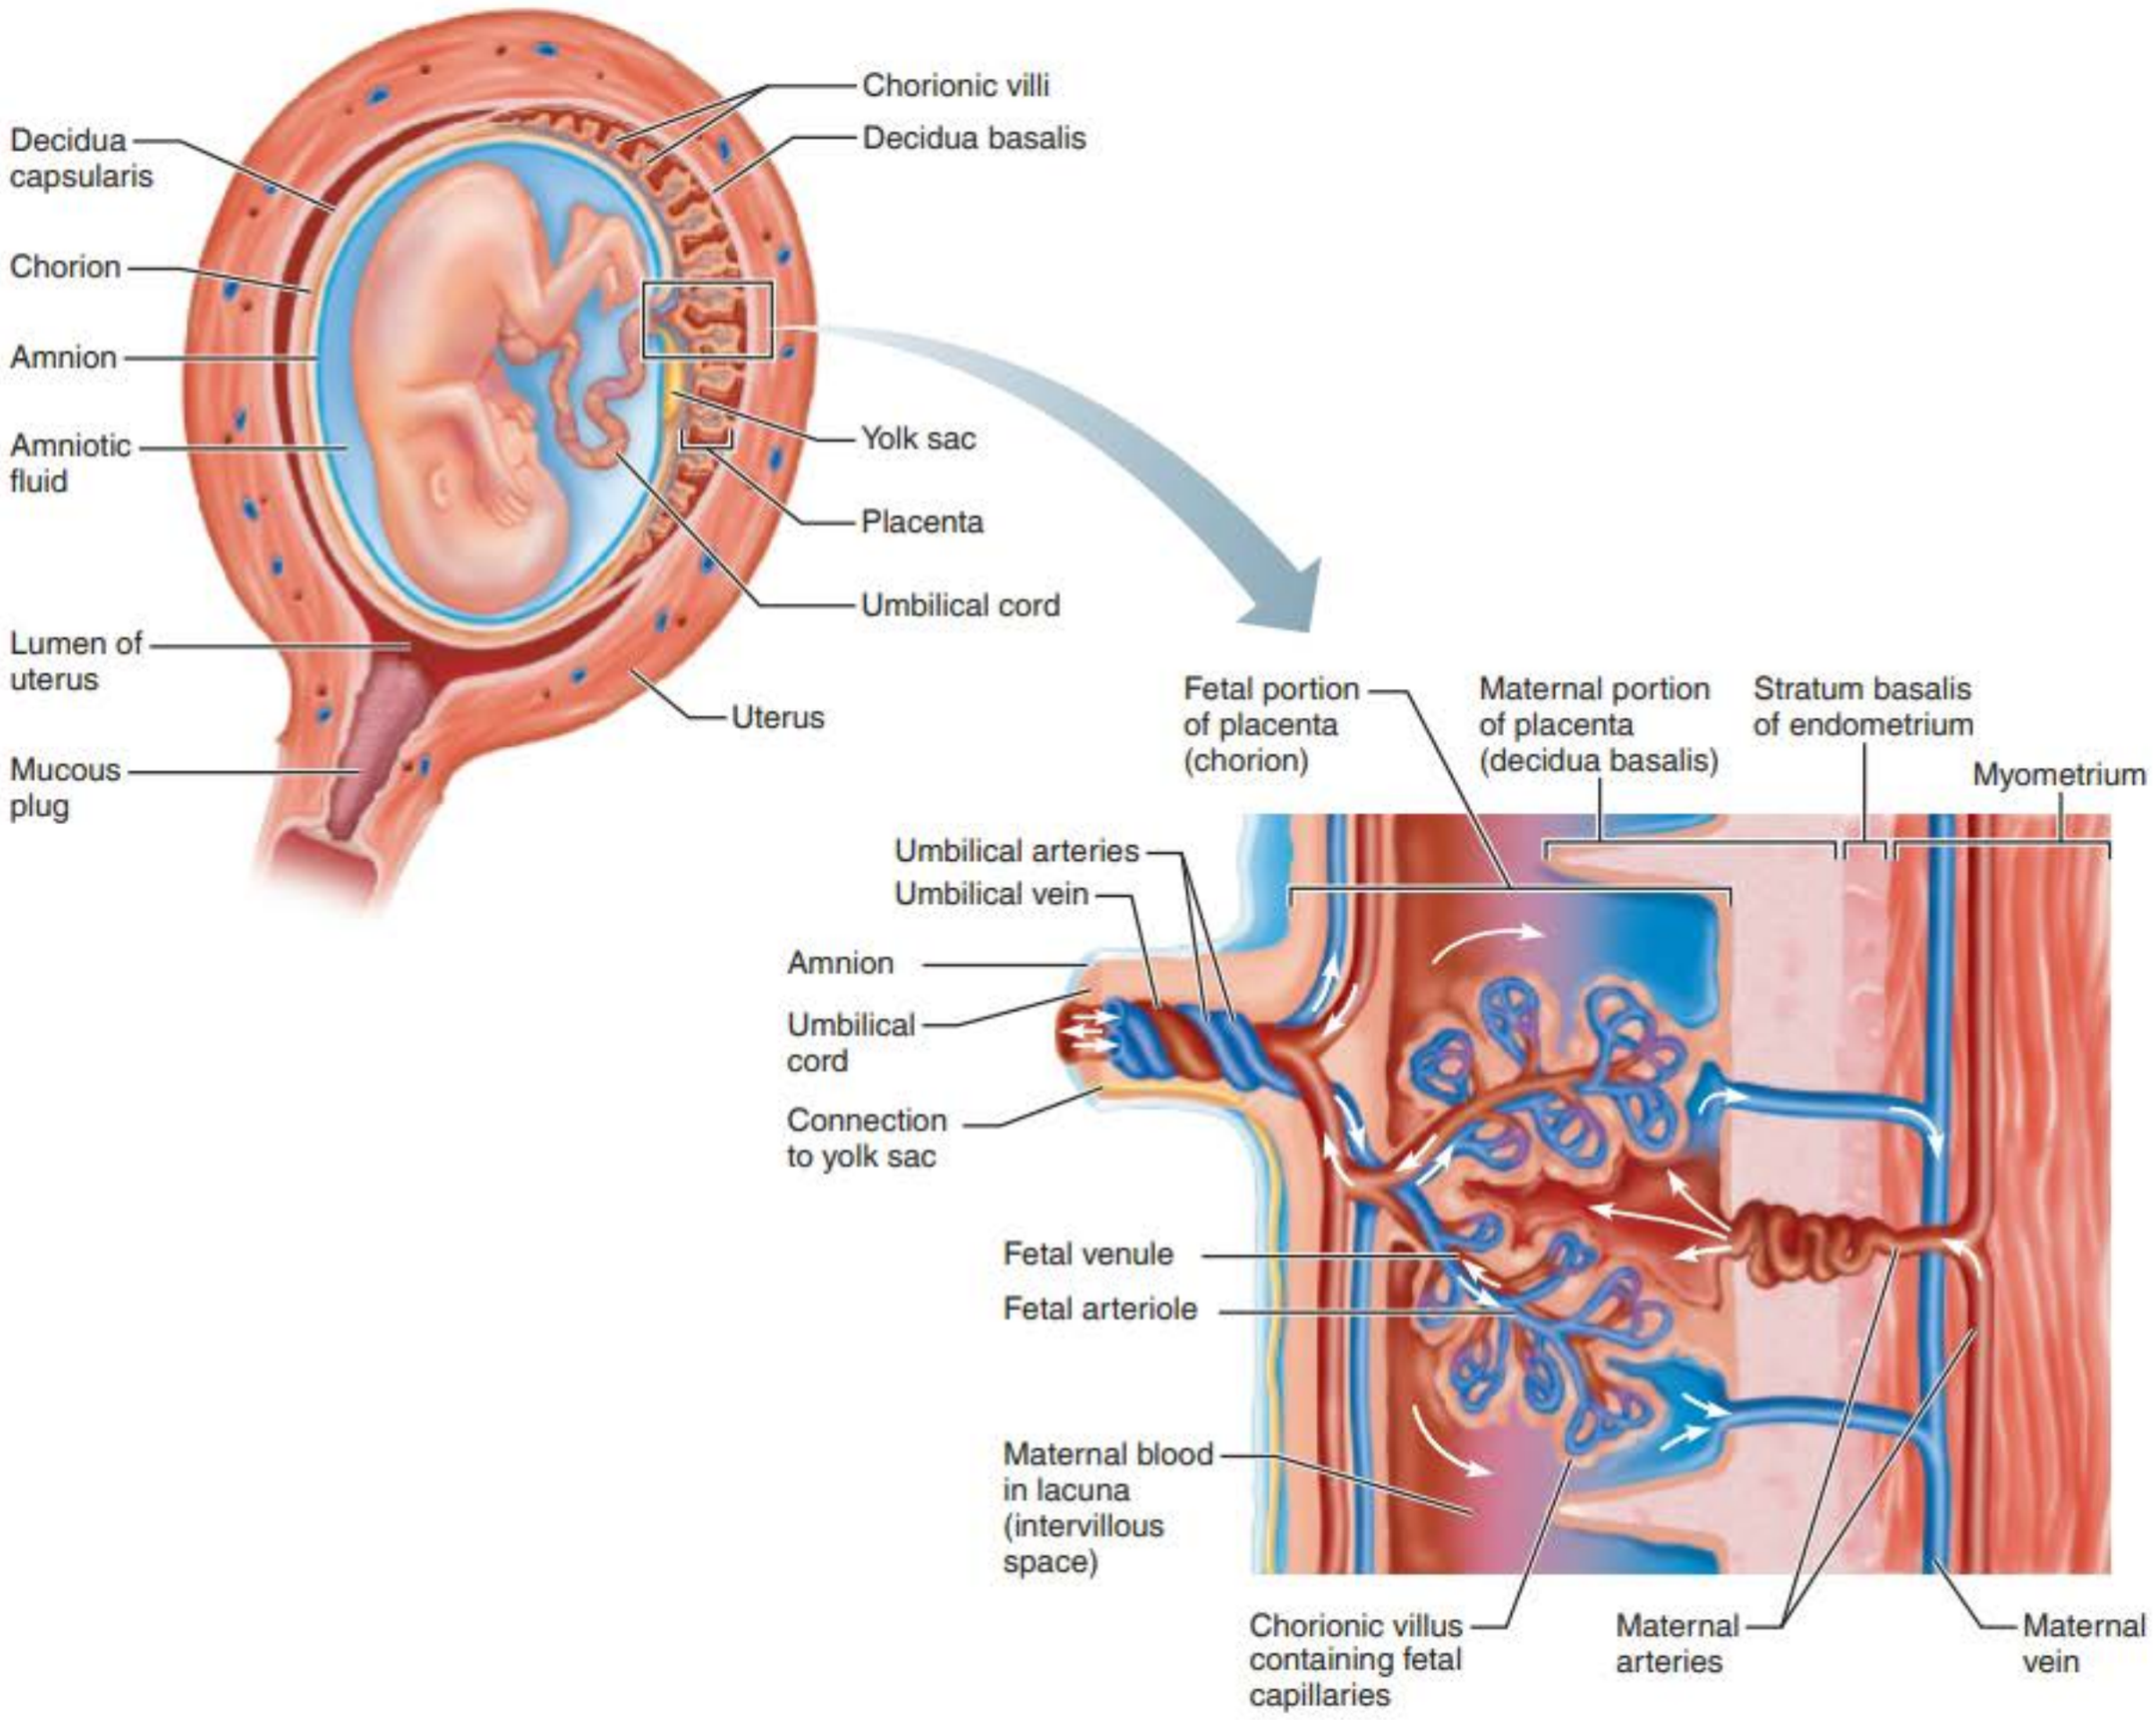


Figure 28.8 Detailed anatomy of the vascular relationships in the mature decidua basalis. This state of development has been accomplished by the end of the third month of development.

intervillous spaces, in the functional layer of the endometrium (◀ Figure 27.18, p. 1065). The villi come to lie in these spaces totally immersed in maternal blood (Figure 28.7d). The part of the endometrium that lies beneath the embryo becomes the **decidua basalis** (de-sid′u-ah), and that surrounding the uterine cavity face of the implanted embryo forms the **decidua capsularis** (Figure 28.7d and e). Together, the chorionic villi and the decidua basalis form the disc-shaped placenta.

The placenta detaches and sloughs off after the infant is born, so the name of the maternal portion—*decidua* ("that which falls off")—is appropriate. During development, the decidua capsularis expands to accommodate the fetus, which eventually fills and stretches the uterine cavity. As the developing fetus grows, the villi in the decidua capsularis are compressed and degenerate, while those in the decidua basalis increase in number and branch even more profusely.

The placenta is usually fully functional as a nutritive, respiratory, excretory, and endocrine organ by the end of the third month of pregnancy. However, well before this time, oxygen and nutrients are diffusing from maternal to embryonic blood, and embryonic metabolic wastes are passing in the opposite direction. The barriers to free passage of substances between the two blood supplies are embryonic barriers—the membranes of the chorionic villi and the endothelium of embryonic capillaries. Although the maternal and embryonic blood supplies are very close, they normally do not intermix (**Figure 28.8**).

The placenta secretes hCG from the beginning, but the ability of its syncytiotrophoblast cells (the "hormone manufacturers")

to produce the estrogens and progesterone of pregnancy matures much more slowly. If, for some reason, placental hormones are inadequate when hCG levels wane, the endometrium degenerates and the pregnancy spontaneously aborts. Throughout pregnancy, blood levels of estrogens and progesterone continue to increase (Figure 28.6). They encourage growth and further differentiation of the mammary glands and ready them for lactation. The placenta also produces other hormones, such as *human placental lactogen* and *relaxin*. We will describe the effects of these hormones on the mother shortly.

Check Your Understanding

6. Which portion of the trophoblast accomplishes implantation?
7. What is the composition of the chorion?
8. What endometrial decidua cooperates with the chorionic villi to form the placenta?
9. Generally speaking, when does the placenta become fully functional?
10. APPLY Amber, wondering if she is pregnant, buys an over-the-counter pregnancy test to assess this possibility. How will the blastocyst, if present, "make itself known"?

For answers, see Answers Appendix.

28.4 Embryonic events include gastrula formation and tissue differentiation, which are followed by rapid growth of the fetus

Learning Outcomes

- **Name and describe the formation, location, and function of the extraembryonic membranes.**
- **Describe gastrulation and its consequences.**
- **Define organogenesis and indicate the important roles of the three primary germ layers in this process.**
- **Describe unique features of the fetal circulation and the changes that occur in this circulation after birth.**
- **Indicate the duration of the fetal period, and note the major events of fetal development.**

Having followed placental development into the fetal stage, we will now backtrack and consider development of the embryo during and after implantation, referring to Figures 28.7 and 28.8. Even while implantation is occurring, the blastocyst is being converted to a **gastrula** (gas′troo-lah), in which the three primary germ layers form, and the extraembryonic membranes develop. The embryoblast first subdivides into two layers—the upper *epiblast* and the lower *hypoblast* (Figure 28.7a, b). The subdivided embryoblast is now called the **embryonic disc**.

Extraembryonic Membranes

The **extraembryonic membranes** that form during the first two to three weeks of development include the amnion, yolk sac, allantois, and chorion (Figures 28.7c and 28.8). The **amnion** (am′ne-on) develops when cells of the epiblast fashion themselves into a transparent membranous sac. This sac surrounds the *amniotic cavity*, which is filled with **amniotic fluid**. Eventually, the amnion extends all the way around the embryo, broken only by the umbilical cord (Figures 28.7d and 28.8).

Sometimes called the "bag of waters," the amnion provides a buoyant environment that protects the developing embryo against physical trauma, and helps maintain a constant temperature. The fluid also prevents the rapidly growing embryonic parts from adhering and fusing together and allows the embryo considerable freedom of movement. Initially, the fluid is derived from the maternal blood, but as the fetal kidneys become functional later in development, fetal urine contributes to amniotic fluid volume.

The **yolk sac** forms from cells of the primitive gut, which arrange themselves into a sac that hangs from the ventral surface of the embryo (Figure 28.7b–e). The amnion and yolk sac resemble two balloons touching one another with the embryonic disc at the point of contact. In many species, the yolk sac is the main source of nutrition for the embryo, but in humans it contains very little yolk and has a nutritive function only during the second and third weeks. Nevertheless, the yolk sac is important in humans because it:

- Forms part of the gut (digestive tube)
- Is the source of the earliest blood cells
- Is the location from which primordial germ cells (◀ p. 1083) migrate to the gonads to form sperm and ova

The **allantois** (ah-lan′to-is) forms as a small outpocketing of embryonic tissue at the caudal end of the yolk sac (Figure 28.7c). In animals that develop in shelled eggs, the allantois is a disposal site for solid metabolic wastes (excreta). In humans, the allantois is the structural base for the **umbilical cord** that links the embryo to the placenta, and ultimately it becomes part of the urinary bladder. The fully formed umbilical cord contains a core of embryonic connective tissue, the umbilical arteries and vein, and is covered externally by amniotic membrane.

We have already described the *chorion*, which helps to form the placenta (Figures 28.7c and 28.8). As the outermost membrane, the chorion encloses the embryonic body and all other membranes.

Gastrulation: Germ Layer Formation

During week 3, the two-layered embryonic disc transforms into a three-layered *embryo* in which the **primary germ layers**—*ectoderm, mesoderm*, and *endoderm*—are present (Figure 28.7c). This process, called **gastrulation** (gas″troo-la′shun), involves cellular rearrangements and migrations.

Figure 28.9 focuses on the changes that take place in the days between Figure 28.7b (12-day embryo) and Figure 28.7c (16-day embryo). Gastrulation begins when a groove with raised edges called the **primitive streak** appears on the dorsal surface of the embryonic disc. This groove establishes the longitudinal axis of the embryo (Figure 28.9e). Surface (epiblast) cells of the embryonic disc then migrate medially and enter the primitive streak. The first cells to enter the groove displace the hypoblast cells of the yolk sac and form the most inferior germ layer, the **endoderm** (Figure 28.9f). Those that follow push laterally between the cells at the upper and lower surfaces, forming the

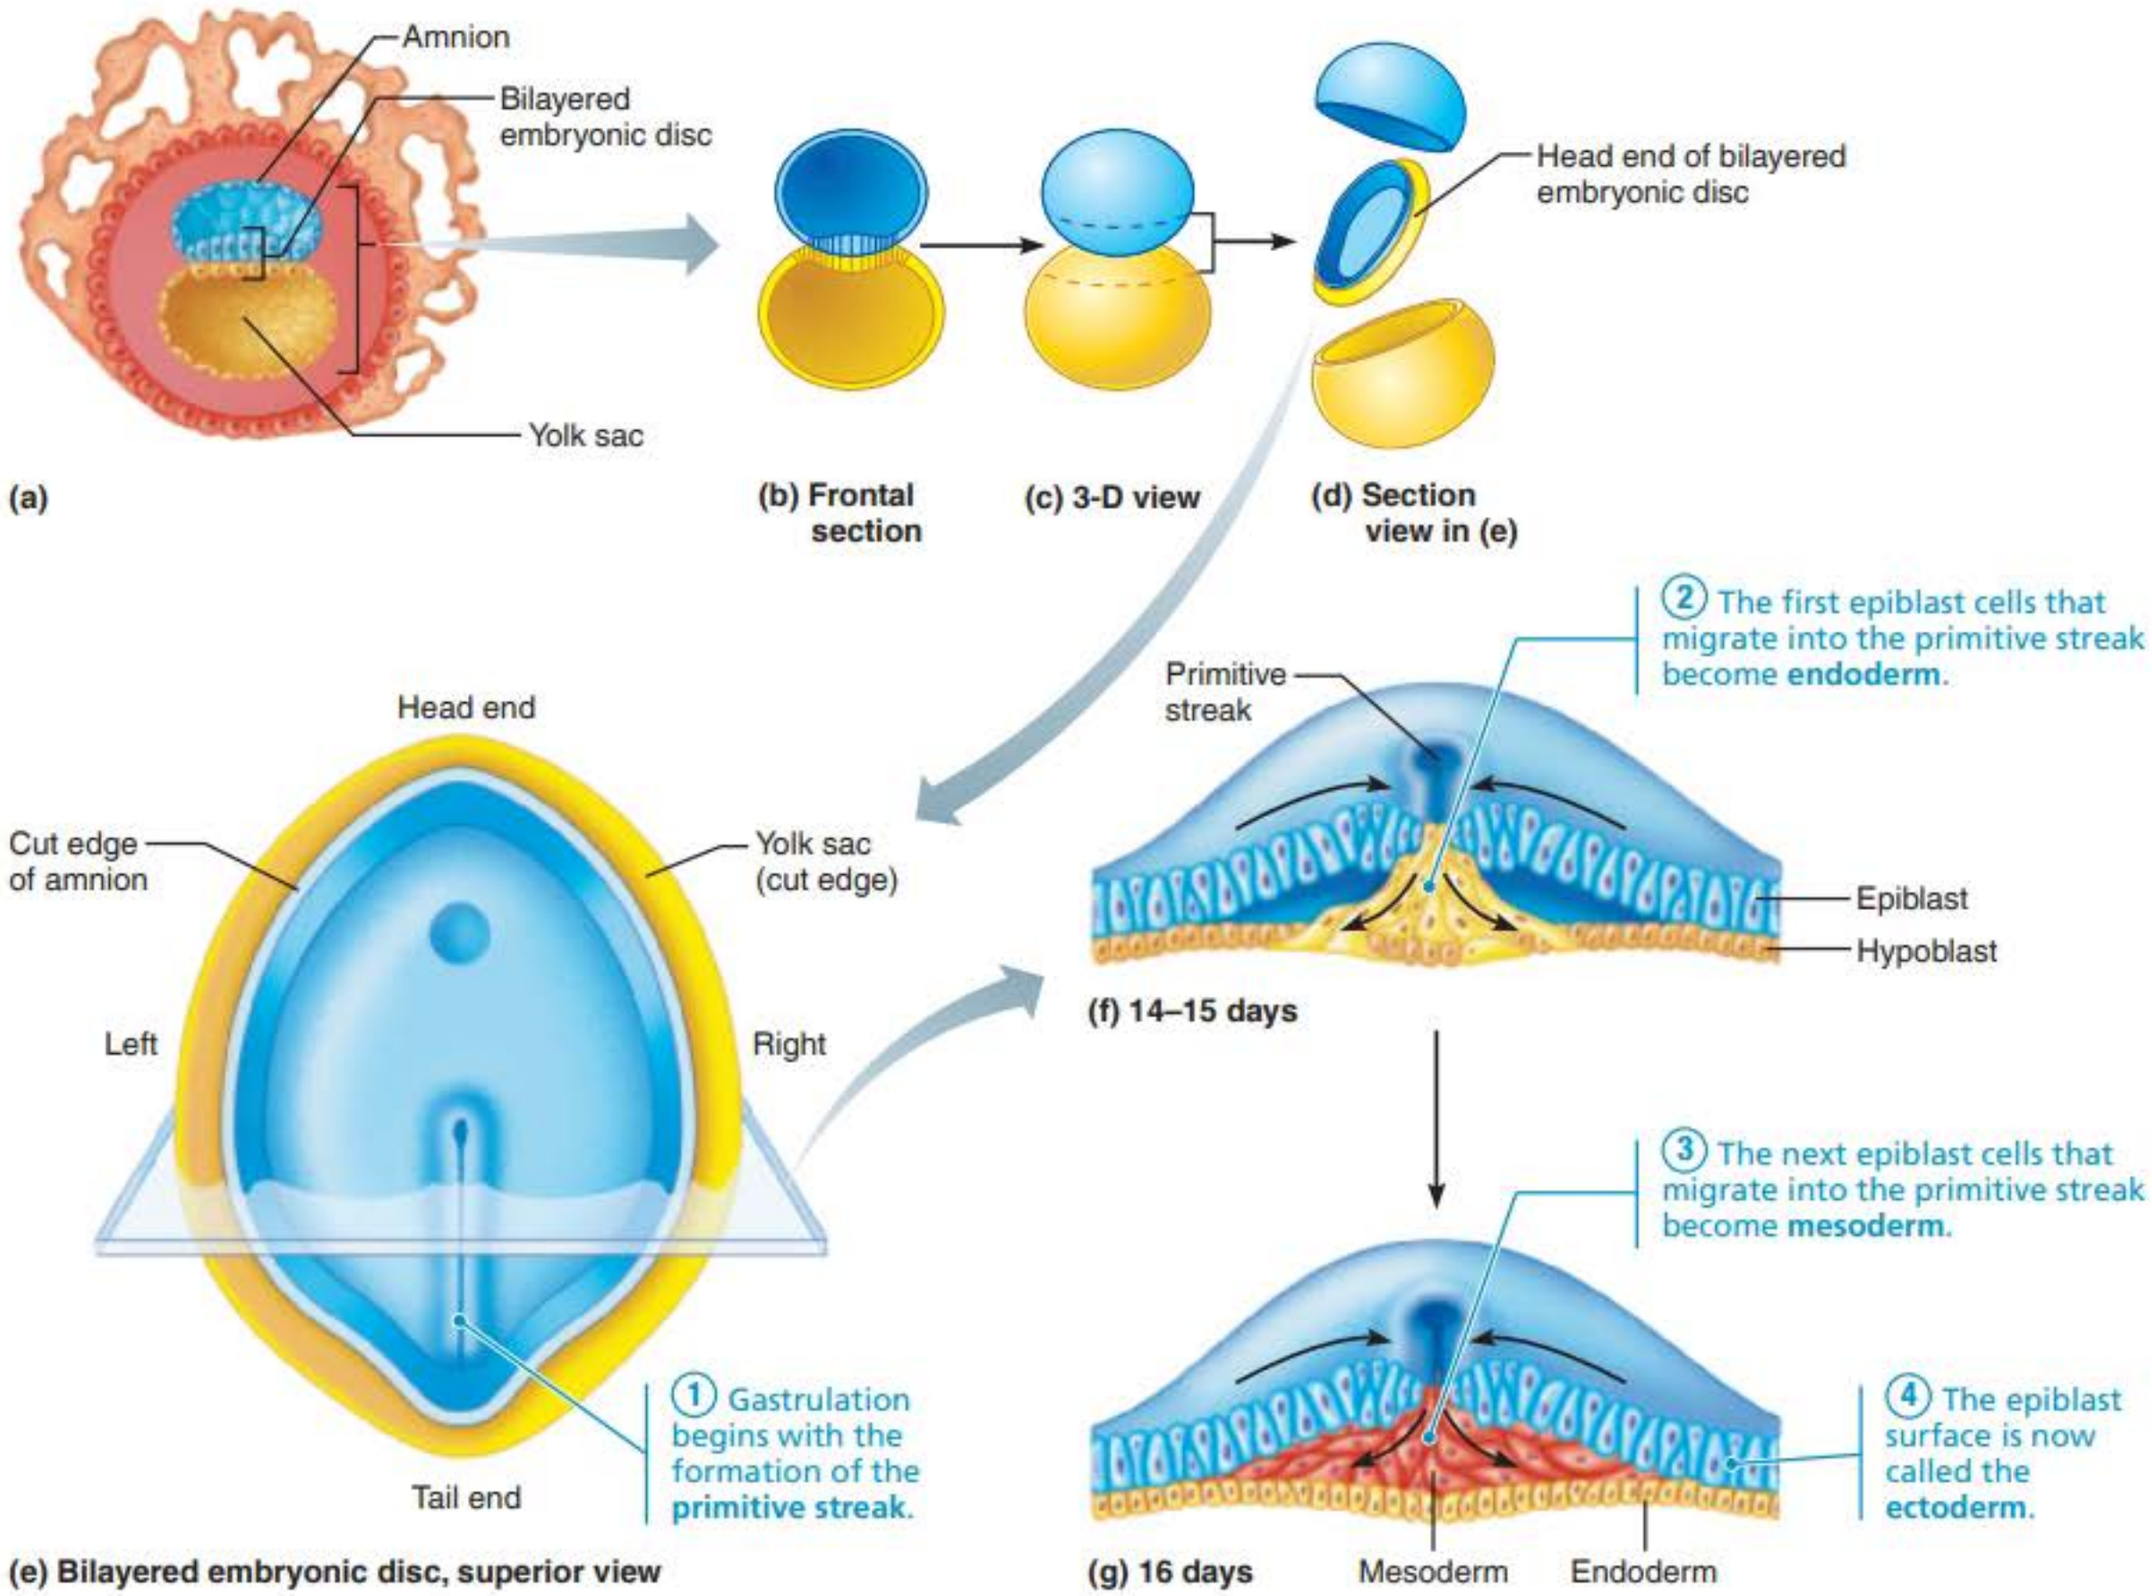

Figure 28.9 Formation of the three primary germ layers. (a–d) Orienting diagrams. **(e)** Surface view of an embryonic disc, amnion and yolk sac removed. **(f, g)** Sections through the embryonic disc at the location shown in (e).

mesoderm (Figure 28.9g). As soon as the mesoderm is formed, the mesodermal cells immediately beneath the early primitive streak aggregate, forming a rod of mesodermal cells called the **notochord** (no′to-kord), the first axial support of the embryo (see Figure 28.12a). The cells that remain on the embryo's dorsal surface are the **ectoderm**. At this point, the embryo is about 2 mm long.

The three primary germ layers serve as the *primitive tissues* from which all body organs derive.

- Ectoderm ("outer skin") fashions structures of the nervous system and the skin epidermis.
- Endoderm ("inner skin") forms the epithelial linings of the digestive, respiratory, and urogenital systems, and associated glands.
- Mesoderm ("middle skin") forms virtually everything else.

Both ectoderm and endoderm consist mostly of cells that are securely joined to each other and are *epithelia*. Mesoderm, by contrast, is a *mesenchyme* [literally, "poured into the middle (of the embryo)"], an embryonic tissue with star-shaped cells that are free to migrate widely within the embryo. Figure 28.13 lists the germ layer derivatives. Some of the details of the differentiation processes are described next.

Organogenesis: Differentiation of the Germ Layers

Gastrulation lays down the basic structural framework of the embryo. It also sets the stage for the rearrangements that occur during **organogenesis** (or″gah-no-jen′ĕ-sis), formation of body organs and organ systems. By the end of the embryonic period at 8 weeks, when the embryo is about 30 mm (slightly more than 1 inch) long from head to buttocks (referred to as the *crown-rump measurement*), all the adult organ systems are recognizable. It is truly amazing how much organogenesis occurs in such a short time in such a small amount of living matter.

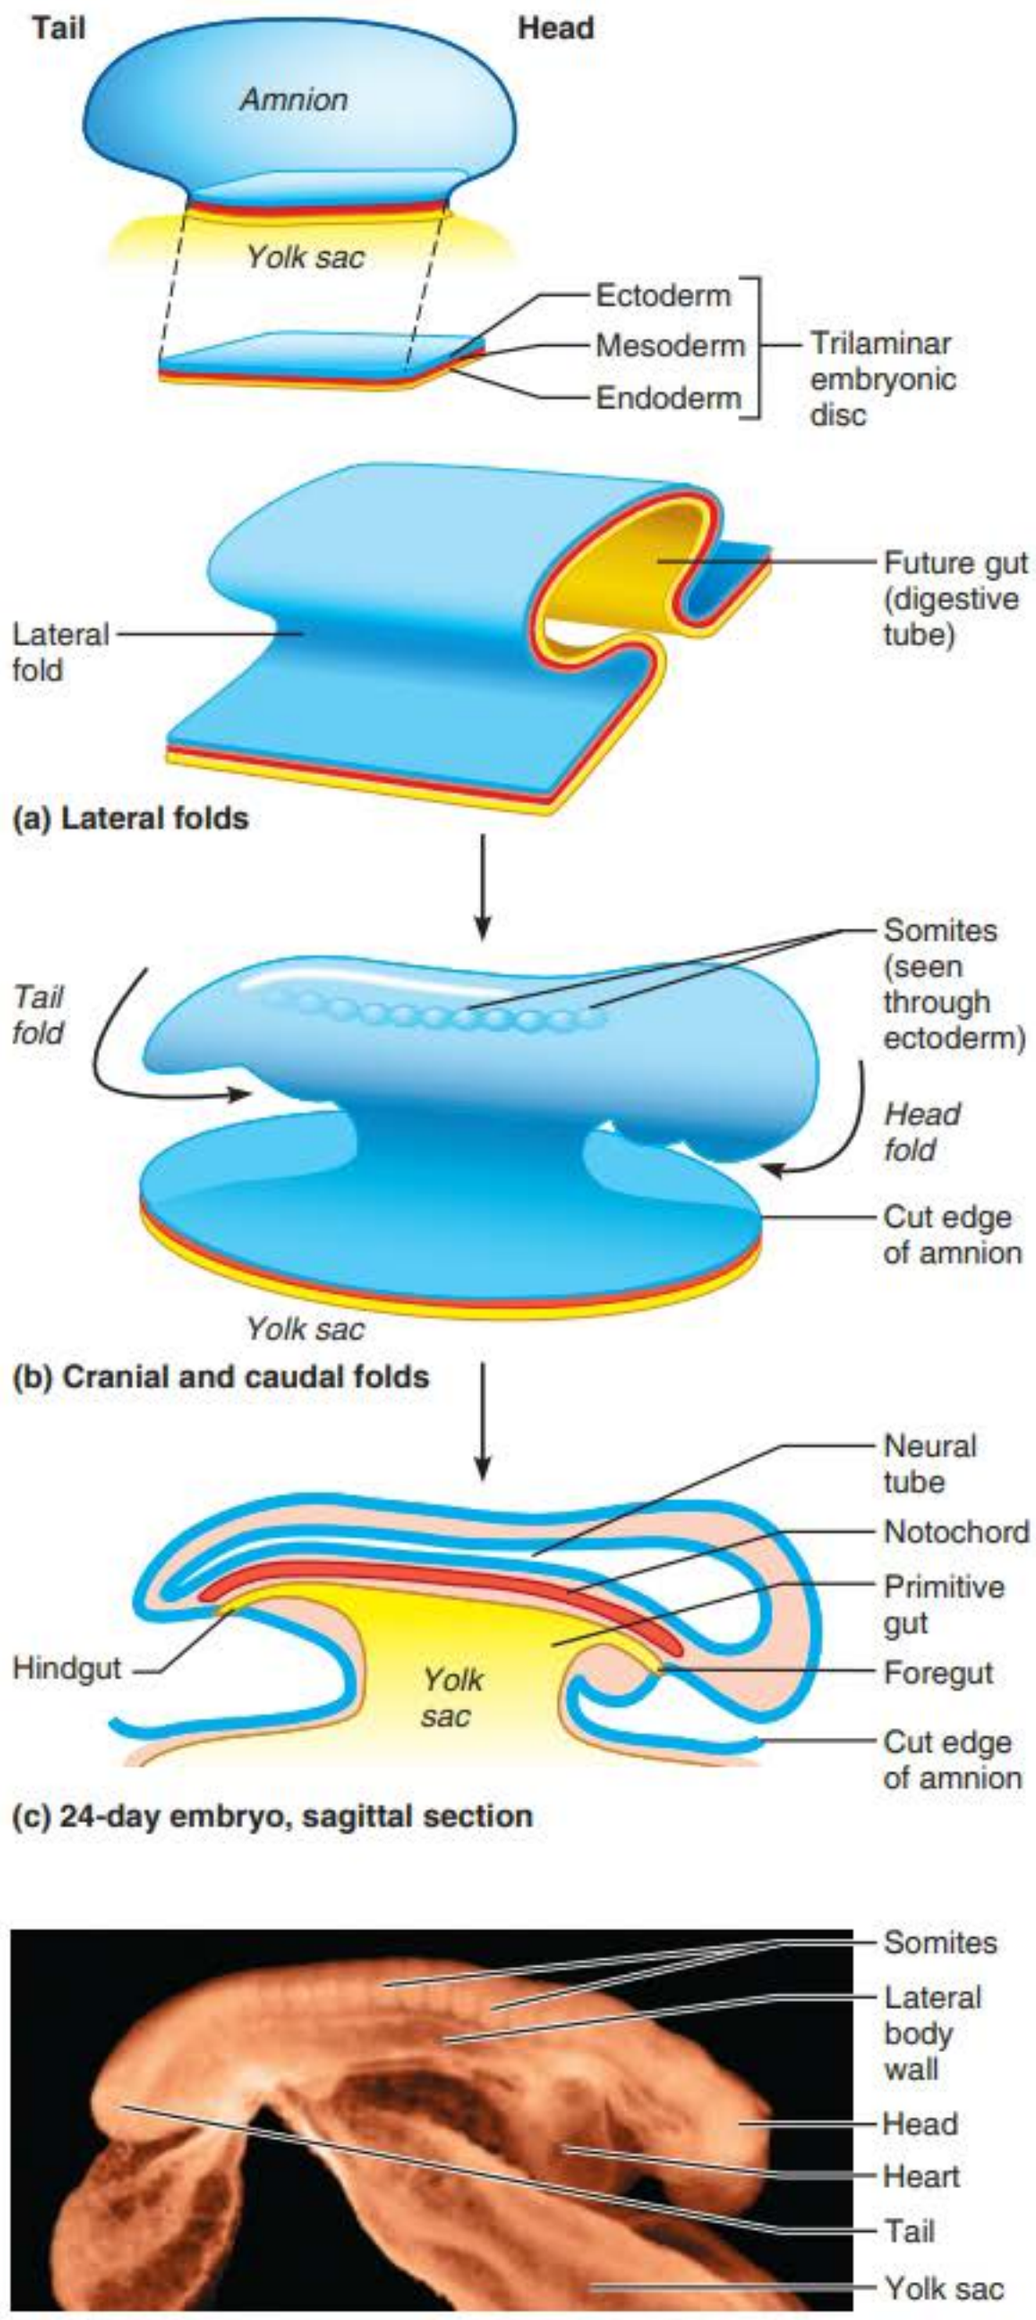

Figure 28.10 Folding of the embryonic body. Lateral views.

As **Figure 28.10** shows, the embryo starts off as a flat plate, but as it grows, it folds to achieve a cylindrical body shape which lifts off the yolk sac and protrudes into the amniotic cavity. In the simplest sense, this process resembles three stacked sheets of paper folding laterally into a tube (Figure 28.10a). At the same time, the folding occurs from both ends (the head and tail regions) and progresses toward the central part of the embryonic body, where the yolk sac and umbilical vessels protrude. As the endoderm undercuts and its edges come together and fuse, it encloses part of the yolk sac (Figure 28.10c).

Specialization of the Endoderm

The tube of endoderm formed by the folding process described above is called the **primitive gut**. It becomes the epithelial lining of the gastrointestinal tract (**Figure 28.11**). The organs of the GI tract (pharynx, esophagus, etc.) quickly become apparent, and then the oral and anal ends of the gut open. The mucosal lining of the respiratory tract forms as an outpocketing of the *foregut*, and glands arise as endodermal outpocketings at various points farther along the tract. For example, the epithelium of the thyroid, parathyroids, and thymus forms from the pharyngeal endoderm.

Specialization of the Ectoderm

The first major event in organogenesis is **neurulation**, the differentiation of ectoderm that produces the brain and spinal cord (**Figure 28.12**). This process is *induced* (stimulated to happen) by chemical signals from the *notochord*, the rod of mesoderm (mentioned earlier) that defines the body axis. The ectoderm overlying the notochord thickens, forming the **neural plate** (Figure 28.12a). Then the ectoderm folds, forming the **neural groove** as well as **neural folds** on either side (Figure 28.12b). By day 22, the superior margins of the neural folds fuse, forming a **neural tube**, which soon pinches off from the ectodermal layer and becomes covered by surface ectoderm (Figure 28.12c).

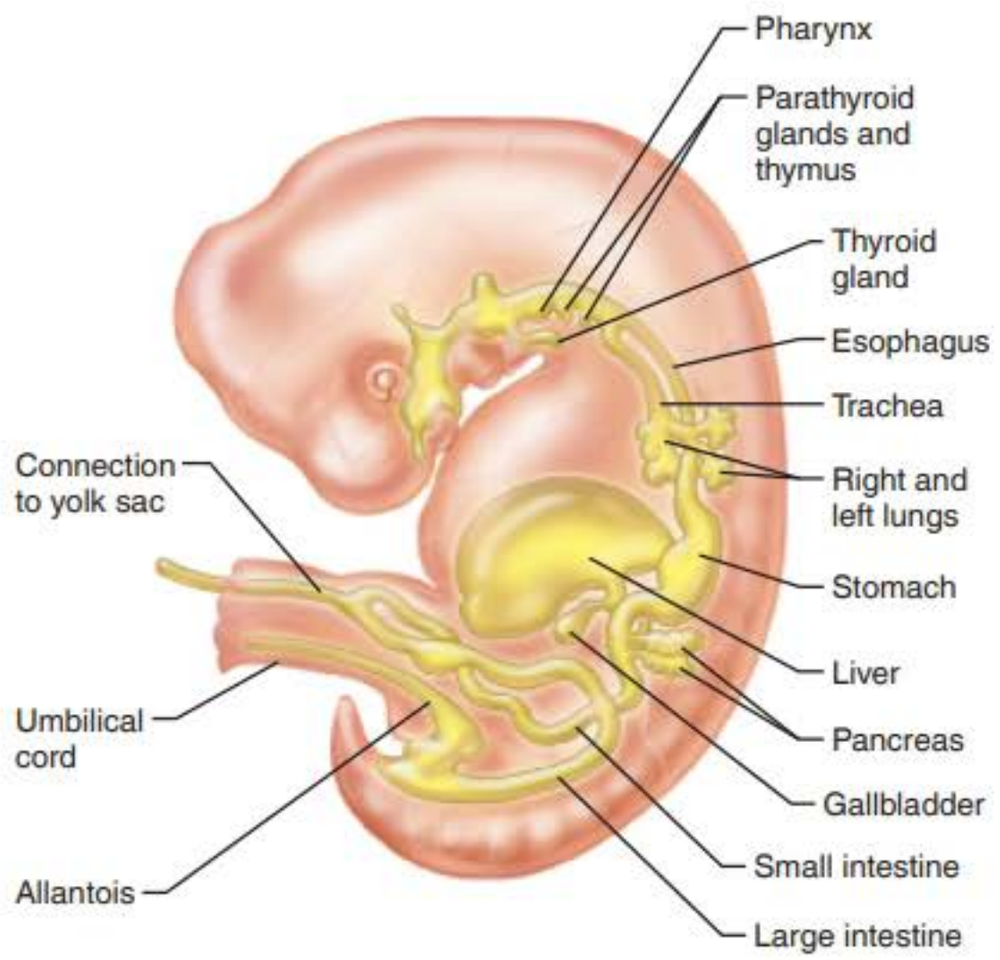

Figure 28.11 Endodermal differentiation. Endoderm forms the epithelial linings of the digestive and respiratory tracts and associated glands.

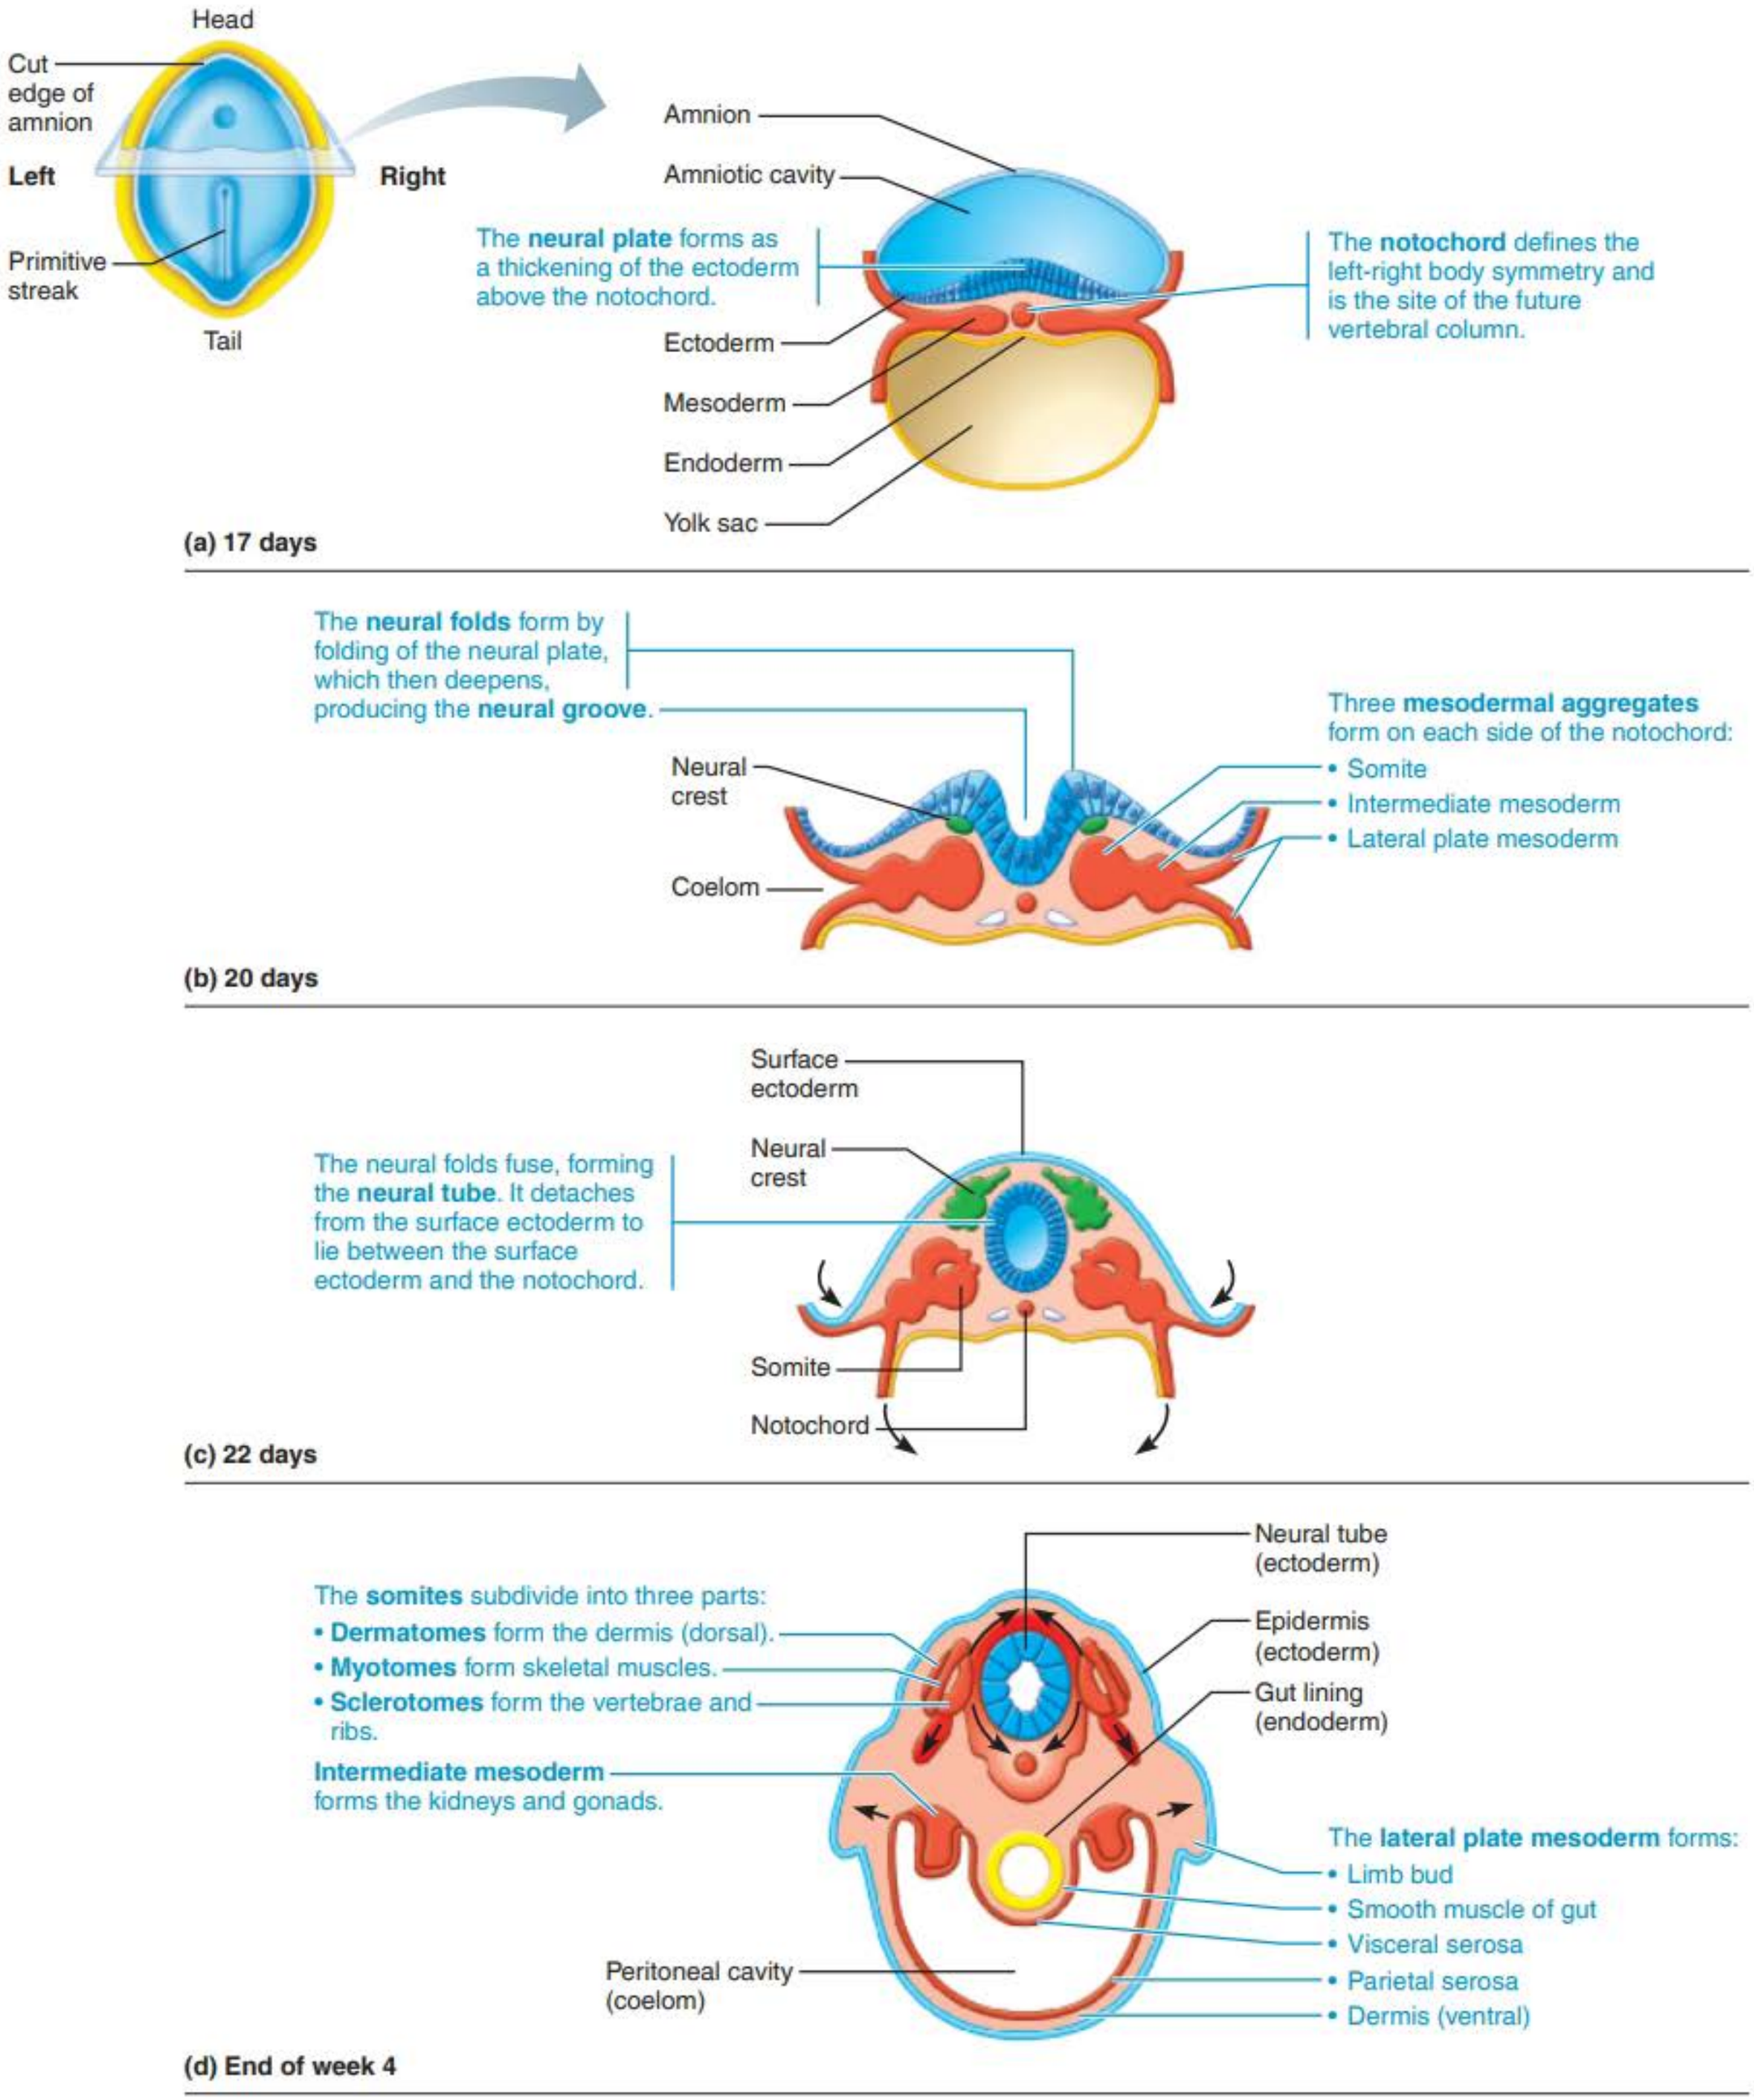

Figure 28.12 Neurulation and early mesodermal differentiation. The embryonic body begins to undercut in (**c**) and undercutting is complete in (**d**).

As we described in Chapter 12 (◀ p. 435), the anterior end of the neural tube becomes the brain and the rest becomes the spinal cord. The associated **neural crest cells** (Figure 28.12c) migrate widely and give rise to the cranial, spinal, and sympathetic ganglia (and associated nerves), to the chromaffin cells of the adrenal medulla (◀ p. 627), and to pigment cells of the skin, and they contribute to some connective tissues.

By the end of the first month of development, the three primary brain vesicles (fore-, mid-, and hindbrain) are apparent (◀ Figure 12.1, p. 435). By the end of the second month, all brain flexures are evident, the cerebral hemispheres cover the top of the brain stem (◀ Figure 12.2, p. 436), and brain waves can be recorded. Most of the remaining ectoderm forming the surface layer of the embryonic body differentiates into the epidermis of the skin. The ectodermal derivatives are summarized in **Figure 28.13**.

Specialization of the Mesoderm

The first evidence of mesodermal differentiation is the appearance of the notochord in the embryonic disc (see Figure 28.12a). The notochord is eventually replaced by the vertebral column, but its remnants persist in the springy *nucleus pulposus* (◀ p. 219) of the intervertebral discs. Shortly thereafter, three mesodermal aggregates develop on either side of the notochord (Figure 28.12b, c). The largest of these, the *somites* (so′mīts), are paired mesodermal blocks that hug the notochord on either side. All of the pairs of somites are present by the end of week 5. Flanking the somites laterally are small clusters of segmented mesoderm called *intermediate mesoderm* and then double sheets of *lateral plate mesoderm*.

Each **somite** has three functional parts—*sclerotome, dermatome*, and *myotome* (Figure 28.12d).

- Cells of the **sclerotome** (skle′ro-tōm; "hard piece") migrate medially, gather around the notochord and neural tube, and produce the vertebra and rib at each associated level.
- **Dermatome** ("skin piece") cells help form the dermis of the skin in the dorsal part of the body.
- The **myotome** (mi′o-tōm; "muscle piece") cells develop in conjunction with the vertebrae. They form the skeletal muscles of the neck, body trunk, and, via their **limb buds**, the muscles of the limbs.

Cells of the **intermediate mesoderm** form the gonads and kidneys. The **lateral plate mesoderm** splits to form paired mesodermal layers: the *somatic mesoderm* and the more inferior *splanchnic mesoderm*. Cells of the somatic mesoderm help to form:

- The skin dermis of the ventral body region
- The parietal serosa that lines the ventral body cavity
- Most tissues of the limbs

The splanchnic mesoderm provides the mesenchymal cells that form the heart and blood vessels and most connective tissues of the body, as well as nearly the entire wall of the digestive and

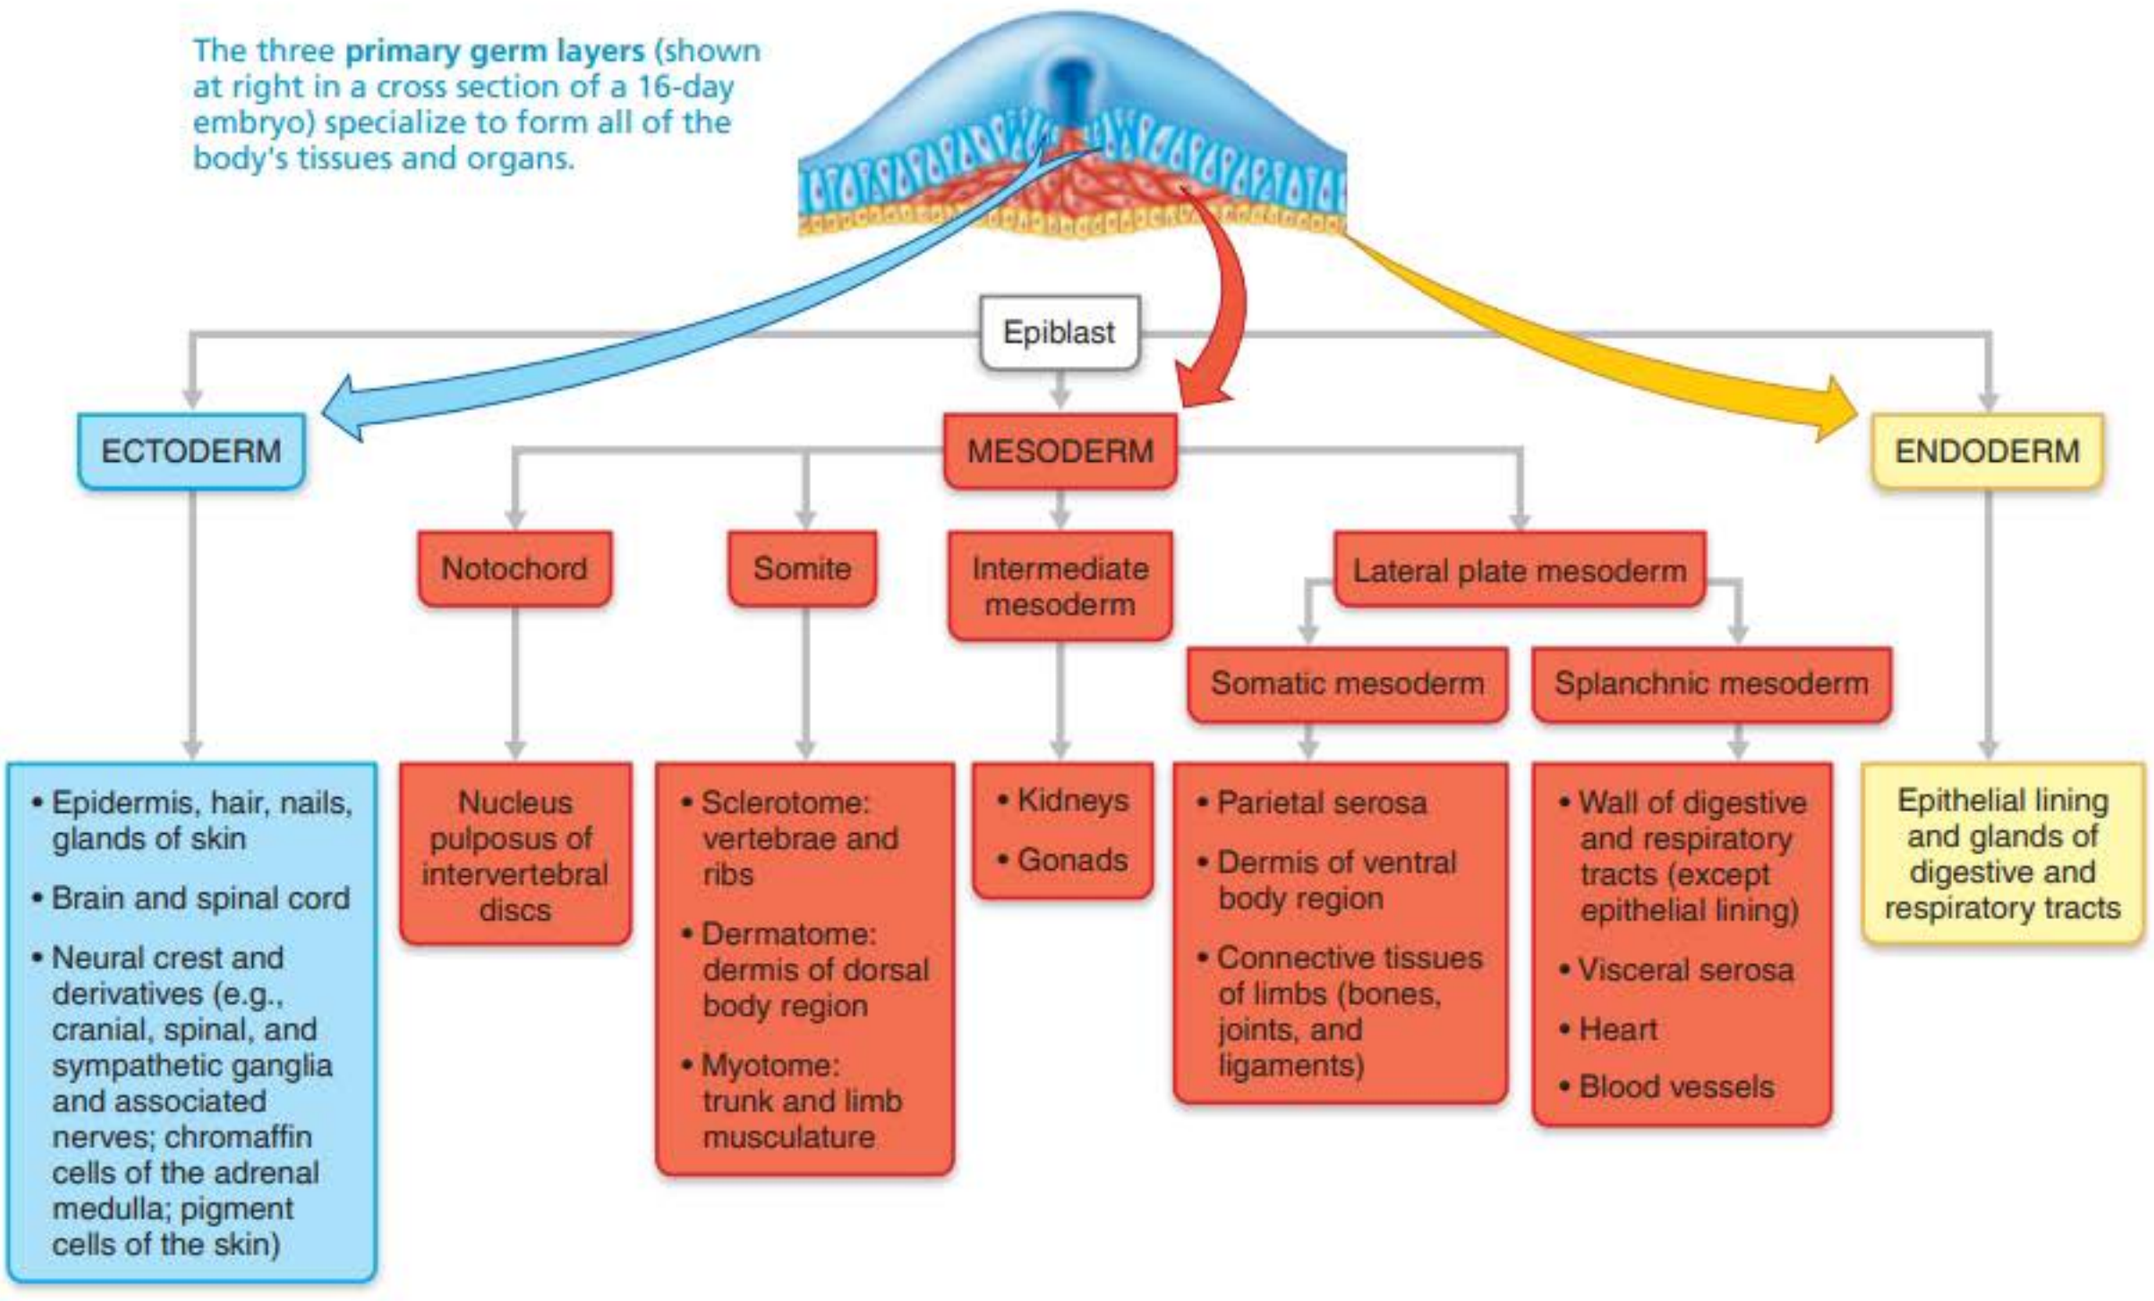

Figure 28.13 Flowchart showing major derivatives of the embryonic germ layers.

respiratory organs. The two layers of the lateral plate mesoderm cooperate to form the serosae of the **coelom** (se′lom), or ventral body cavity. The mesodermal derivatives are summarized in Figure 28.13.

The Fetal Circulation

Embryonic development of the cardiovascular system lays the groundwork for the fetal circulatory pattern, which is converted to the adult pattern at birth. The first blood cells arise in the yolk sac. Before week 3 of development, tiny spaces appear in the splanchnic mesoderm. These are quickly lined by endothelial cells, covered with mesenchyme, and linked together into rapidly spreading vascular networks, destined to form the heart, blood vessels, and lymphatics. By the end of week 3, the embryo has a system of paired blood vessels, and the two vessels forming the heart have fused (◀ Figure 18.22b, p. 701). By 22 days, the miniature heart is pumping blood for an embryo less than 2 mm (0.1 inch) long.

Unique cardiovascular modifications seen only during prenatal development include the **umbilical arteries** and **vein** and three *vascular shunts*. All of these structures are occluded (blocked off) at birth. They are described in *Focus on Fetal and Newborn Circulation* (**Focus Figure 28.2** on pp. 1108–1109) and summarized in **Table 28.1**.

As you read about these structures, keep in mind that the blood is flowing from and to the fetal heart but that O_2, CO_2, nutrition, and waste exchanges occur *at the placenta*. The large umbilical vein carries freshly oxygenated blood returning from the placenta into the embryonic body, where it is conveyed to the liver. There, some of the returning blood percolates through the liver sinusoids and out the hepatic veins. Most of the blood coursing through the umbilical vein, however, enters the **ductus venosus** (duk′tus ve-no′sus), a venous shunt that bypasses the liver sinusoids. Both the hepatic veins and the ductus venosus empty into the inferior vena cava where the placental blood mixes with deoxygenated blood returning from the lower parts of the fetus's body. The vena cava in turn conveys this mixed blood directly to the right atrium of the heart.

After birth, the liver plays an important role in nutrient processing, but during embryonic life the mother's liver performs these functions. Consequently, blood flow through the fetal liver during development is important only to ensure that the liver cells remain healthy.

Blood entering and leaving the heart encounters two more shunt systems, each serving to bypass the nonfunctional lungs (Focus Figure 28.2, left side). (The lungs *do* receive adequate blood to maintain their growth.)

Occlusion of Vascular Shunts After Birth

After birth the special umbilical blood vessels and fetal shunts are no longer necessary (Focus Figure 28.2, right side). The umbilical arteries and vein constrict and become fibrosed. The proximal parts of the umbilical arteries persist as the *superior vesical arteries* that supply the urinary bladder, and their distal parts become the **median umbilical ligaments**. The remnant of the umbilical vein becomes the **round ligament** of the liver, or **ligamentum teres** (◀ p. 894), which attaches the umbilicus to the liver. The ductus venosus collapses as blood stops flowing through the umbilical vein and is eventually converted to the **ligamentum venosum** on the liver's undersurface.

Table 28.1 Special Fetal Circulation Structures

FETAL STRUCTURE	POSTNATAL STRUCTURE	FUNCTION IN FETUS
Foramen ovale	Fossa ovalis	Diverts blood from the right atrium to the left atrium
Ductus arteriosus	Ligamentum arteriosum	Diverts blood from the pulmonary trunk to the aorta
Ductus venosus	Ligamentum venosum	Carries blood from the umbilical vein through the liver (bypassing sinusoids) into the inferior vena cava
Umbilical arteries	Median umbilical ligaments	Paired vessels carry blood from the fetus to the placenta
Umbilical vein	Round ligament of the liver (ligamentum teres)	Single vessel carries oxygenated blood from the placenta to the fetus

As the pulmonary circulation becomes functional, pressure in the left side of the heart increases and that in the right side of the heart decreases, causing the pulmonary shunts to close. The flap of the **foramen ovale** is pushed to the shut position, and its edges fuse to the septal wall. Ultimately, only a slight depression, the **fossa ovalis** (◀ p. 674), marks its position. The **ductus arteriosus** constricts in response to rising blood oxygen levels and is converted to the cordlike **ligamentum arteriosum**, connecting the aorta and pulmonary trunk.

Except for the foramen ovale, all of the special circulatory adaptations of the fetus are functionally occluded within 30 minutes after birth. Closure of the foramen ovale is usually complete within the year. Failure of the ductus arteriosus or foramen ovale to close are common congenital heart defects.

Events of Fetal Development

By the end of the embryonic period (8 weeks), the bones have begun to ossify and the skeletal muscles are well formed and contracting spontaneously. Metanephric kidneys are developing (◀ p. 1006), gonads are formed, and the lungs and digestive organs are attaining their final shape and body position. Blood delivery to and from the placenta via the umbilical vessels is constant and efficient. The heart and the liver are competing for space and form a conspicuous bulge on the ventral surface of the embryo's body. All this by the end of eight weeks in an embryo about 3 cm (slightly more than 1 inch) long from crown to rump and a weight of approximately 2 g (0.06 ounce)!

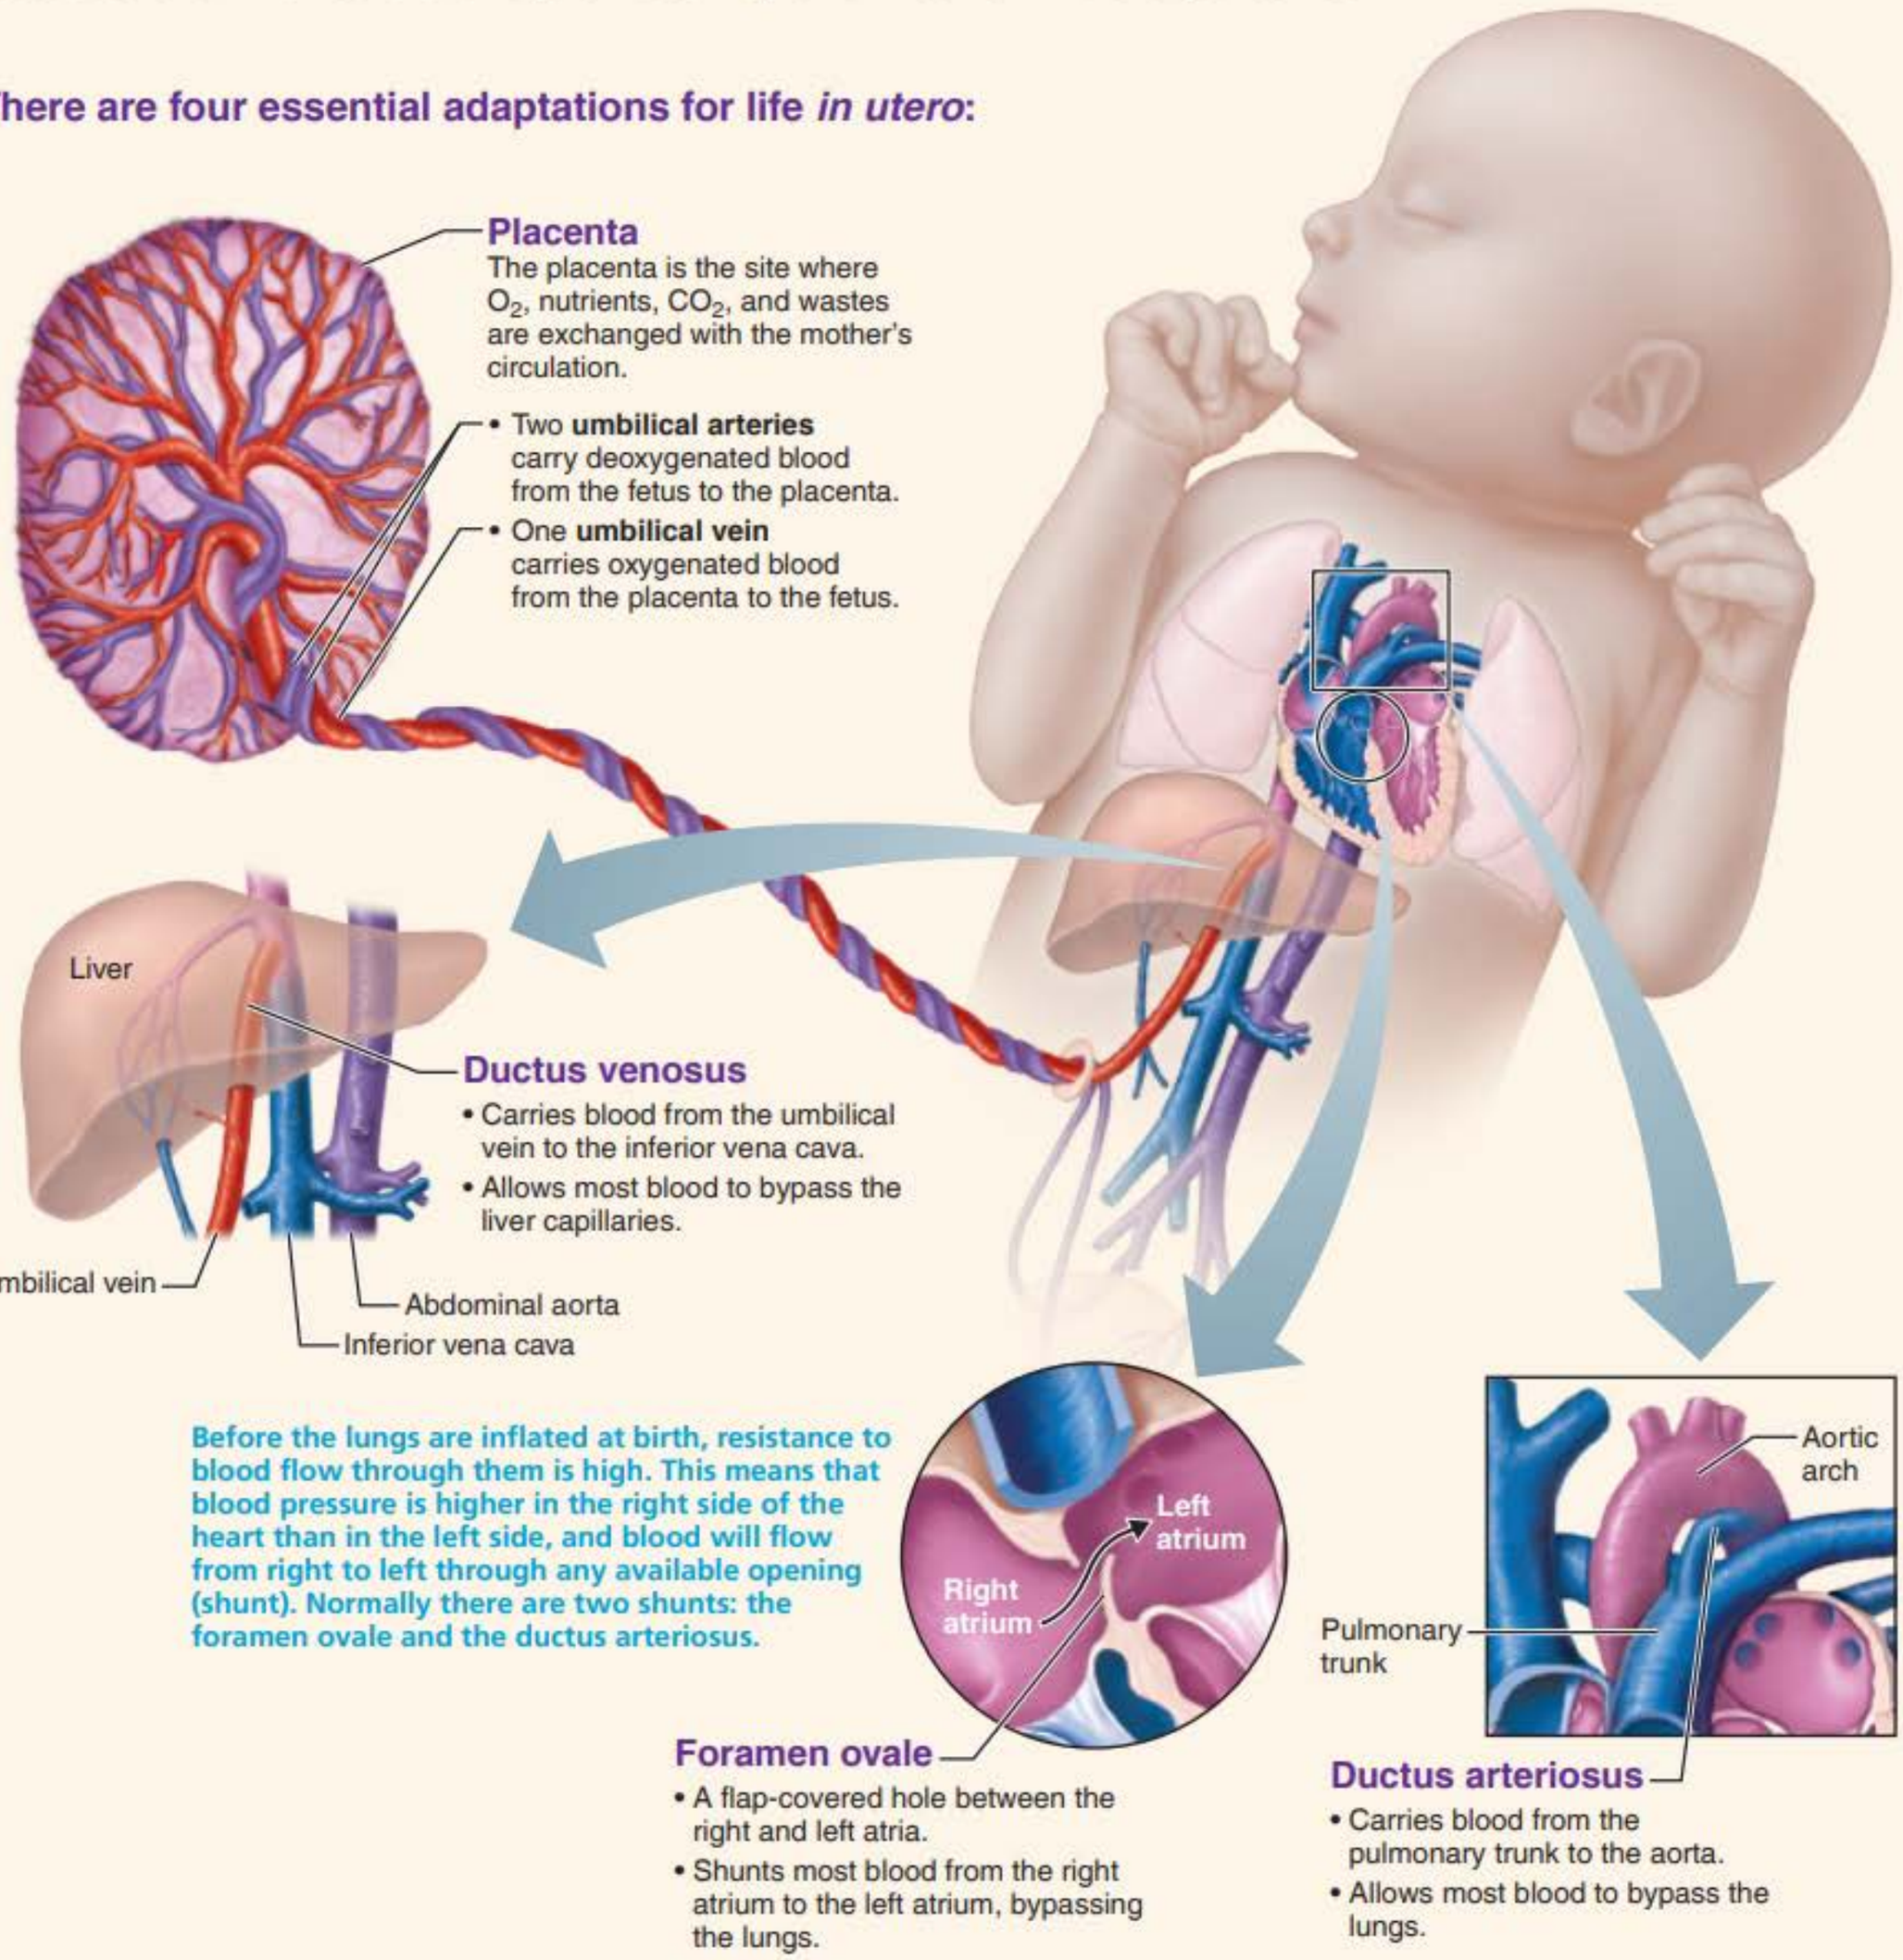
During the fetal period, the developing fetus grows to about 360 mm (14 inches) and 3.2 kg (7 lb) or more. (Total body length at birth is about 550 mm, or 22 inches.) As you might expect with such tremendous growth, the changes in fetal appearance

(Text continues on p. 1110.)

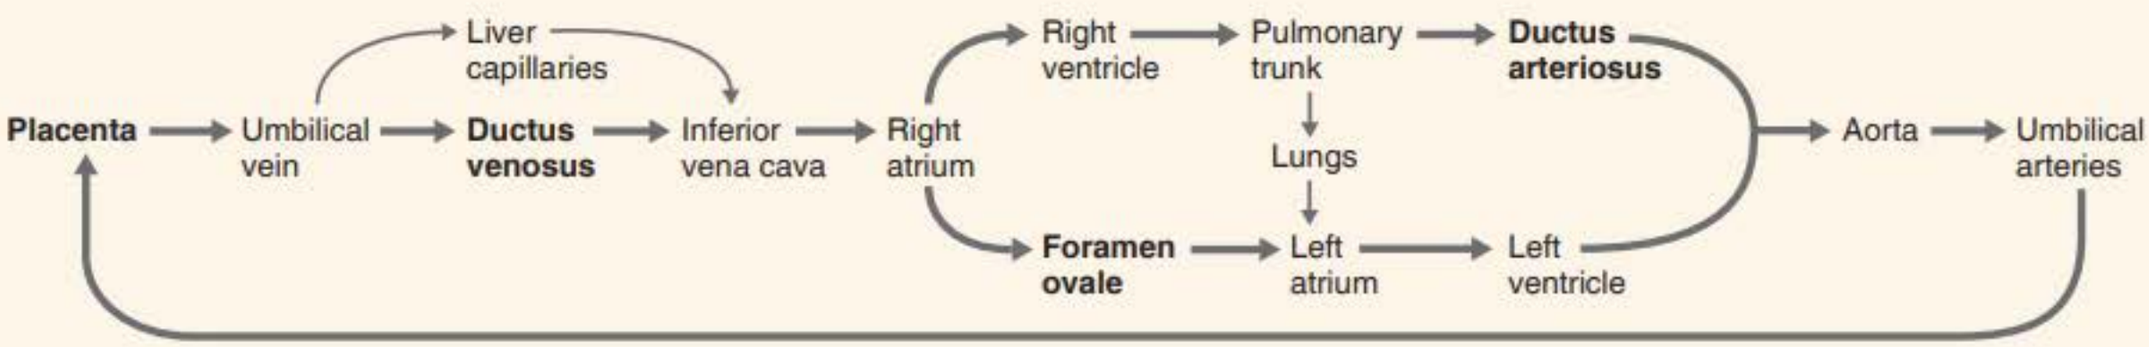
FOCUS FIGURE 28.2 Fetal and Newborn Circulation

Before birth, fetal blood bypasses the nonfunctional lungs and liver because their functions are provided by the mother via the placenta.

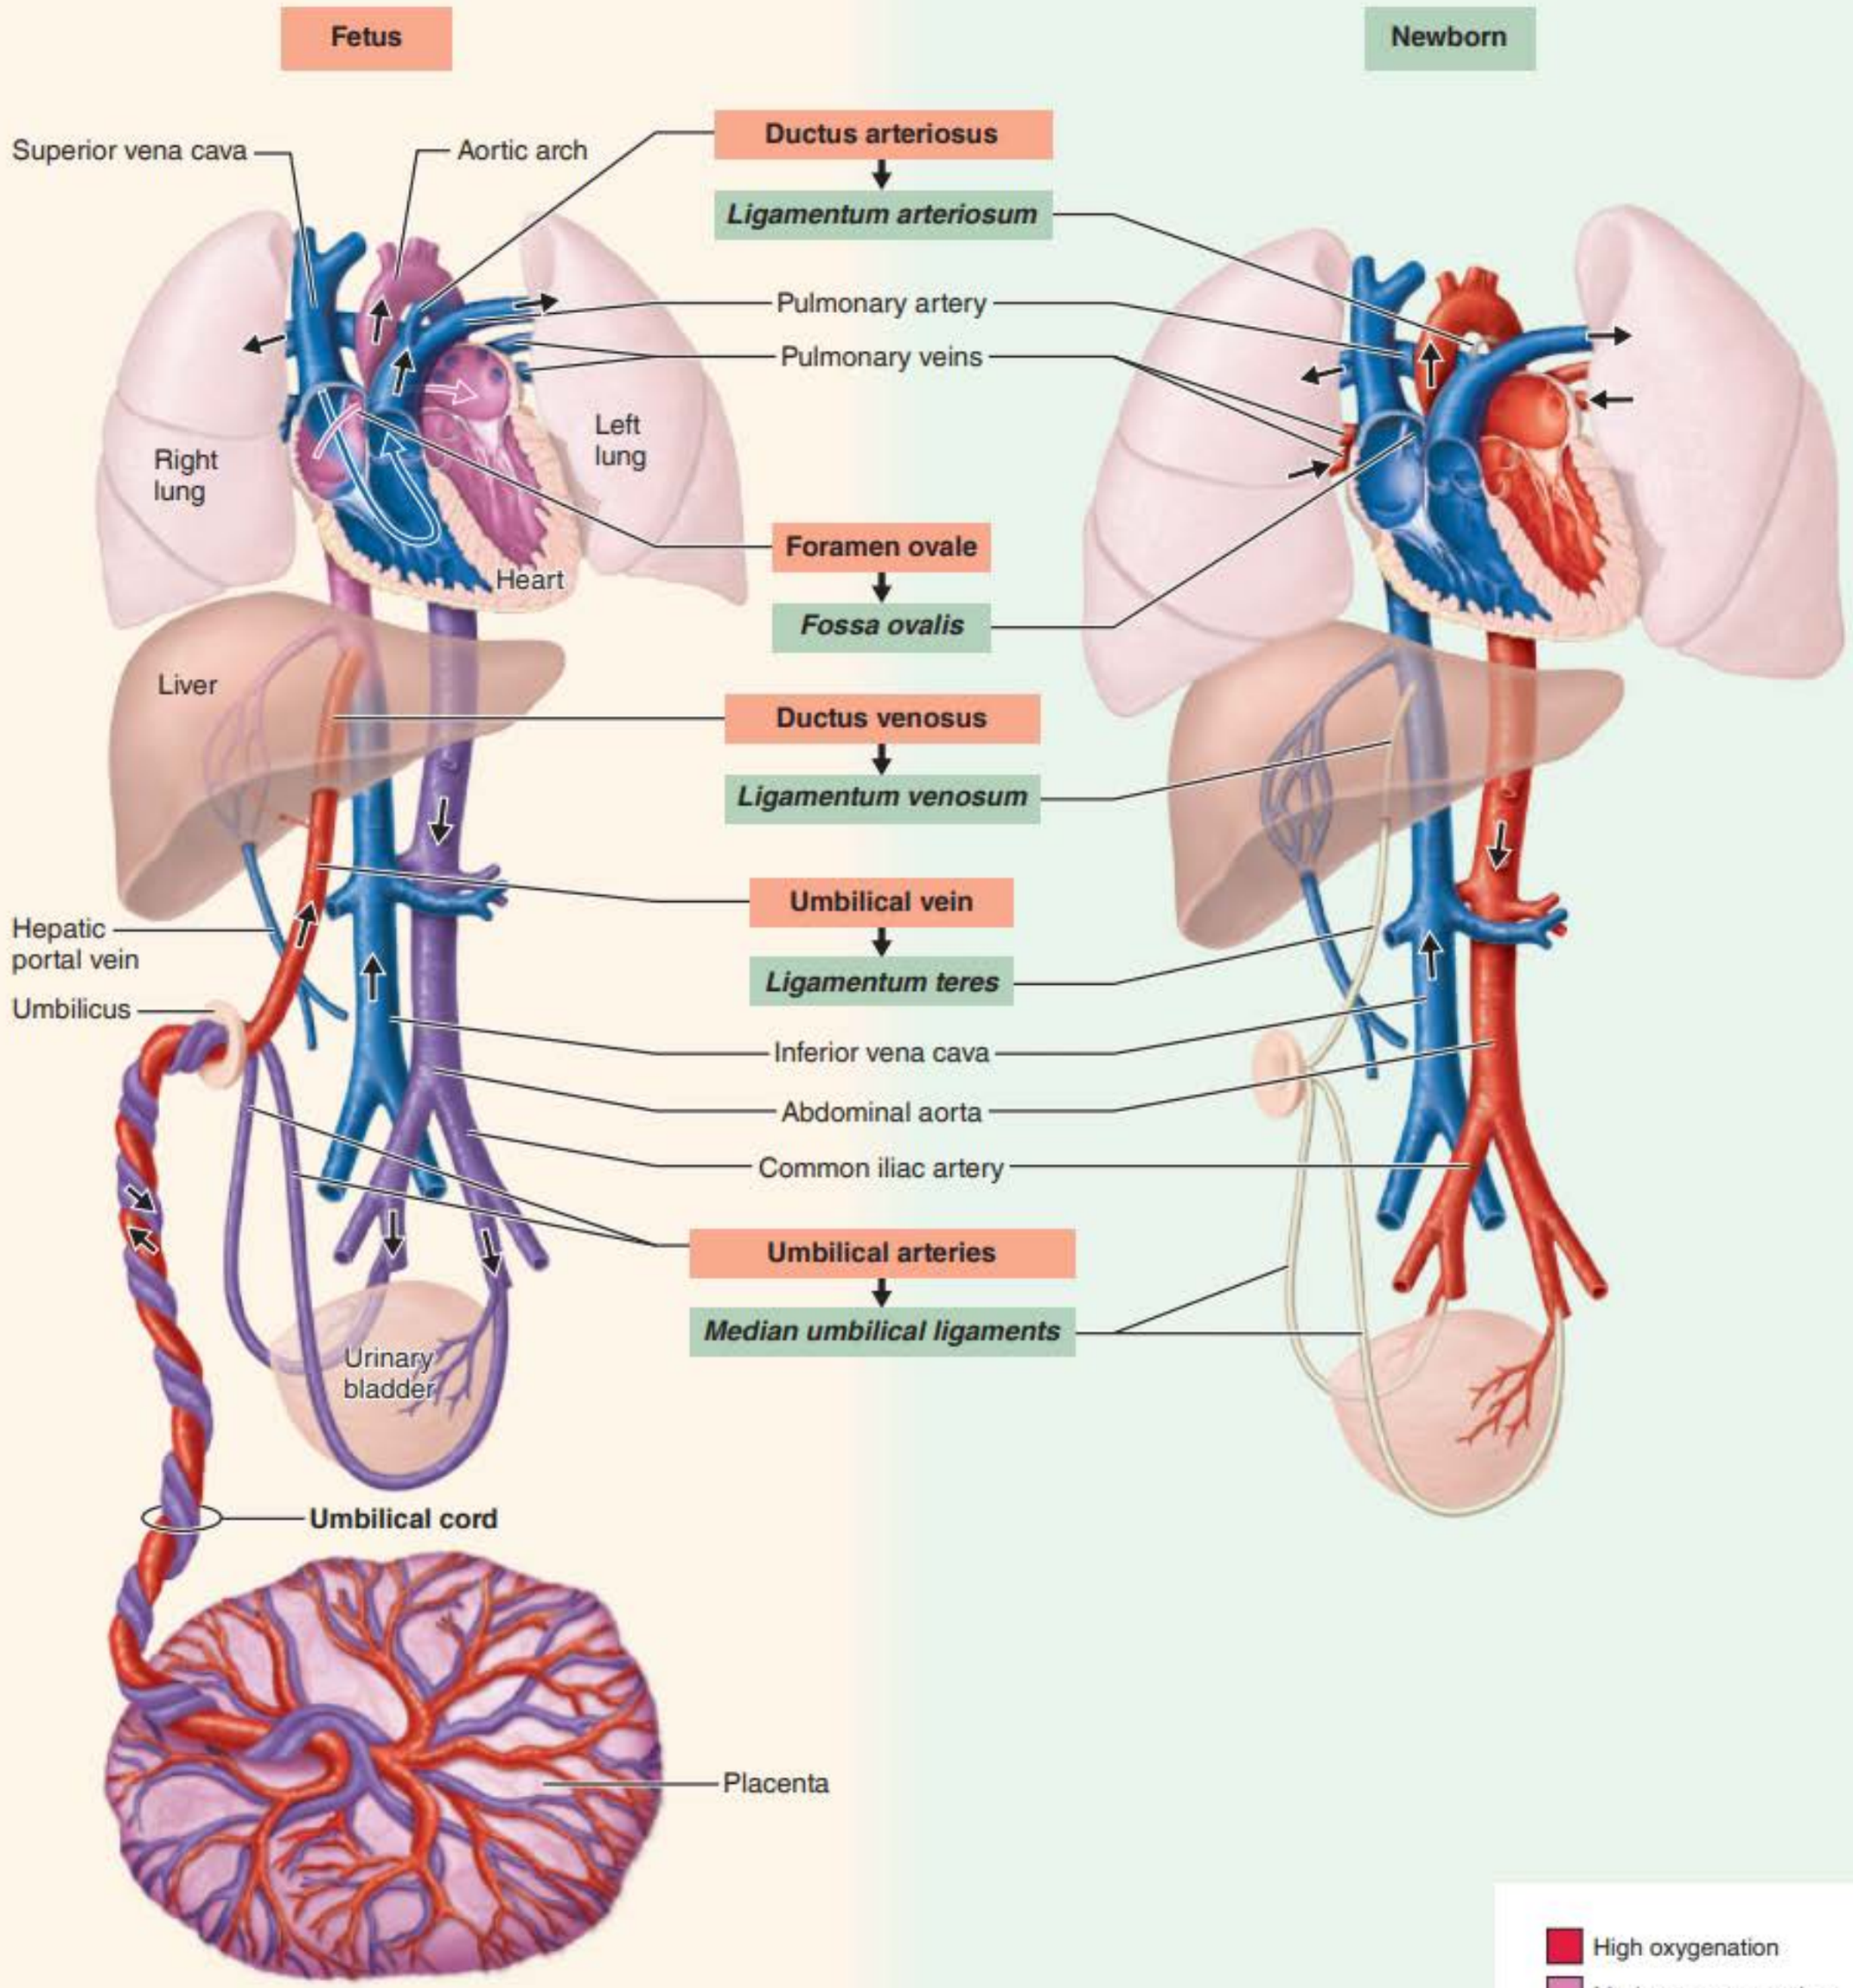
There are four essential adaptations for life *in utero*:



Below is a simplified pathway of blood through the fetus:



The cardiovascular system changes at birth.
The umbilical vessels as well as the liver and lung bypasses are occluded.



are quite dramatic (**Figure 28.14**). The fetal period is a time of rapid growth of the body structures that were established in the embryo. During the first half of this period, cells are still differentiating into specific cell types to form the body's distinctive tissues and are completing the fine details of body structure. The main events of the fetal period—weeks 9 through 38—are listed chronologically in **Table 28.2**. The greatest amount of growth occurs in the first 8 weeks of life, when the embryo grows from one cell to a fetus of about 1 inch.

Check Your Understanding

11. The early embryo is flat like a three-layered pancake. What event must occur before organogenesis can get going in earnest?

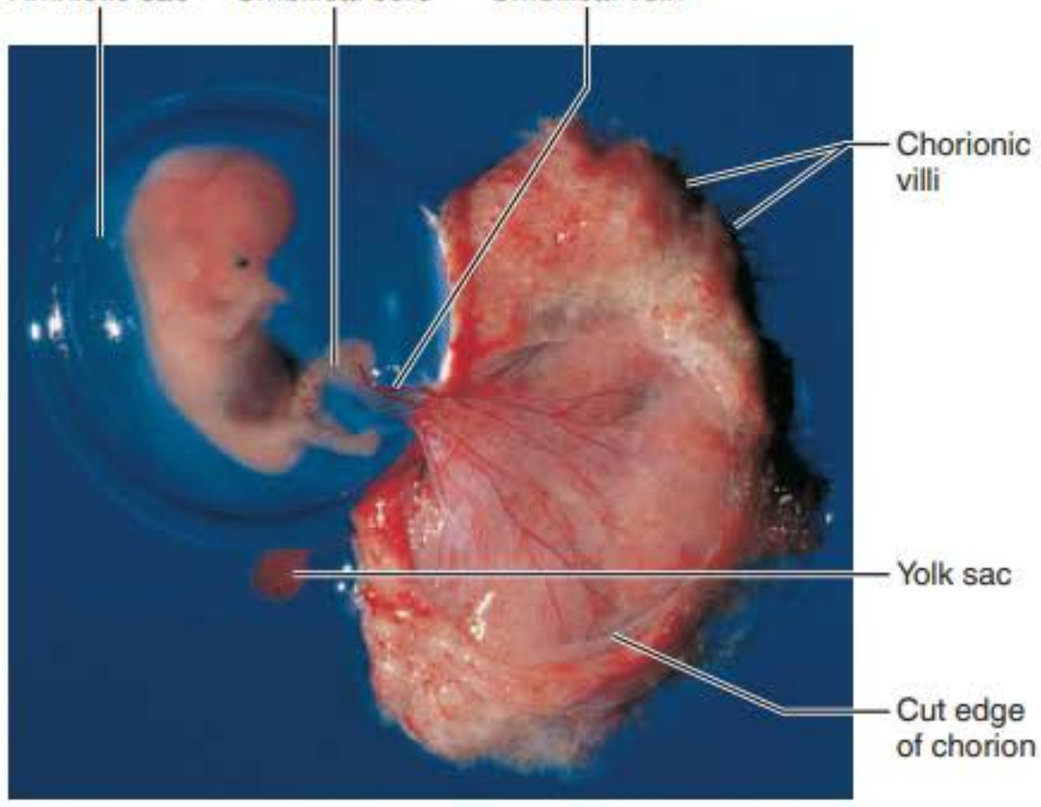
12. What germ layer gives rise to essentially all body tissues except nervous tissue, the epidermis, and mucosae?

13. What happens to the special fetal circulatory modifications after birth?

14. DRAW What two modifications of the fetal circulation allow most blood to bypass parts of the heart? Draw in and label these two modifications in the schematic heart and great vessels below.

15. PREDICT The amnion is crucial for development. What problems would arise if it wasn't there?

For answers, see Answers Appendix.



(a) Embryo at week 7, about 18 mm long.

(b) Fetus in month 3, about 6 cm long.

(c) Fetus late in month 5, about 19 cm long.

Figure 28.14 Photographs of a developing fetus. By birth, the fetus is typically 36 cm long from crown to rump.

Table 28.2 Developmental Events of the Fetal Period

TIME AFTER FERTILIZATION		CHANGES AND ACCOMPLISHMENTS
8 weeks (end of embryonic period)	8 weeks	Head nearly as large as body; all major brain regions present; first brain waves in brain stem Liver disproportionately large; begins to form blood cells Limbs present; digits are initially webbed, but fingers and toes are free by the end of week 8 Ossification begun; weak, spontaneous muscle contractions occur Cardiovascular system fully functional (heart has been pumping blood since week 4) All body systems present in at least rudimentary form Approximate crown-to-rump length: 30 mm (1.2 inches); weight: 2 grams (0.06 ounce)
9–12 weeks (month 3)	12 weeks	Head still dominant, but body elongating; brain continues to enlarge; cervical and lumbar enlargements apparent in spinal cord; retina of eye is present Skin epidermis and dermis obvious; facial features present in crude form Liver prominent, bile being secreted; palate is fusing Heartbeat can be detected externally; blood cell formation begins in bone marrow Lungs begin to develop; fetus inhales and exhales amniotic fluid Sex of the fetus can be determined from the genitals Approximate crown-to-rump length at end of interval: 90 mm (3.5 inches)
13–16 weeks (month 4)	16 weeks	Cerebellum prominent; general sensory organs differentiated, blinking of eyes and sucking motions of lips occur Growth of the body beginning to outpace that of the head Glands developed in GI tract; intestines collecting meconium (dark green fetal intestinal contents) Kidneys attain typical structure Most bones are now distinct and joint cavities are apparent Approximate crown-to-rump length at end of interval: 140 mm (5.5 inches)
17–20 weeks (month 5)		Vernix caseosa (fatty secretions of sebaceous glands) covers body; lanugo (silklike hair) covers skin Fetal position (body flexed anteriorly) assumed because of space restrictions Limbs reach near-final proportions Mother can feel fetal movements (quickening) Approximate crown-to-rump length at end of interval: 190 mm (7.5 inches)
21–30 weeks (months 6 and 7)	At birth	Period of substantial increase in weight (may survive if born prematurely at 27–28 weeks, but hypothalamic temperature regulation and lung production of surfactant are still inadequate) Myelination of spinal cord begins Distal limb bones are beginning to ossify Skin is wrinkled; fingernails and toenails are complete Body is lean and well proportioned Bone marrow becomes sole site of blood cell formation Testes descend to scrotum in month 7 (males) Approximate crown-to-rump length at end of interval: 280 mm (11 inches)
30–38 weeks (term) (months 8 and 9)		Fat accumulates in hypodermis; skin thickens Approximate crown-to-rump length at end of interval: 360 mm (14 inches); weight: 3.2 kg (7 lb)

28.5 During pregnancy, the mother undergoes anatomical, physiological, and metabolic changes

Learning Outcomes

- **Describe functional changes in maternal reproductive organs and in the cardiovascular, respiratory, and urinary systems during pregnancy.**
- **Indicate the effects of pregnancy on maternal metabolism and posture.**

The mean duration of pregnancy is 38 weeks from the time of ovulation to birth. Pregnancy can be a difficult time for the mother because profound adaptations occur in several body systems. Not only are there anatomical changes, but striking changes in her metabolism and physiology occur to support the pregnancy and prepare her body for delivery and lactation.

Anatomical Changes

As pregnancy progresses, the female reproductive organs become increasingly vascular and engorged with blood, and the vagina develops a purplish hue (*Chadwick's sign*). Prodded by rising levels of estrogens and progesterone, the breasts enlarge and engorge with blood, and their areolae darken. Some women develop increased pigmentation of facial skin of the nose and cheeks, a condition called *chloasma* (klo-az′mah; "to be green") or the "mask of pregnancy."

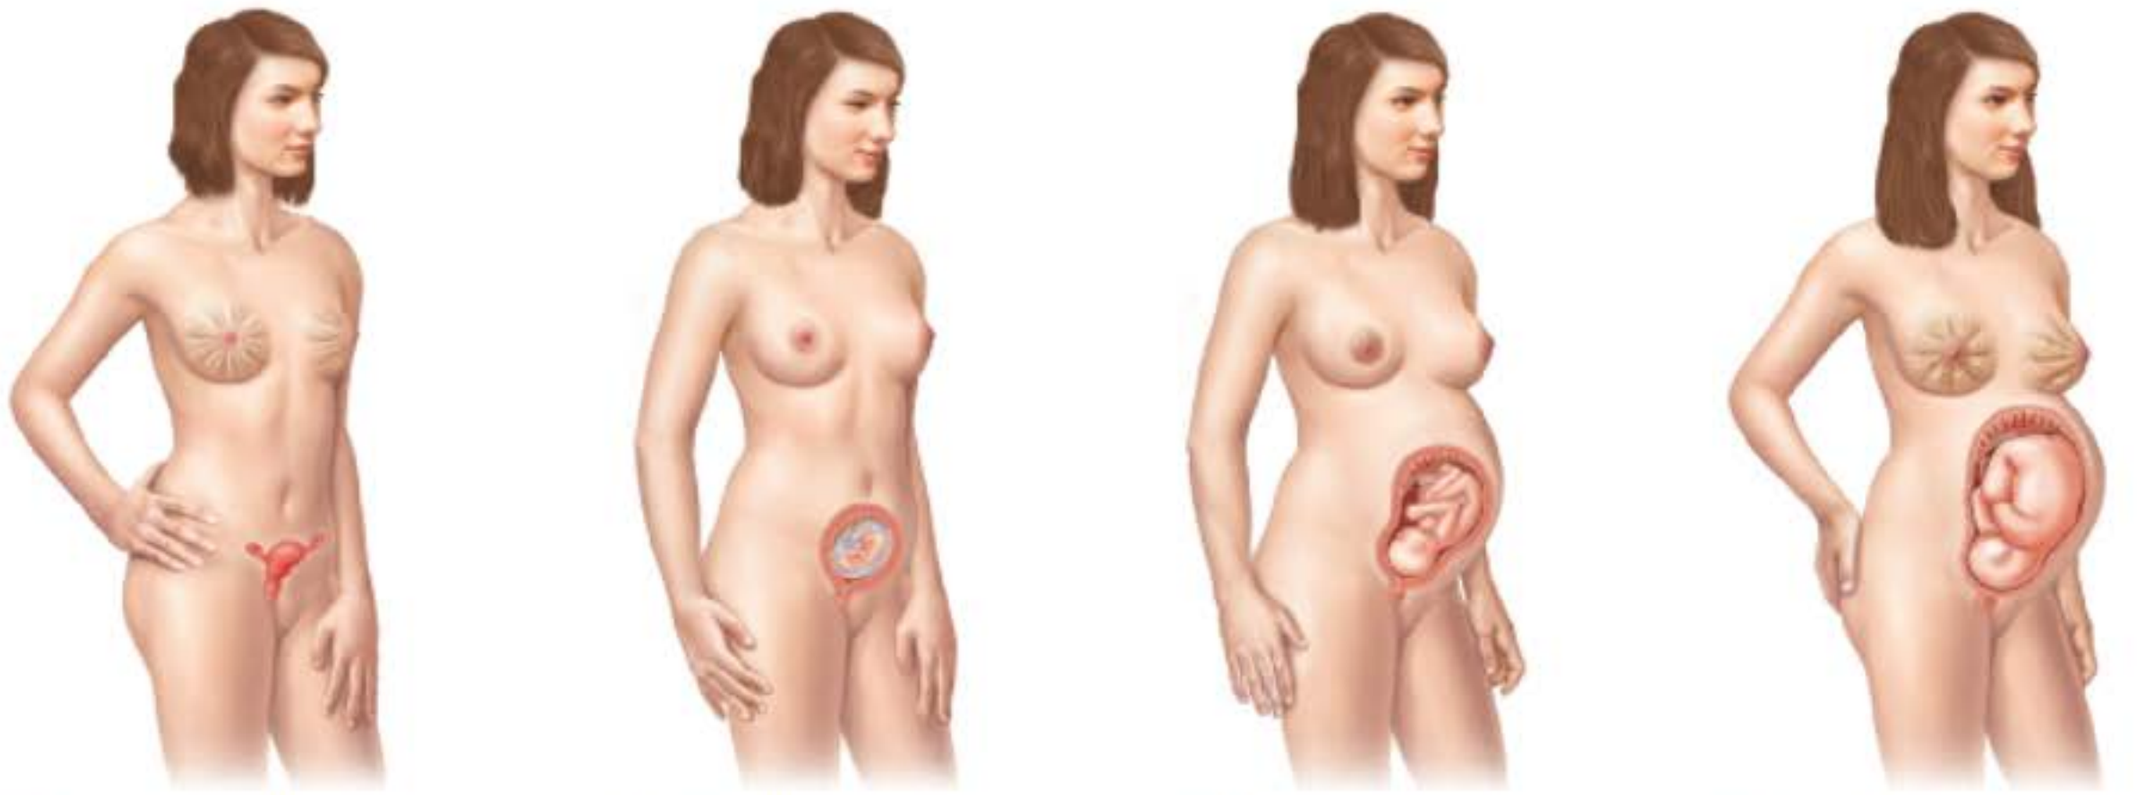
The degree of uterine enlargement during pregnancy is remarkable. Starting as a fist-sized organ, the uterus fills most of the pelvic cavity by 16 weeks (**Figure 28.15a, b**). Though the fetus is only about 140 mm long (crown-to-rump) at this time, the placenta is fully formed, uterine muscle is hypertrophied, and amniotic fluid volume is increasing.

As pregnancy continues, the uterus pushes higher into the abdominal cavity, exerting pressure on abdominal and pelvic organs (Figure 28.15c). As birth nears, the uterus reaches the level of the sternum's xiphoid process and occupies most of the abdominal cavity (Figure 28.15d). The crowded abdominal organs press superiorly against the diaphragm, which intrudes on the thoracic cavity. As a result, the ribs flare, causing the thorax to widen.

The increasing bulkiness of the anterior abdomen changes the woman's center of gravity, and many women develop *lordosis* (accentuated lumbar curvature) and backaches during the last few months of pregnancy. **Relaxin**, produced by the corpus luteum and placenta, causes pelvic ligaments and the pubic symphysis to relax, widen, and become more flexible. This increased flexibility eases passage of the baby during birth, but it may result in a waddling gait in the meantime.

Considerable weight gain occurs during a normal pregnancy. Because some women are over- or underweight before pregnancy begins, it is almost impossible to state the ideal or desirable weight gain. However, summing up the weight increases resulting from fetal and placental growth, increased size of the maternal reproductive organs and breasts, and greater blood volume during pregnancy, a weight gain of approximately 13 kg (about 28 lb) is fairly typical.

Good nutrition is necessary all through pregnancy if the developing fetus is to have all the building materials (especially proteins, calcium, and iron) needed to form its tissues. The B vitamin folic acid reduces the risk of having a baby with neural tube problems such as spina bifida and anencephaly (◀ p. 483). A pregnant woman needs only 300 additional calories daily to



(a) Before conception Uterus is the size of a fist and resides in the pelvis. Mammary gland structure is largely rudimentary.

(b) 4 months Fundus of the uterus is halfway between the pubic symphysis and the umbilicus.

(c) 7 months Fundus is well above the umbilicus.

(d) 9 months Fundus reaches the xiphoid process. Glandular tissue of mammary glands is fully developed.

Figure 28.15 Relative size of the uterus before conception and during pregnancy.

sustain proper fetal growth. The emphasis should be on eating high-quality food, not just more food.

Metabolic Changes

As the placenta enlarges, it secretes various hormones that influence the mother's metabolism.

- **Placental growth hormone** suppresses and replaces the mother's growth hormone. It enhances nutrient availability to the fetus by stimulating lipolysis and glucose production (gluconeogenesis).
- **Human placental lactogen (hPL)** (also called *human chorionic somatomammotropin*) is secreted in amounts proportional to the placenta's size. In cooperation with estrogens and progesterone, it stimulates maturation of the breasts for lactation (Figure 28.15), promotes growth of the fetus, and exerts a glucose-sparing effect in the mother. This means that maternal cells metabolize more fatty acids and less glucose than usual, sparing glucose for use by the fetus. It also reduces insulin sensitivity. Consequently, gestational diabetes mellitus occurs in about 3–10% of pregnancies. Over half of these women go on to develop type 2 diabetes later in life.
- **Corticotropin-releasing hormone (CRH)** (◀ p. 616) levels rise dramatically toward the end of pregnancy. This rise is thought to be related to the timing of birth. As CRH levels rise, the mother's ACTH and cortisol (◀ p. 625) levels rise, too. This may protect her in times of stress, such as giving birth. Rising cortisol levels in the fetus promote maturation, particularly of the lungs.

Plasma levels of activated vitamin D rise two- to threefold during pregnancy, which increases absorption of dietary calcium. This rise in vitamin D occurs in spite of levels of parathyroid hormone that are normal or even low when intake of calcium is adequate. This ensures that the developing fetus will have adequate calcium to mineralize its bones.

Physiological Changes

Physiological changes take place in many systems during pregnancy. A few of these changes are described next.

Gastrointestinal System

The nausea and vomiting (commonly called morning sickness) suffered by many women during the first few months of pregnancy are believed to be related to elevated levels of hCG, estrogens, and progesterone. *Heartburn*, due to reflux of stomach acid into the esophagus, is common because the esophagus is displaced and the stomach is crowded by the growing uterus. *Constipation* occurs as the motility of the digestive tract decreases.

HOMEOSTATIC IMBALANCE 28.1 CLINICAL

Because many potentially harmful substances can cross placental barriers and enter the fetal blood, a pregnant woman should be aware of what she is taking into her body, particularly during the embryonic period when the body's foundations are laid down. **Teratogens** (ter′ah-to-jenz; *terato* = monster), factors that may cause severe congenital abnormalities or even fetal death, include alcohol, nicotine, many drugs (anticoagulants, sedatives, antihypertensives, and others), and maternal infections, particularly rubella. For example, when a woman drinks alcohol, her fetus becomes inebriated as well. However, the fetal consequences may be much more lasting and result in the *fetal alcohol syndrome* (*FAS*) typified by microcephaly (small head), intellectual disability, and abnormal growth. Smoking hinders oxygen delivery to the fetus, impairing normal growth and development.

Urinary System

The kidneys produce more urine during pregnancy because of the mother's increased metabolic rate, greater blood volume, and the additional burden of disposing of fetal metabolic wastes. As the growing uterus compresses the bladder, urination becomes more frequent, more urgent, and sometimes uncontrollable (*stress incontinence*).

Respiratory System

The nasal mucosa responds to estrogens by becoming edematous and congested. Thus, nasal stuffiness and occasional nosebleeds may occur. Tidal volume (◀ p. 840) increases markedly during pregnancy, while respiratory rate is relatively unchanged and residual volume (◀ p. 841) decreases. The increase in tidal volume is due to (1) the increased production of CO_2 and (2) enhancement of the sensitivity of the medullary respiratory center to CO_2 caused by progesterone. Many women exhibit *dyspnea* (disp-ne′ah), or difficult breathing, during the later stages of pregnancy when the diaphragm is pushed superiorly by the increasing size of the uterus.

Cardiovascular System

The most dramatic physiological changes occur in the cardiovascular system. Total body water rises, and blood volume may increase as much as 40% by the 32nd week to accommodate the additional needs of the fetus. The rise in blood volume also safeguards against blood loss during birth. Mean blood pressure typically decreases during midpregnancy, but then rises to normal levels during the third trimester. Cardiac output increases by 35–40% at various stages of pregnancy. This helps propel the greater circulatory volume around the body. The uterus presses on the pelvic blood vessels, which may impair venous return from the lower limbs, resulting in *varicose veins* and leg edema (◀ p. 734).

Interestingly, some fetal cells do make their way into the maternal circulation. Because these cells are undifferentiated, they can take up residence in various maternal tissues and differentiate into the types of cells that surround them. It is not clear what consequences this may have—they may predispose a woman to autoimmune diseases or they may protect her against certain diseases. Time and research will tell.

HOMEOSTATIC IMBALANCE 28.2 CLINICAL

Preeclampsia, a dangerous complication affecting about 5% of pregnancies after 20 weeks, is characterized by hypertension and proteinuria. Proteinuria often leads to edema (◀ p. 734), and severe hypertension can lead to numerous complications. Even worse, preeclampsia can lead to **eclampsia**, generalized seizures that can be fatal. The only cure is delivery of the baby.

Check Your Understanding

16. What causes the difficult breathing that some women experience during pregnancy? What causes the waddling gait seen in some?
17. What is the role of the hormone hPL?
18. MAKE CONNECTIONS Pregnant women often experience edema of their lower limbs. Explain this edema in terms of an increase or decrease in one of the pressures that drives bulk flow at the capillaries. (Hint: See Focus Figure 19.1 on pp. 732–733.)

For answers, see Answers Appendix.

28.6 The three stages of labor are the dilation, expulsion, and placental stages

Learning Outcome

▶ **Explain how labor is initiated, and describe the three stages of labor.**

Parturition (par″tu-rish′un; "bringing forth young") is the culmination of pregnancy—giving birth to the baby. It usually occurs within 15 days of the calculated due date (280 days from the last menstrual period). The series of events that expel the infant from the uterus are collectively called **labor**.

Initiation of Labor

The fetus largely determines its own birth date, and several events and hormones interlock to trigger labor. As the fetal hypothalamus and adrenal glands mature during the last few weeks of pregnancy, increased CRH from the fetal hypothalamus leads to increased fetal cortisol release. Fetal cortisol then begins a positive feedback loop with *placental* CRH—cortisol increases placental CRH release, which increases cortisol release even more—leading to a rapid rise in fetal cortisol levels. Fetal cortisol triggers the final maturation of the fetal lungs, which increases the production and release of *surfactant protein A* (*SP-A*). SP-A, in turn, acts as an additional signal that the fetus is ready to be born. The rapid increase in cortisol levels also causes a rapid increase in estrogen production by the placenta.

Remember that the placenta produces both estrogens and progesterone, and that levels of both of these hormones steadily increase throughout pregnancy. A major function of progesterone during pregnancy is to suppress contraction of uterine smooth muscle as it is stretched by the growing fetus. This quieting action of progesterone is important for preventing preterm labor. As estrogen levels rise at the end of pregnancy, they switch the progesterone receptor to a less effective type. The increase in estrogens (together with the decrease in progesterone's action) has the following effects:

- **It prepares the cervix for dilation.** Estrogens increase the synthesis of both **prostaglandins** (pros″tah-glan′dinz) (◀ p. 48) and their receptors. Prostaglandins play a major role in the thinning and softening of the cervix just before and during labor.
- **It prepares the myometrium of the uterus for contraction.** Additional contractile machinery (including actin, myosin, and myosin light chain kinase) is synthesized so that the uterus can contract more forcefully. Like the heart, the uterus needs to contract as a unit. As the onset of labor nears, gap junctions are formed between myometrial cells to tie them together electrically. As a result, the myometrium becomes increasingly irritable. Weak, irregular uterine contractions begin to occur. These contractions, called *Braxton Hicks contractions*, have caused many women to go to the hospital, only to be told that they were in **false labor** and sent home.
- **It increases the sensitivity of the myometrium to chemical messengers that cause it to contract.** Under the influence of rising estrogen action and decreasing progesterone action, the myometrial cells make abundant receptors for **oxytocin** (ok″sĭ-to′sin) (◀ p. 612) and prostaglandin (**Figure 28.16**). These are the two chemical messengers that will drive myometrial contraction during true labor.

As birth nears, the now powerful uterine muscle is highly sensitive to prostaglandins and oxytocin. Under the influence

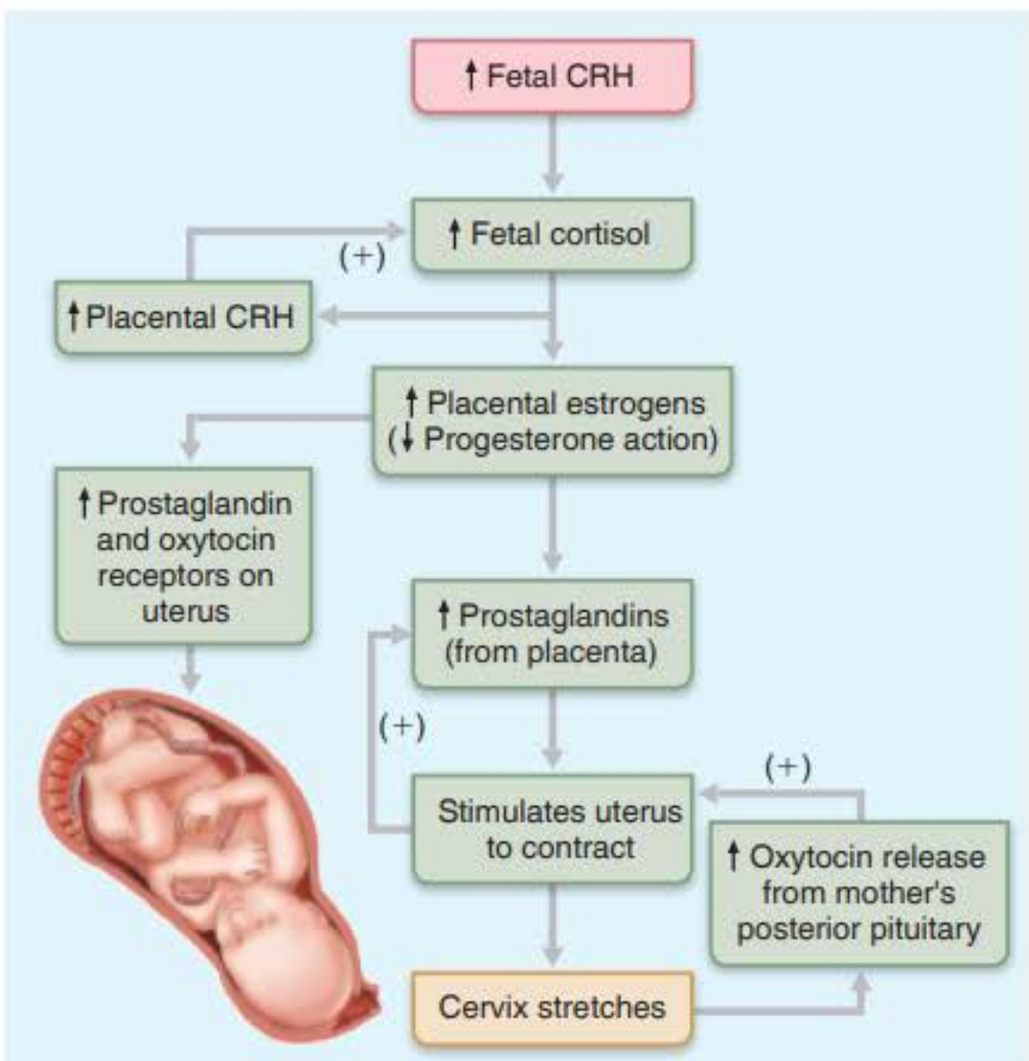


Figure 28.16 Hormonal induction of labor. Note that three different positive feedback loops are involved in labor.

of estrogens, the placenta releases prostaglandins that trigger the rhythmic expulsive contractions of true labor. Pressure from the baby's head dilates the cervix. Increasing cervical distension activates the mother's hypothalamus, which signals for oxytocin release by the posterior pituitary.

Several *positive feedback mechanisms* (◀ p. 11) involving prostaglandins and oxytocin are propelled into action—contractions and greater distension of the cervix cause the release of more prostaglandins and oxytocin, which cause greater contractile force, and so on (Figure 28.16). Expulsion of the baby is aided by a chemical change in *fetal fibronectin*, the natural "stickum" (adhesive protein) that bound the fetal and maternal tissues of the placenta together up to this point in pregnancy.

As mentioned earlier, prostaglandins are essential for initiating labor in humans, and interfering with their production will hinder onset of labor. For example, antiprostaglandin drugs such as ibuprofen can inhibit the early stages of labor and such drugs are used occasionally to prevent preterm births.

Stages of Labor

Labor includes the dilation, expulsion, and placental stages illustrated in **Figure 28.17**.

① **Dilation stage.** The **dilation stage** is the time from labor's onset until the cervix is fully dilated by the baby's head (about 10 cm in diameter). As labor starts, weak but regular contractions begin in the upper part of the uterus and move toward the vagina. At first, only the superior uterine muscle is active; contractions are 15–30 minutes apart, and last for 10–30 seconds. As labor progresses, the contractions become more vigorous and rapid, and the lower part of the uterus gets involved. As the infant's head is forced against the cervix with each contraction, the cervix softens, *effaces* (thins), and dilates. Eventually the amnion ruptures, releasing the amniotic fluid, an event commonly referred to as the mother's "water breaking."

The dilation stage is the longest part of labor, lasting 6–12 hours or more. Several events happen during this phase. *Engagement* occurs when the infant's head enters the true pelvis (◀ p. 238). As descent continues through the vagina (sometimes referred to as the birth canal), the baby's head rotates so that its greatest dimension is in the anteroposterior line, which allows it to navigate the narrow dimensions of the pelvic outlet (Figure 28.17 ⑯).

② **Expulsion stage.** The **expulsion stage** lasts from full dilation to delivery of the infant, or actual childbirth. By the time the cervix is fully dilated, strong contractions occur every 2–3 minutes and last about 1 minute. In this stage, a mother undergoing labor without local anesthesia has an increasing urge to push or bear down with the abdominal muscles. Although this phase may last 2 hours, it is typically 50 minutes in a first birth and around 20 minutes in subsequent births.

Crowning occurs when the largest dimension of the baby's head distends the vulva. At this point, an *episiotomy* (e-piz″e-ot′o-me) is sometimes done to reduce tissue tearing. An episiotomy is an incision made to widen the vaginal orifice. The baby's neck extends as the head exits from the

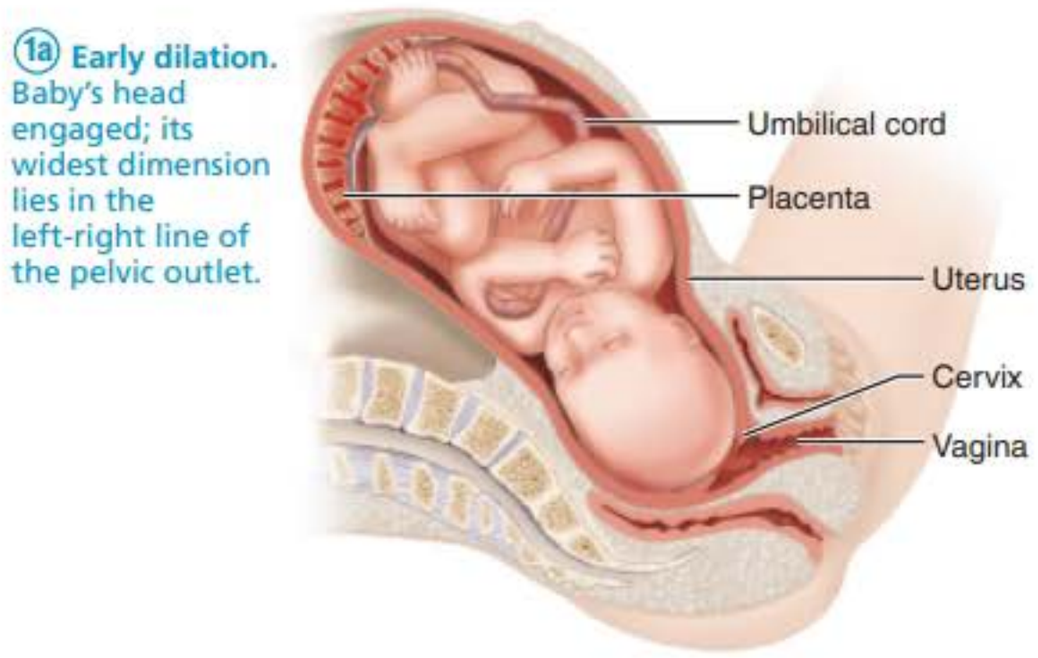

Figure 28.17 Stages of labor.

perineum, and once the head has been delivered, the rest of the baby's body is delivered much more easily. After birth, the umbilical cord is clamped and cut.

When the infant is in the usual *vertex*, or head-first, *presentation*, the skull (its largest diameter) acts as a wedge to dilate the cervix. The head-first presentation also allows the baby to be suctioned free of mucus and to breathe even before it has completely exited from the birth canal. In *breech* (buttock-first) and other nonvertex presentations, these advantages are lost and delivery is much more difficult, often requiring the use of forceps, or a C-section (see below).

③ **Placental stage.** The **placental stage**, or the delivery of the placenta and its attached fetal membranes, collectively called the **afterbirth**, is usually accomplished within 30 minutes after birth of the infant. The strong uterine contractions that continue after birth compress uterine blood vessels, limit bleeding, and shear the placenta off the uterine wall (cause placental detachment). The blood vessels in the umbilical cord are counted after the placenta is delivered to verify the presence of two umbilical arteries and one umbilical vein because the absence of one umbilical artery is often associated with cardiovascular disorders in the newborn.

HOMEOSTATIC IMBALANCE 28.3 CLINICAL

If a woman has a deformed or narrow malelike pelvis, labor may be prolonged and difficult. This condition is called *dystocia* (dis-to′se-ah; *dys* = difficult, *toc* = birth). Besides extreme maternal fatigue, another possible consequence of dystocia is fetal brain damage, resulting in cerebral palsy or epilepsy. To prevent these outcomes, a *cesarean* (*C*-) *section* (se-sa′re-an) is performed in many such cases. A C-section is delivery of the infant through an incision made through the abdominal and uterine walls.

Check Your Understanding

19. What is a breech presentation?

20. What chemical is most responsible for triggering true labor?

21. Why does a baby's head rotate as it descends through the true pelvis?

For answers, see Answers Appendix.

28.7 An infant's extrauterine adjustments include taking the first breath and closure of vascular shunts

Learning Outcome

▶ **Outline the events leading to the first breath of a newborn.**

The **neonatal period** is the four-week period following birth. Here we will be concerned with the events of just the first few hours after birth in a normal infant. As you might suspect, birth represents quite a shock to the infant. Exposed to physical trauma during the birth process, it is suddenly cast out of its watery, warm environment and its placental life supports are severed. Now it must do for itself all that the mother had been doing for it—breathe, obtain nutrients, excrete, and maintain its body temperature.

Two critical adjustments must occur.

- **Taking the first breath.** The crucial first requirement is to breathe. Vasoconstriction of the umbilical arteries, initiated when they are stretched during birth, leads to loss of placental support. Once carbon dioxide is no longer removed by the placenta, it accumulates in the baby's blood, causing central acidosis. This excites respiratory control centers in the baby's brain and triggers the first inspiration. The first breath requires a tremendous effort—the airways are tiny, and the lungs are collapsed. However, once the lungs have been inflated in full-term babies, surfactant (◀ p. 839) in alveolar fluid reduces surface tension in the alveoli, and breathing is easier. The rate of respiration is rapid (about 45 respirations/min) during the first two weeks and then gradually decreases.

  Keeping the lungs inflated is much more difficult for premature infants (those weighing less than 2500 g, or about 5.5 lb, at birth) because surfactant production occurs during the last months of prenatal life. Consequently, preemies are usually put on a ventilator until their lungs are mature enough to function on their own.

- **Occlusion of special fetal blood vessels and vascular shunts.** After birth the special umbilical blood vessels and fetal shunts are occluded as we described previously (see p. 1107 and Focus Figure 28.2).

At 1 and 5 minutes after birth, the infant's physical status is assessed based on five signs: heart rate, respiration, color, muscle tone, and reflexes. Each observation is given a score of 0 to 2, and the total is called the **Apgar score**. An Apgar score of 8 to 10 indicates a healthy baby. Lower scores reveal problems in one or more of the physiological functions assessed.

For 6–8 hours after birth, infants pass through an unstable **transitional period** marked by alternating periods of increased activity and sleep. During the activity periods, vital signs are irregular and the baby gags frequently as it regurgitates mucus and debris. After this, the infant stabilizes, with waking periods (dictated by hunger) occurring every 3–4 hours.

Check Your Understanding

22. What is an Apgar score?

23. MAKE CONNECTIONS Surfactant decreases surface tension in the alveoli of a newborn. What property of the lung does surfactant affect, making breathing easier? (Hint: See Chapter 22.)

For answers, see Answers Appendix.

28.8 Lactation is milk secretion by the mammary glands in response to prolactin

Learning Outcome

▶ **Explain how the breasts are prepared for lactation.**

Lactation is production of milk by the hormone-prepared mammary glands. Rising levels of (placental) estrogens,

progesterone, and human placental lactogen toward the end of pregnancy stimulate the hypothalamus to release prolactin-releasing factors (PRFs). The anterior pituitary gland responds by secreting **prolactin** (◀ p. 616). (This mechanism is described below.) After a delay of two to three days following birth, true milk production begins.

During the initial delay (and during late gestation), the mammary glands secrete a yellowish fluid called **colostrum** (ko-los′trum). It has less lactose than milk and almost no fat, but it contains more protein, vitamin A, and minerals than true milk. Like milk, colostrum is rich in IgA antibodies (◀ p. 799). Since these antibodies are resistant to digestion in the stomach, they may help to protect the infant's digestive tract against bacterial infection.

After birth, prolactin release gradually wanes, and continued milk production depends on mechanical stimulation of the nipples, normally provided by the suckling infant. Mechanoreceptors in the nipple send action potentials to the hypothalamus, stimulating secretion of PRFs. This results in a burstlike release of prolactin, which stimulates milk production for the next feeding.

The same action potentials also prompt hypothalamic release of oxytocin from the posterior pituitary via a *positive feedback mechanism*. Oxytocin causes the **let-down reflex**, the actual ejection of milk from the alveoli of the mammary glands (**Figure 28.18**). Let-down occurs when oxytocin binds to myoepithelial cells surrounding the glands, after which milk is ejected from *both* breasts, not just the suckled one. During nursing, oxytocin also stimulates the recently emptied uterus to contract, helping it to return to (nearly) its prepregnant size.

Breast milk has advantages for the infant:

- *Its fats and iron are better absorbed and its amino acids are metabolized more efficiently* than those of cow's milk.
- *It has a host of beneficial chemicals*, including IgA, complement, lysozyme, interferon, and lactoperoxidase, that protect infants from life-threatening infections. Mother's milk also contains interleukins and prostaglandins that prevent overzealous inflammatory responses, and a glycoprotein that deters the ulcer-causing bacterium (*Helicobacter pylori*) from attaching to the stomach mucosa.
- *It helps beneficial bacteria to colonize the infant's gut* by providing certain oligosaccharides (sugars) they need to grow.
- *Its natural laxative effect helps to cleanse the bowels of* **meconium** (mĕ-ko′ne-um), a tarry green-black paste containing sloughed-off epithelial cells, bile, and other substances. Since meconium, and later feces, provides the route for eliminating bilirubin from the body, clearing meconium as quickly as possible helps to prevent *physiological jaundice* (see Related Clinical Terms, p. 1120).

When nursing is discontinued, the stimulus for prolactin release and milk production ends, and the mammary glands stop producing milk. Women who nurse their infants for six months or more lose a significant amount of calcium from their bones, but those on sound diets usually replace lost bone calcium after weaning the infant.

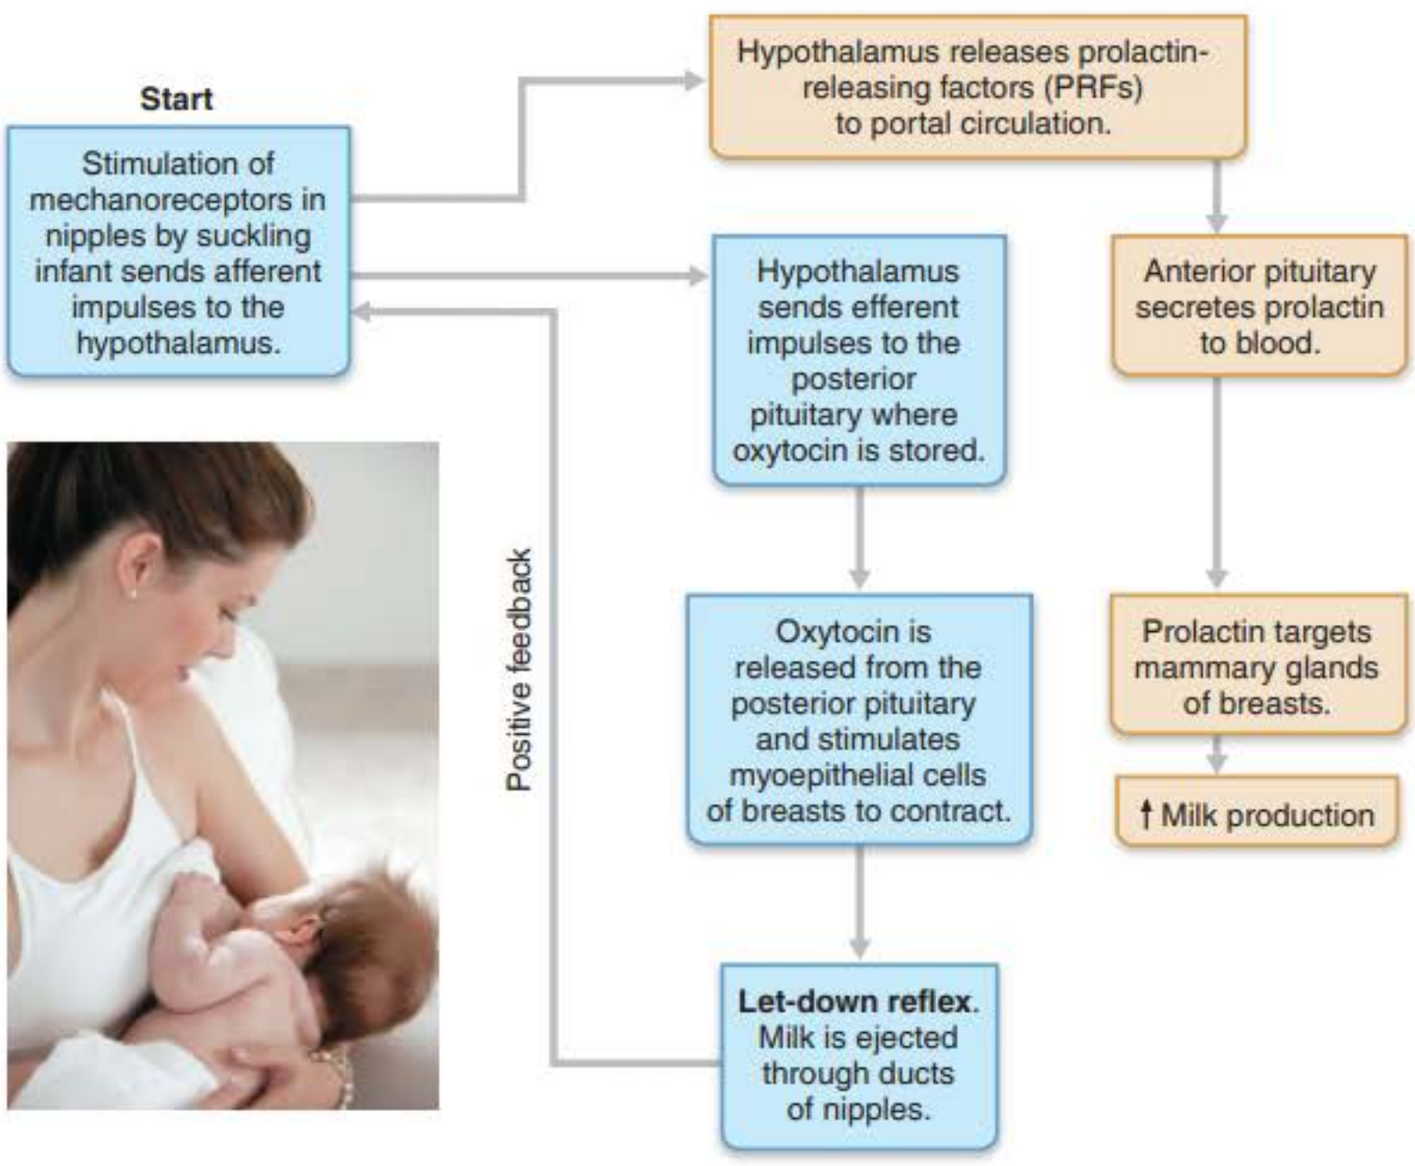

Figure 28.18 **Milk production and the positive feedback mechanism of the milk let-down reflex.**

Contraception: To Be or Not To Be

In a world such as ours, **contraception** (*contra* = against, *cept* = taking), commonly called birth control, is often seen as a necessity. The key to birth control is dependability. As the red arrows in the accompanying flowchart show, the birth control techniques currently available have many sites of action for blocking reproduction. Generally speaking, birth control methods can be categorized into three groups based on how each prevents pregnancy—behavioral methods, barrier methods, or hormonal methods. Let's examine a few of them more closely.

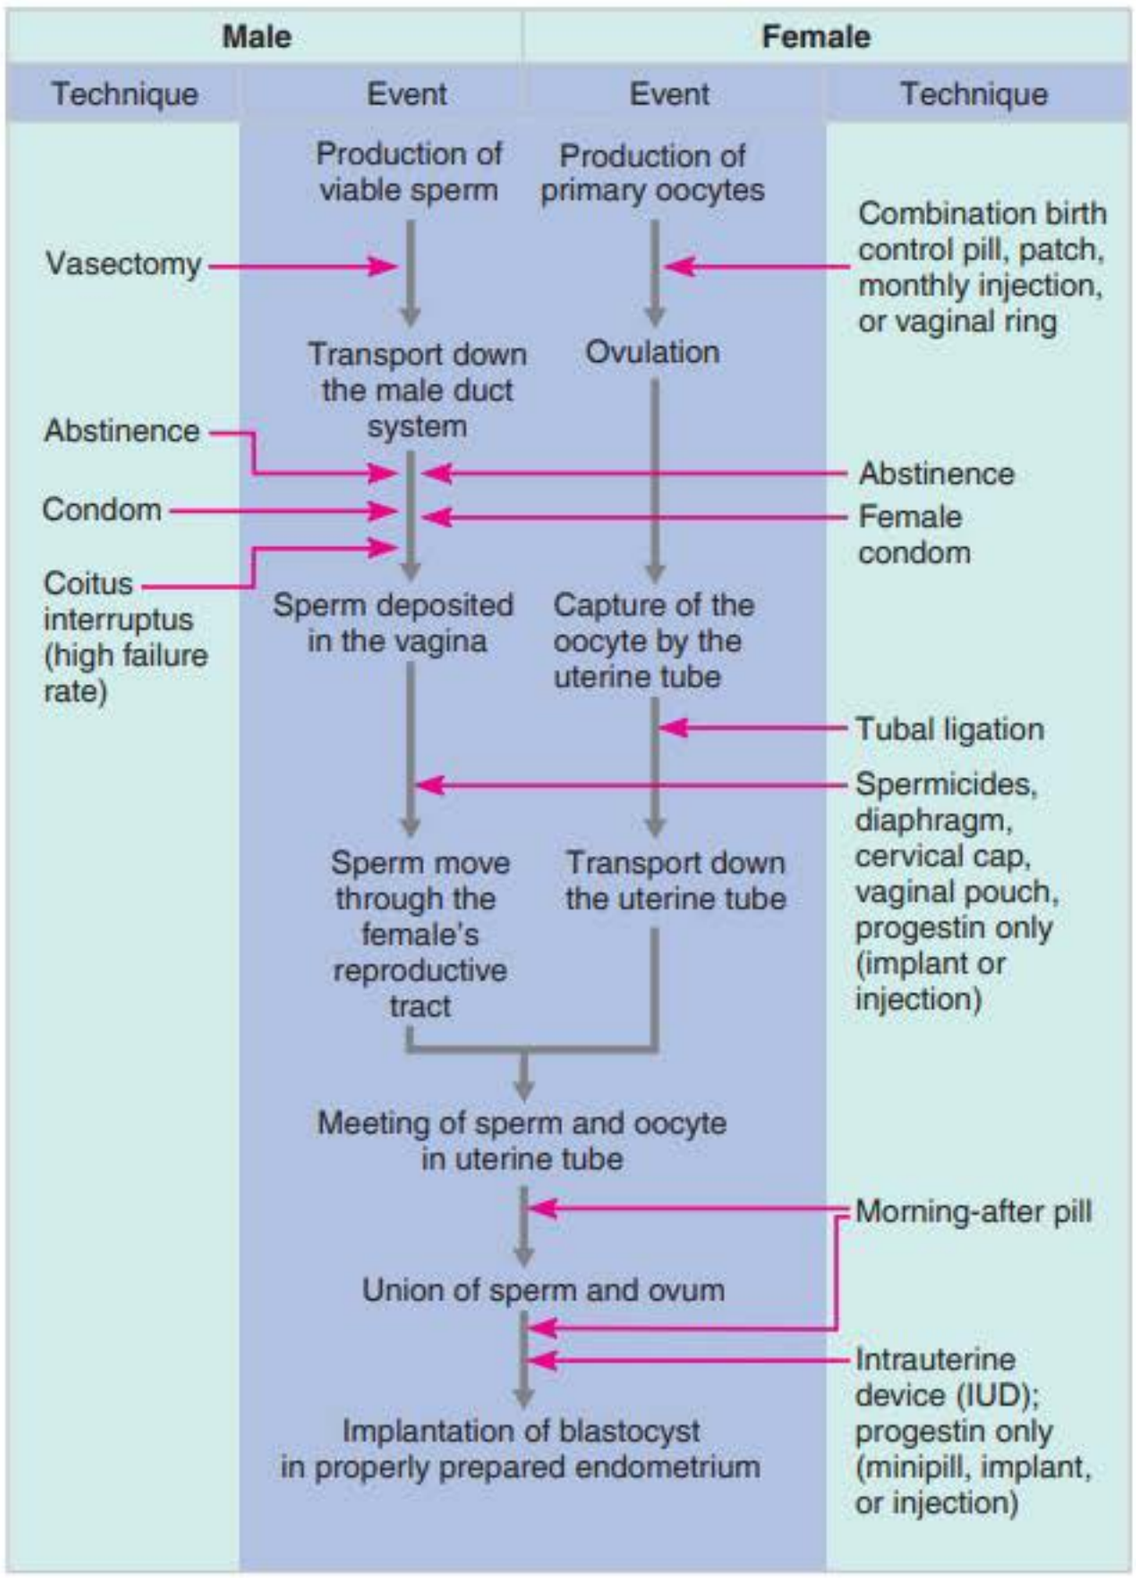
Behavioral methods (coitus interruptus, the rhythm method, and abstinence) consist of altering behavior to prevent pregnancy. *Coitus interruptus*, or withdrawal of the penis just before ejaculation, is unreliable because control of ejaculation is never ensured.

Rhythm or temporary abstinence methods involve avoiding intercourse during periods of ovulation or fertility. Ovulation can be detected by recording daily basal body temperatures (body temperature drops slightly immediately prior to ovulation and then rises slightly after ovulation). This technique requires accurate record keeping for several cycles before it can be used with confidence, and can have a high success rate for those willing and able to take the time necessary. However, the average failure rate is 24% per year.

Barrier methods include diaphragms, cervical caps, male and female condoms, and spermicides. These techniques prevent the sperm and egg from meeting and implanting. They are quite effective, especially when used in combination—for example, condoms and spermicides.

Hormonal methods include a broad variety of hormone-containing contraceptive products (the pill, IUD, patches, vaginal ring, and implanted or injected agents). These methods are highly effective when used consistently, with a failure rate of less than 1% for oral contraceptives, and have a low risk of adverse effects in most women.

The most-used contraceptive product in North America is the *oral contraceptive pill* (*OCP*) or simply "the pill." The pill is available in various formulations containing estrogens and progestins (progesterone-like hormones). Some are taken daily, others according to a different schedule.



Mechanisms of contraception. Techniques or products that interfere with events from production of gametes to implantation are indicated by red arrows at the site of interference. They act to prevent the next step from occurring.

The pill tricks the hypothalamic-pituitary-gonadal axis by making it appear that the woman is pregnant (estrogens and progesterone are produced throughout pregnancy). Mature ovarian follicles do not develop, ovulation ceases, and menstrual flow is much reduced. However, since hormonal balance is one of the most precisely controlled body functions, some women cannot tolerate these changes—they become nauseated and/or hypertensive.

The pill has adverse cardiovascular effects in a small number of users, and there is still debate about whether it increases the risk of breast cancer. On the other hand, it decreases the risk of ovarian and endometrial cancers. Presently, well over 10 million U.S. women use the pill.

Other delivery methods using the combination hormone approach include two slow-release products—a flexible ring that is inserted into the vagina, and a transdermal (skin) patch. Failure rates and side effects of the vaginal ring and skin patch are comparable to those of the pill.

Other hormonal approaches to contraception use progestin-only products that thicken the cervical mucus enough to block sperm entry into the uterus, decrease the frequency of ovulation, and make the endometrium inhospitable to implantation. These include match-sized silicone rods →

implanted just under the skin that release progestin over a five-year period (e.g., Nexplanon®), and an injectable form that lasts for three months (Depo-Provera®). New intrauterine devices (IUDs) that are inserted into the uterus provide sustained local delivery of synthetic progesterone to the endometrium. The failure rates of progestin treatments are even less than that of the pill.

Morning-after pills, or *emergency contraceptive pills*, are based on progesterone-like hormones and used for postcoital contraception. They should be taken as soon as possible within 3–5 days after unprotected intercourse. They interfere with normal hormonal signals enough to prevent either fertilization or implantation. They have a failure rate of less than 25%.

Sterilization techniques permanently prevent gamete release. *Tubal ligation* or *vasectomy* (cutting or cauterizing the uterine tubes or ductus deferentes, respectively) are nearly foolproof and are the choice of approximately 33% of couples of childbearing age in the United States. However, these techniques are usually permanent, making them unpopular with individuals who still plan to have children but want to select the time.

This summary doesn't even begin to touch on the experimental birth control drugs now awaiting clinical trials and male contraceptives that are currently being evaluated. Other methods are sure to be developed in the near future. In the final analysis, however, the only 100% effective means of birth control is the age-old one—total abstinence.

While prolactin levels are high, the normal hypothalamic-pituitary controls of the ovarian cycle are damped, probably because stimulation of the hypothalamus by suckling causes it to release beta endorphin, a peptide hormone that inhibits hypothalamic release of GnRH and, consequently, the release of gonadotropins by the pituitary. Because of this inhibition of ovarian function, nursing has been called natural birth control. However, there is a good deal of "slippage" in these controls. Most women begin to ovulate even while continuing to nurse their infants and so *can* become pregnant again.

Check Your Understanding

24. What hormone causes the let-down reflex?

For answers, see Answers Appendix.

28.9 Assisted reproductive technology may help an infertile couple have offspring

Learning Outcome

- **Describe some techniques of ART including IVF, ZIFT, and GIFT.**

So far we have been describing how babies are made. But if a couple lacks that capability for some reason, what recourse do they have? Hormone therapy may increase sperm or egg production in cases where that is the problem, and surgery can open blocked uterine tubes. Perhaps the simplest intervention is *artificial insemination*. This can help by concentrating sperm (to make up for low sperm counts) and by giving the sperm a "head start" past the cervical mucus.

Beyond that are *assisted reproductive technology* (*ART*) procedures that entail surgically removing oocytes from a woman's ovaries following hormone stimulation, fertilizing the oocytes, and then returning them to the woman's body. These procedures, now performed worldwide in major medical centers, have produced thousands of infants. However, they are expensive, emotionally draining, and painful for the oocyte donor. Unused oocytes, sperm, and embryos can be frozen for later attempts at accomplishing pregnancy.

In the most common ART process, *in vitro fertilization* (*IVF*), harvested oocytes are incubated with sperm in culture dishes (*in vitro*) for several days to allow fertilization to occur. In cases where the quality or number of sperm is low, the oocytes are injected with sperm. Embryos reaching the two-cell or blastocyst stage are then carefully transferred into the woman's uterus in the hope that implantation will occur.

In *zygote intrafallopian transfer* (*ZIFT*), oocytes fertilized *in vitro* are immediately transferred to the woman's uterine (fallopian) tubes. The goal is to have development to the blastocyst stage occur followed by normal implantation in the uterus.

In *gamete intrafallopian transfer* (*GIFT*), no *in vitro* procedures are used. Instead, sperm and harvested oocytes are transferred together into the woman's uterine tubes in the hope that fertilization will take place there.

Check Your Understanding

25. What is the most common ART technique?

For answers, see Answers Appendix.

In this chapter, we have focused on changes that occur during human development *in utero*. But having a baby is not always the goal, and we humans have devised a variety of techniques for preventing this outcome (see **A Closer Look** above).

RELATED CLINICAL TERMS

Abortion (*abort* = born prematurely) Termination of a pregnancy that is in progress; may be spontaneous or induced.

Abruptio placenta (ah-brup′she-o; *abrupt* = broken away from) Premature separation of the placenta from the uterine wall; if this occurs before labor, it can result in fetal death due to anoxia.

Ectopic pregnancy (ek-top′ik; *ecto* = outside) A pregnancy in which the embryo implants in any site other than the uterus; most often the site is a uterine tube (tubal pregnancy). Since the uterine tube (as well as most other ectopic sites) is unable to establish a placenta or accommodate growth, the uterine tube ruptures unless the condition is diagnosed early, or the pregnancy spontaneously aborts.

Hydatid (hydatidiform) mole (hi′dah-tid; *hydat* = watery) Developmental abnormality of the placenta; the conceptus degenerates and the chorionic villi convert into a mass of vesicles that resemble tapioca. Signs include vaginal bleeding, which contains some of the grapelike vesicles.

Physiological jaundice (jawn′dis) Jaundice sometimes occurring in normal newborns within three to four days after birth. Fetal erythrocytes are short-lived, and they break down rapidly after birth; the infant's liver may be unable to process the bilirubin (breakdown product of hemoglobin pigment) (◀ p. 649) fast enough to prevent its accumulation in blood and subsequent deposit in body tissues.

Placenta previa (pre′ve-ah) Placental formation adjacent to or across the internal os of the uterus. This is a problem because as the uterus and cervix stretch, separation of the placenta may occur. Additionally, the placenta precedes the infant during labor.

Ultrasonography (ul″trah-son-og′rah-fe) Noninvasive technique that uses sound waves to visualize the position and size of the fetus and placenta (◀ A Closer Look, pp. 16–17).

CHAPTER SUMMARY

1. The gestation period of approximately 280 days extends from the woman's last menstrual period to birth. The conceptus undergoes embryonic development for 8 weeks after fertilization, and fetal development from week 9 to birth.

28.1 Fertilization combines the sperm and egg chromosomes, forming a zygote (pp. 1092–1096)

1. An oocyte is fertilizable for up to 24 hours; sperm are best able to fertilize an oocyte within the first one to two days after intercourse.
2. Sperm must survive the hostile environment of the vagina and become capacitated (capable of reaching and fertilizing the oocyte).
3. Hundreds of sperm must release their acrosomal enzymes to break down the egg's corona radiata and zona pellucida.
4. When one sperm binds to receptors on the egg, it triggers two events that block polyspermy: the oocyte membrane block and the cortical and zona reactions.
5. Following sperm penetration, the secondary oocyte completes meiosis II. Then the ovum and sperm pronuclei fuse (fertilization), forming a zygote.

28.2 Embryonic development begins as the zygote undergoes cleavage and forms a blastocyst en route to the uterus (pp. 1097–1098)

1. Early development consists of cleavage, a rapid series of mitotic divisions without intervening growth, that begins with the zygote and ends with a blastocyst. The blastocyst consists of the trophoblast and an embryoblast. Cleavage produces a large number of cells with a favorable surface-to-volume ratio.

28.3 Implantation occurs when the embryo burrows into the uterine wall, triggering placenta formation (pp. 1098–1102)

1. The trophoblast adheres to, digests, and implants in the endometrium. Implantation is completed when the blastocyst is entirely surrounded by endometrial tissue, about 12 days after ovulation.
2. hCG released by the trophoblast (and later the chorion) maintains hormone production by the corpus luteum, preventing menses. hCG levels decline after four months.
3. The placenta acts as the respiratory, nutritive, and excretory organ of the fetus and produces the hormones of pregnancy. It is formed from embryonic (chorionic villi) and maternal (endometrial decidua) tissues. The chorion develops when the trophoblast becomes associated with extraembryonic mesoderm. Typically, the placenta is functional as an endocrine organ by the third month.

28.4 Embryonic events include gastrula formation and tissue differentiation, which are followed by rapid growth of the fetus (pp. 1102–1111)

Extraembryonic Membranes (p. 1102)

1. The fluid-filled amnion forms from cells of the superior surface (epiblast) of the embryonic disc. It protects the embryo from physical trauma and adhesion formation, provides a constant temperature, and allows fetal movements.
2. The yolk sac forms from the hypoblast of the embryonic disc; it is the source of early blood cells.
3. The allantois, a caudal outpocketing adjacent to the yolk sac, forms the structural basis of the umbilical cord.
4. The chorion is the outermost membrane and takes part in placentation.

Gastrulation: Germ Layer Formation (pp. 1102–1103)

5. Gastrulation involves cellular migrations that ultimately transform the embryoblast into a three-layered embryo (gastrula) containing ectoderm, mesoderm, and endoderm. Cells that move through the midline primitive streak become endoderm if they form the most inferior layer of the embryonic disc and mesoderm if they ultimately occupy the middle layer. Cells remaining on the superior surface become ectoderm.

Organogenesis: Differentiation of the Germ Layers (pp. 1103–1107)

6. Endoderm forms the epithelial lining of the digestive and respiratory systems, and the epithelial cells of all associated glands (thyroid, parathyroids, thymus, liver, pancreas). It becomes a continuous tube when the embryonic body undercuts and fuses ventrally.
7. Ectoderm forms the nervous system and the epidermis of the skin and its derivatives. The first event of organogenesis is neurulation, which produces the brain and spinal cord. By the eighth week, all major brain regions are formed.
8. Mesoderm forms all other organ systems and tissues. It segregates early into (1) a dorsal superior notochord, (2) paired somites that form the vertebrae, skeletal trunk muscles, and part of the dermis, and (3) paired masses of intermediate and lateral plate mesoderm. The intermediate mesoderm forms the kidneys and gonads. The lateral plate mesoderm forms the dermis of skin; parietal serosa; bones and muscles of the limbs; the cardiovascular system; and the visceral serosae.

The Fetal Circulation (p. 1107)

9. The fetal cardiovascular system is formed in the embryonic period. The umbilical vein delivers nutrient- and oxygen-rich blood to the embryo; the paired umbilical arteries return oxygen-poor, waste-laden blood to the placenta. The ductus venosus allows most of the blood to bypass the liver; the foramen ovale and ductus arteriosus are pulmonary shunts.
10. Inflation of the lungs causes pressure changes in the circulation; as a result, the umbilical arteries and vein, ductus venosus, and ductus arteriosus collapse, and the foramen ovale closes. The occluded blood vessels are converted to fibrous cords; the site of the foramen ovale becomes the fossa ovalis.

Events of Fetal Development (pp. 1107–1111)

11. All organ systems are laid down during the embryonic period; growth and tissue/organ specialization are the major events of the fetal period.
12. During the fetal period, fetal length increases from about 30 mm to 360 mm, and weight increases from less than an ounce to 7 pounds or more.

28.5 During pregnancy, the mother undergoes anatomical, physiological, and metabolic changes (pp. 1112–1114)

Anatomical Changes (pp. 1112–1113)

1. Maternal reproductive organs and breasts become increasingly vascularized during pregnancy, and the breasts enlarge.
2. The uterus eventually occupies nearly the entire abdominopelvic cavity. Abdominal organs are pushed superiorly and encroach on the thoracic cavity, causing the ribs to flare.
3. The increased abdominal mass changes the woman's center of gravity; lordosis and backache are common. A waddling gait occurs as pelvic ligaments and joints are loosened by placental relaxin.
4. A typical weight gain during pregnancy in a woman of normal weight is 28 pounds.

Metabolic Changes (p. 1113)

5. The placenta releases hormones that affect the mother's metabolism: placental growth hormone, CRH, and human placental lactogen. Human placental lactogen has anabolic effects and promotes glucose sparing in the mother.

Physiological Changes (pp. 1113–1114)

6. Many women suffer morning sickness, heartburn, and constipation during pregnancy.
7. The kidneys produce more urine, and pressure on the bladder may cause frequency, urgency, and stress incontinence.
8. Respiratory tidal volume increases, but residual volume decreases. The respiratory rate remains relatively unchanged. Dyspnea is common.
9. Total body water and blood volume increase dramatically and cardiac output rises. Blood pressure declines in midpregnancy and then rises to normal levels during the third trimester.

28.6 The three stages of labor are the dilation, expulsion, and placental stages (pp. 1114–1116)

1. Parturition encompasses a series of events called labor.

Initiation of Labor (pp. 1114–1115)

2. Rising fetal CRH levels signal that the fetus is ready for birth. CRH increases fetal cortisol secretion, which increases estrogen release from the placenta and decreases the action of progesterone. Together, the increased estrogen levels and decreased progesterone action ready the myometrium for delivery by increasing myometrial oxytocin and prostaglandin receptors, and causing the formation of gap junctions between myometrial cells.
3. Prostaglandins and oxytocin stimulate contraction of uterine muscle. Increasing distension of the cervix activates the hypothalamus, causing oxytocin release from the mother's posterior pituitary; this sets up a positive feedback loop resulting in true labor.

Stages of Labor (pp. 1115–1116)

4. The dilation stage is from the onset of rhythmic, strong contractions until the cervix is fully dilated. The head of the fetus rotates as it descends through the pelvic outlet.
5. The expulsion stage extends from full cervical dilation until birth of the infant.
6. The placental stage is the delivery of the afterbirth (the placenta and attached fetal membranes).

28.7 An infant's extrauterine adjustments include taking the first breath and closure of vascular shunts (p. 1116)

1. The infant's Apgar score is recorded immediately after birth.
2. After the umbilical cord is clamped, carbon dioxide accumulates in the infant's blood, causing respiratory centers in the brain to trigger the first inspiration.
3. Once the lungs are inflated, breathing is eased by the presence of surfactant, which decreases the surface tension of the alveolar fluid.
4. During transition, the first 8 hours after birth, the infant is physiologically unstable and adjusting. After stabilizing, the infant wakes approximately every 3–4 hours in response to hunger.

28.8 Lactation is milk secretion by the mammary glands in response to prolactin (pp. 1116–1119)

1. The breasts are prepared for lactation during pregnancy by high blood levels of estrogens, progesterone, and human placental lactogen.
2. Colostrum, a premilk fluid, is a fat-poor fluid that contains more protein, vitamin A, and minerals than does true milk. It is

produced toward the end of pregnancy and for the first two to three days after birth.

3. True milk is produced around day 3 in response to suckling, which stimulates the hypothalamus to prompt anterior pituitary release of prolactin and posterior pituitary release of oxytocin. Prolactin stimulates milk production. Oxytocin triggers milk let-down. Continued breast-feeding is required for continued milk production.
4. At first, ovulation and menses are absent or irregular during nursing, but in most women the ovarian cycle is eventually reestablished while still nursing.

28.9 Assisted reproductive technology may help an infertile couple have offspring (p. 1119)

1. Assisted reproductive technology (ART) procedures assist infertile couples to bear children. Among the most-used techniques are IVF, ZIFT, and GIFT. IVF and ZIFT attempt to fertilize harvested oocytes *in vitro* and then return the embryo or zygote to the woman's body. GIFT utilizes *in vivo* methods—sperm and oocytes are transferred together to the woman's uterine tubes.

REVIEW QUESTIONS

To access additional practice questions using your smartphone, tablet, or computer: MasteringA&P® > Study Area > Practice Tests & Quizzes

Level 1 Remember/Understand

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Indicate whether each of the following statements is describing **(a)** cleavage or **(b)** gastrulation.
   ____ **(1)** period during which a morula forms
   ____ **(2)** period when vast amounts of cell migration occur
   ____ **(3)** period when the three embryonic germ layers appear
   ____ **(4)** period during which the blastocyst is formed
2. Most systems are operational in the fetus by four to six months. Which system is the exception to this generalization, affecting premature infants? **(a)** the circulatory system, **(b)** the respiratory system, **(c)** the urinary system, **(d)** the digestive system.
3. The outer layer of the blastocyst, which later attaches to the uterus, is the **(a)** decidua, **(b)** trophoblast, **(c)** amnion, **(d)** embryoblast.
4. Match each adult structure in column B with the embryonic structure it derives from in column A.

Column A	Column B
____ **(1)** notochord	**(a)** kidney
____ **(2)** ectoderm (not neural tube)	**(b)** peritoneal cavity
____ **(3)** intermediate mesoderm	**(c)** pancreas, liver
____ **(4)** lateral plate mesoderm	**(d)** parietal serosa, most tissues of limbs
____ **(5)** sclerotome	**(e)** nucleus pulposus
____ **(6)** coelom	**(f)** hair and epidermis
____ **(7)** neural tube	**(g)** brain
____ **(8)** endoderm	**(h)** ribs and vertebrae

5. In the fetus, the ductus arteriosus carries blood from **(a)** the pulmonary artery to the pulmonary vein, **(b)** the liver to the inferior vena cava, **(c)** the right ventricle to the left ventricle, **(d)** the pulmonary trunk to the aorta.
6. Which of the following changes occur in the baby's cardiovascular system after birth? **(a)** umbilical arteries and vein become fibrosed, **(b)** pulmonary circulation begins to function, and pressure in the left side of the heart increases, **(c)** the ductus venosus becomes obliterated, as does the ductus arteriosus, **(d)** all of these.
7. The umbilical vein carries **(a)** waste products to the placenta, **(b)** oxygen and food to the fetus, **(c)** oxygen and food to the placenta, **(d)** oxygen and waste products to the fetus.
8. The germ layer from which the epidermis and brain are derived is the **(a)** ectoderm, **(b)** endoderm, **(c)** mesoderm.
9. The most important hormone in initiating and maintaining lactation after birth is **(a)** estrogen, **(b)** FSH, **(c)** prolactin, **(d)** oxytocin.
10. The initial stage of labor, during which the neck of the uterus is stretched, is the **(a)** dilation stage, **(b)** expulsion stage, **(c)** placental stage.
11. Cite two problems with a breech presentation.
12. What factors are believed to bring about uterine contractions at the termination of pregnancy?
13. During Mrs. Li's labor, the obstetrician decided that it was necessary to perform an episiotomy. What is an episiotomy, and why is it done?

Level 2 Apply/Analyze

14. What is the function of hCG and why is it not important after the first trimester of pregnancy?
15. Cleavage is an embryonic event that mainly involves mitotic divisions. How does cleavage differ from mitosis occurring during life after birth, and what are its important functions?
16. The life span of the ovarian corpus luteum is extended for nearly three months after implantation, but otherwise it deteriorates. **(a)** Explain why this is so. **(b)** Explain why it is important that the corpus luteum remain functional following implantation.
17. Why is it that only one sperm out of the hundreds (or thousands) available enters the oocyte?
18. What is the function of gastrulation?
19. Explain how the flat embryonic disc takes on the cylindrical shape of a tadpole.
20. Jenna, a freshman in your dormitory, tells you she just discovered that she is three months pregnant. She recently bragged that since she came to college she has been drinking alcohol heavily and experimenting with every kind of recreational drug she could find. From the following, select the advice you would give her, and explain why it is the best choice. **(a)** She must stop taking drugs, but they could not have affected her fetus during these first few months of her pregnancy. **(b)** Harmful substances usually cannot pass from mother to embryo, so she can keep using drugs. **(c)** There could be defects in the fetus, so she should stop using drugs and visit a doctor as soon as possible. **(d)** If she has not taken any drugs in the last week, she is okay.
21. While Mark was cramming for his anatomy test, he read that some parts of the mesoderm become segmented. He suddenly realized that he could not remember what segmentation is. Define segmentation, and give two examples of segmented structures in the embryo.

Level 3 Evaluate/Synthesize

22. Fertilization involves much more than a mere restoration of the diploid chromosome number. **(a)** What does the process of fertilization entail on the part of both the egg and sperm? **(b)** What are the effects of fertilization?

23. The placenta is a marvelous, but temporary, organ. Starting with a description of its formation, show how it is an intimate part of both fetal and maternal anatomy and physiology during the gestation period.

24. A woman in substantial pain called her doctor and explained (between sobs) that she was about to have her baby "right here." The doctor calmed her and asked how she had come to that conclusion. She said that her water had broken and that her husband could see the baby's head. **(a)** Was she right? If so, what stage of labor was she in? **(b)** Do you think that she had time to make it to the hospital 60 miles away? Why or why not?

25. Claire is a heavy smoker and has ignored a friend's advice to stop smoking during her pregnancy. On the basis of what you know about the effect of smoking on physiology, describe how Claire's smoking might affect her fetus.

CLINICAL CASE STUDY

38-Year-Old Female with Preeclampsia

Ms. Johansen, 38, is 26 weeks pregnant with her first child. She was diagnosed with preeclampsia (see p. 1114) three weeks ago. Antihypertensive drugs (◀ p. 724) and daily home care monitoring were initiated. However, her blood pressure is continuing to rise and is now 162/108 mm Hg. She complains of a constant headache, exhibits edema, and her urinalysis is positive for protein.

Her doctor has her admitted and orders further blood tests to assess Ms. Johansen's platelet level and liver function. "We may have to deliver because that's the only cure for preeclampsia," she says to you during your clinical rotation in obstetrics. "But if we do, then the baby will have problems. It's a tough decision because we have to balance both the mother's and the baby's health."

1. Although blood volume increases during pregnancy, blood pressure normally decreases. You know that blood pressure depends on cardiac output (CO) and total peripheral resistance (TPR) (◀ Figure 19.10, p. 719). How does increased blood volume affect CO, and what factor(s) must change so that blood pressure decreases?

2. One of your fellow nurses says that preeclampsia is characterized by vasoconstriction. Does this make sense? Why or why not?

3. + NCLEX-STYLE Her doctor wants to put delivery off as long as possible because premature babies have multiple problems. One possible problem is that the ductus arteriosus does not close. Why would this be a problem?

- **a.** If the ductus arteriosus doesn't close, the liver will not get an adequate blood supply.
- **b.** If the ductus arteriosus doesn't close, blood will continue to perfuse the umbilical cord with a risk of fatal hemorrhage.
- **c.** If the ductus arteriosus doesn't close, the right atrium will continually be overloaded with blood.
- **d.** If the ductus arteriosus doesn't close, the lungs will continually receive too much blood.

Ms. Johansen's tests indicate liver and kidney damage. Her doctor schedules delivery for tomorrow morning and orders an injection of cortisol for Ms. Johansen.

4. What roles does cortisol play in a developing fetus and how would an injection of cortisol help a premature infant?

5. + NCLEX-STYLE Cortisol prompts the fetal lungs to begin synthesizing surfactant. Why is this important?

- **a.** Surfactant reduces surface tension in the alveoli, allowing the alveoli to inflate.
- **b.** Surfactant causes vasodilation, allowing blood to flow through the lungs.
- **c.** Surfactant is necessary to protect the cells lining the respiratory tract from drying out.
- **d.** Surfactant attracts white blood cells into the lungs to protect them against pathogens.

29 Heredity

In this chapter, you will learn that

Genes direct human development and characteristics

- by asking **29.1** What terms are used to describe genetics?
- next looking at **29.2** Sexual sources of genetic variation
- then learning about **29.3** Patterns of inheritance
  - and asking **29.4** How do environmental factors affect gene expression?
    - then exploring **29.5** Other inheritance mechanisms
- finally asking **29.6** How to detect genetic disorders

The wondrous growth and development of a new individual is guided by the gene-bearing chromosomes it receives from its parents in egg and sperm. As we described in Chapter 3, individual *genes*, or DNA segments, contain the "recipes" or genetic blueprints for proteins. Many of these proteins are enzymes that dictate the synthesis of virtually all the body's molecules. Consequently, gene expression leads to observable traits such as your hair color, sex, blood type, and so on.

Genes, however, do not act as free agents. As you will see, a gene's ability to prompt the development of a specific trait can be enhanced or inhibited by interactions with other genes, as well as by environmental factors.

The science of genetics, which studies the mechanism of heredity (*genes* = origin), is relatively young, but our understanding of how human genes act and interact has advanced considerably since Gregor Mendel first proposed the basic principles of heredity in the mid-1800s. Mendel studied characteristics that vary in an either-or fashion, which is easier to understand than the more-or-less fashion in which most human traits vary.

Go to Mastering A&P® > Study Area > Animations and Videos or use quick access URL https://goo.gl/88srfV

The urge to understand human inheritance is powerful. Our ability to manipulate DNA enables us to engineer genes to examine their expression. Research in this area has tremendous promise for more sophisticated genetic screening, and for developing personalized drugs to treat or cure disease. Although we touch upon some of these newer topics, we will concentrate on the principles of heredity discovered by Mendel more than a century ago.

29.1 Genes are the vocabulary of genetics

Learning Outcomes

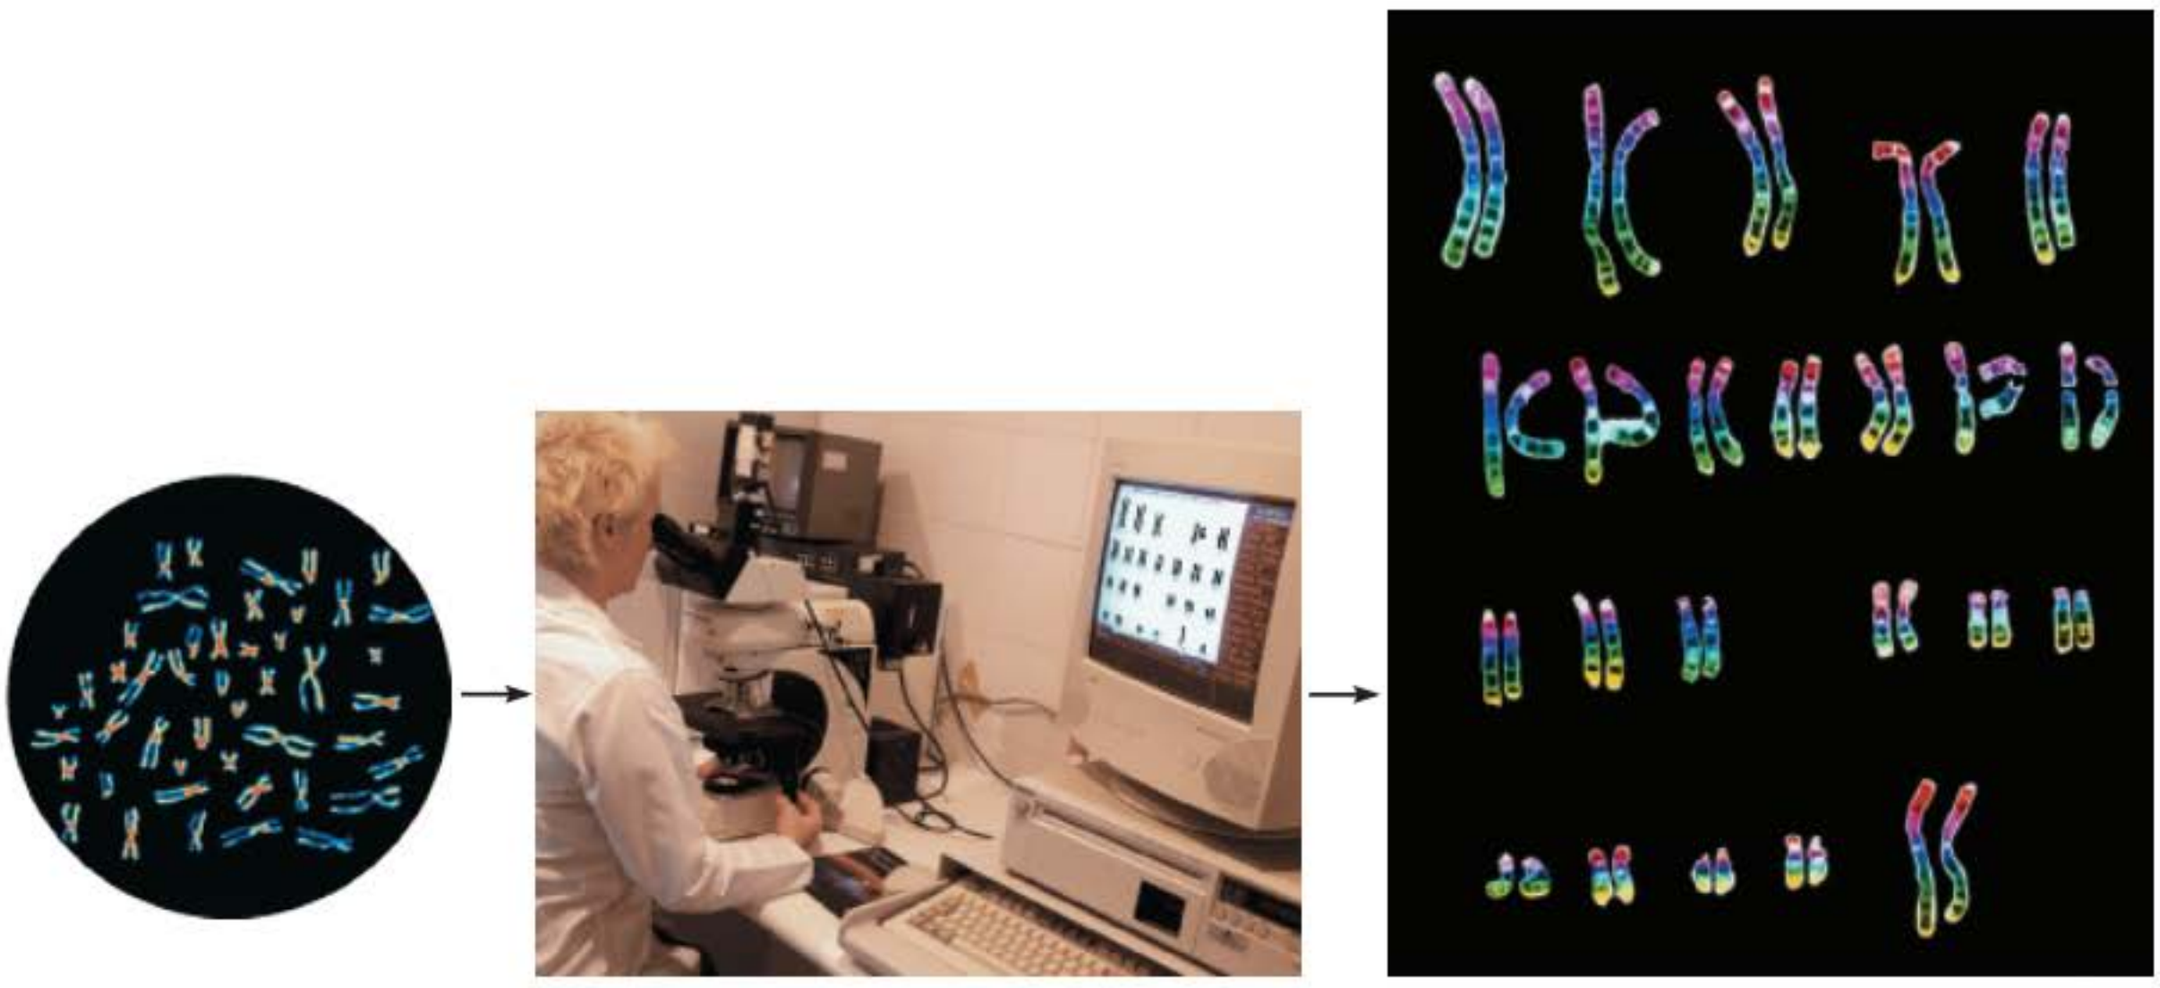
- **Define allele.**
- **Differentiate between genotype and phenotype.**

The nuclei of all human cells except gametes contain the diploid number of chromosomes (46), consisting of 23 pairs of homologous chromosomes. Recall that *homologous chromosomes* are pairs of chromosomes—one from the father (sperm) and one from the mother (egg)—that look similar and carry genes for the same traits, but do not necessarily bring about the same expressions of those traits. Two of the 46 chromosomes are **sex chromosomes** (X and Y), which determine genetic sex (male = XY; female = XX). The other 44 are the 22 pairs of **autosomes** that guide the expression of most other traits.

The complete human **karyotype** (kar′e-o-tīp), or diploid chromosomal complement displayed in homologous pairs, is illustrated in **Figure 29.1** ③. The diploid **genome** (je′nōm) is our genetic (DNA) makeup, and represents two sets of genetic instructions—one from the egg and the other from the sperm.

Gene Pairs (Alleles)

Because chromosomes are paired, it follows that the genes in them are paired as well. Consequently, each of us receives *two* genes, one from each parent (for the most part), that interact to dictate each trait. Different versions of the same genes are called **alleles** (ah-lēlz′). They occur at the same *locus* (location) on homologous chromosomes. Alleles may code for the same or for alternative forms of a given trait. Suppose, for example, that a single gene codes for the tightness of thumb ligaments. One allele might code for tight thumb ligaments and the other for loose ligaments (the double-jointed thumb condition). When the two alleles controlling a trait are the same, a person is said to be **homozygous** (ho-mo-zi′gus) for that gene. When the two alleles are different, the individual is **heterozygous** (het″er-o-zi′gus) for the gene.



① **Chromosomes are photographed.**
- Division of lymphocytes is arrested in metaphase by a drug (colchicine).
- Chromosomes are dispersed and stained for imaging.

② **Chromosomes are analyzed and manipulated.**
- The chromosomes are electronically arranged into homologous pairs according to size and structure.
- The pattern of stained bands helps identify specific chromosomes and parts of chromosomes.

③ **The resulting display is a karyotype.**
- A karyotype is an organized display of condensed chromosomes.
- The karyotype can be screened for defective chromosomes or abnormal chromosome numbers associated with certain diseases such as Down syndrome.

Figure 29.1 Preparing a karyotype.

Sometimes, one allele masks or suppresses the expression of its partner. Such an allele is said to be **dominant**, whereas the allele that is masked is said to be **recessive**. By convention, a dominant allele is represented by a capital letter (for example, *J*), and a recessive allele by the lowercase form of the same letter (*j*). Dominant alleles are expressed, or make themselves "known," when they are present in either single or double dose. For recessive alleles to be expressed, they must be present in double dose, that is, the homozygous condition. Returning to our thumb example, a person whose genetic makeup includes either the gene pair *JJ* (the homozygous dominant condition) or the gene pair *Jj* (the heterozygous condition) would have double-jointed thumbs. The combination *jj* (the homozygous recessive condition) would be needed to produce tight thumb ligaments.

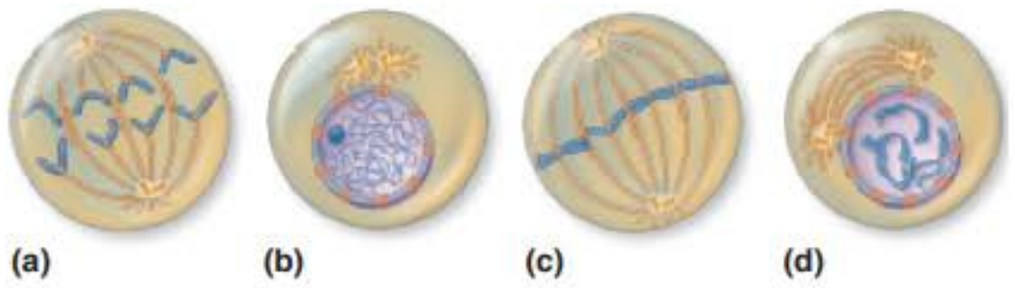
Keep in mind that dominant and recessive do not refer to how frequently an allele occurs in the population. A dominant allele that is lethal, for example, will be very rare. Even dominant alleles for relatively harmless conditions are often not widespread.

Genotype and Phenotype

A person's genetic makeup is referred to as his or her **genotype** (jēn′o-tīp). The expression of that genotype in the body is called one's **phenotype** (fe′no-tīp). In our example, the double-jointed condition is the phenotype produced by a genotype of *JJ* or *Jj*.

Check Your Understanding

1. What term refers to chromosomes other than our sex chromosomes?
2. Is an allele represented by a capital letter presumed to be dominant or recessive?
3. Adam is homozygous for the dominant alleles *HH, CC*, and *LL*, and heterozygous for *Bb* and *Kk*. He is blond and blue-eyed and has a very hairy chest. Which of these descriptions refer to his phenotype?
4. MAKE CONNECTIONS The drawings below show cells in various stages of the cell cycle (not in order). Identify the stage that would be used to make a karyotype. Why are chromosomes in this stage used? (Hint: See Chapter 3.)



For answers, see Answers Appendix.

29.2 Genetic variation results from independent assortment, crossing over, and random fertilization

Learning Outcome

- **Describe events that lead to genetic variability of gametes.**

Before we examine how genes interact, let us consider why (with the possible exception of identical twins) each of us is one of a kind, with a unique genotype and phenotype. This variability reflects three events:

- Independent assortment of chromosomes
- Crossing over of homologous chromosomes
- Random fertilization of eggs by sperm

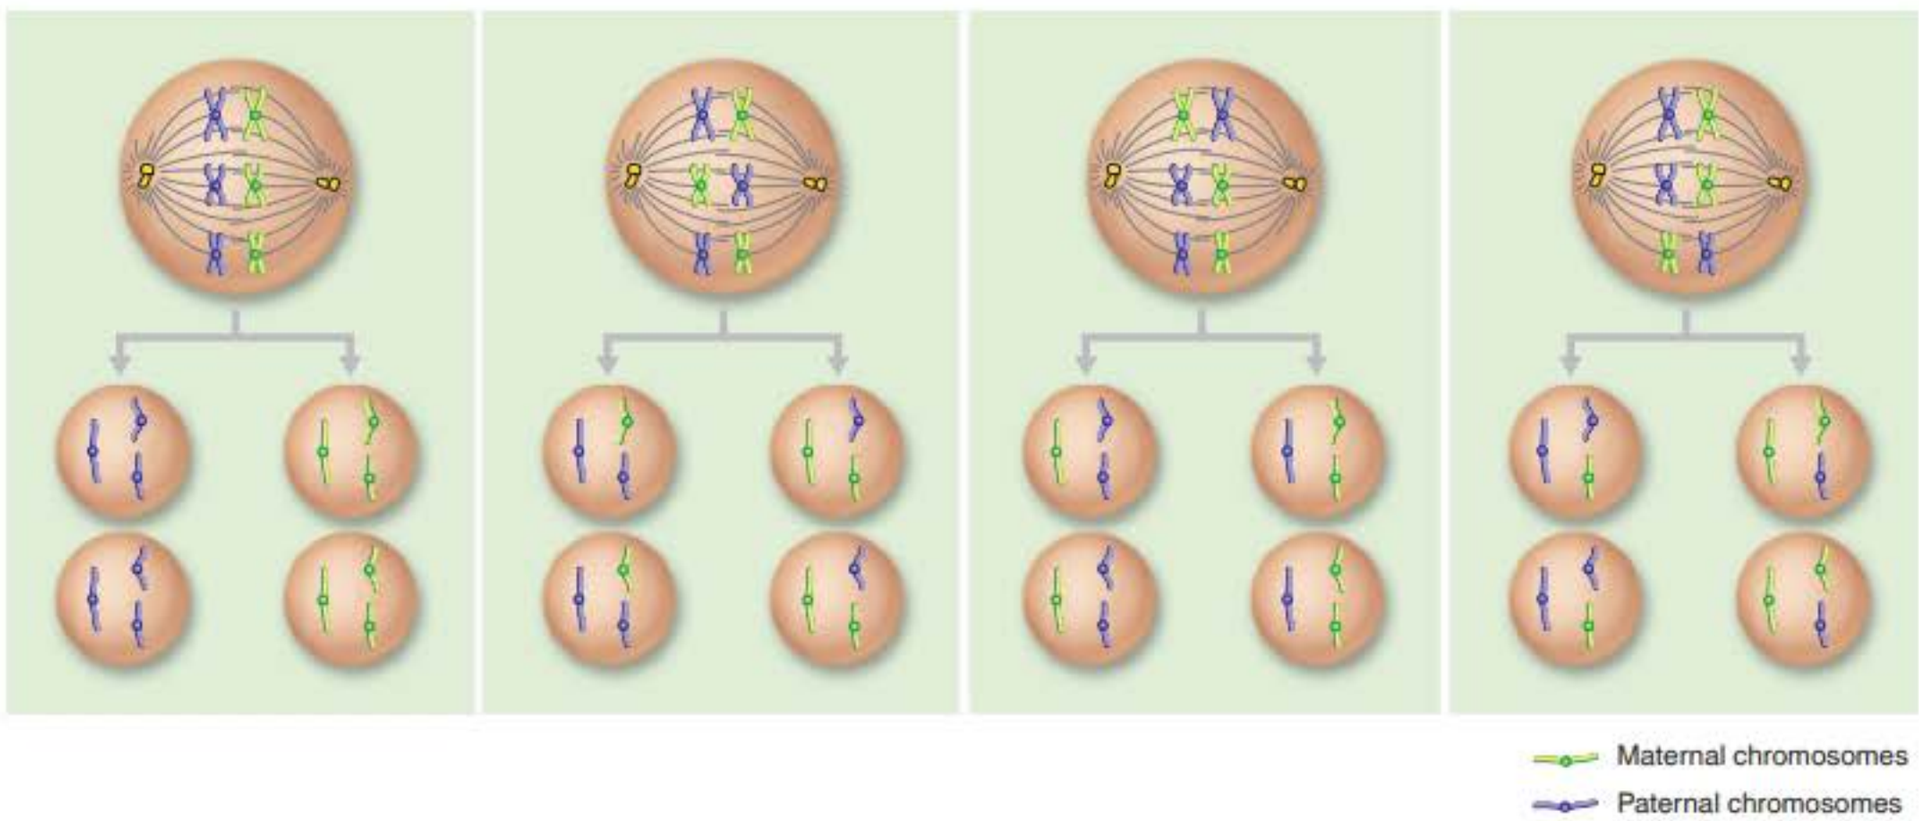


Figure 29.2 Gamete variability resulting from independent assortment. During metaphase of meiosis I, the tetrads of homologous chromosomes align independently of other tetrads. The large circles depict the possible alignments in a parent cell having a diploid number of 6. The small circles show the gametes arising from each alignment. Some gametes contain all maternal or all paternal chromosomes; others have various combinations of maternal and paternal chromosomes.

Chromosome Segregation and Independent Assortment

Recall that during meiosis, each pair of replicated homologous chromosomes synapses during meiosis I, forming a tetrad (◀ p. 1044). This happens during both spermatogenesis and oogenesis. Because chance determines how the tetrads align (line up) on the meiosis I metaphase spindle, maternal and paternal chromosomes are randomly distributed to daughter nuclei.

As illustrated in **Figure 29.2**, this simple event leads to an amazing amount of variation in gametes. The cell in our example has a diploid number of 6, and so three tetrads form. As you can see, the possible combinations of alignments of the three tetrads result in eight gamete possibilities. Because the way each tetrad aligns is random, and because many cells are undergoing meiosis simultaneously, each alignment and each type of gamete occurs with the same frequency as all others.

Two important points about metaphase of meiosis I:

- The two alleles determining each trait are **segregated**, which means that they are distributed to different gametes. Errors in this important process have been linked to cancer progression and Down syndrome.
- Alleles on different pairs of homologous chromosomes are distributed independently of each other. The net result is that each gamete has a single allele for each trait, and that allele represents only one of the two possible parental alleles.

The number of different gamete types resulting from this **independent assortment** of homologues during meiosis I can be calculated for any genome from the formula 2^n, where n is the number of homologous pairs. In our example, $2^n = 2^3$ ($2 \times 2 \times 2$), for a total of 8 different gamete types.

Note that the number of gamete types increases dramatically as the chromosome number increases. A cell with six pairs of homologues would produce 2^6, or 64, kinds of gametes. In a man's testes, the number of gamete types that can be produced on the basis of independent assortment alone is 2^{23}, or about 8.5 million—an incredible variety. The number of different gamete types produced in a woman's ovaries is substantially less because her ovaries complete at most 500 reduction divisions in her lifetime. Still, each ovulated oocyte will most likely be novel genetically because of independent assortment.

Crossing Over of Homologues and Gene Recombination

Another aspect of gamete variation results from the **crossing over** and exchange of chromosomal parts during meiosis I. Genes are arranged linearly along a chromosome's length, and genes on the same chromosome are said to be **linked** because they are transmitted as a unit to daughter cells during mitosis. However, during meiosis, chromosomes can break and precisely exchange gene segments with their homologous counterparts (◀ p. 1044). This exchange gives rise to **recombinant chromosomes** that have mixed contributions from each parent.

In the hypothetical example shown in **Figure 29.3**, the genes for hair and eye color are linked. The paternal chromosome contains alleles coding for blond hair and blue eyes, and the maternal alleles code for brown hair and brown eyes. In the **chiasma**, or *crossover*, shown, the break occurs between these linked genes, resulting in one gamete with alleles for blond hair

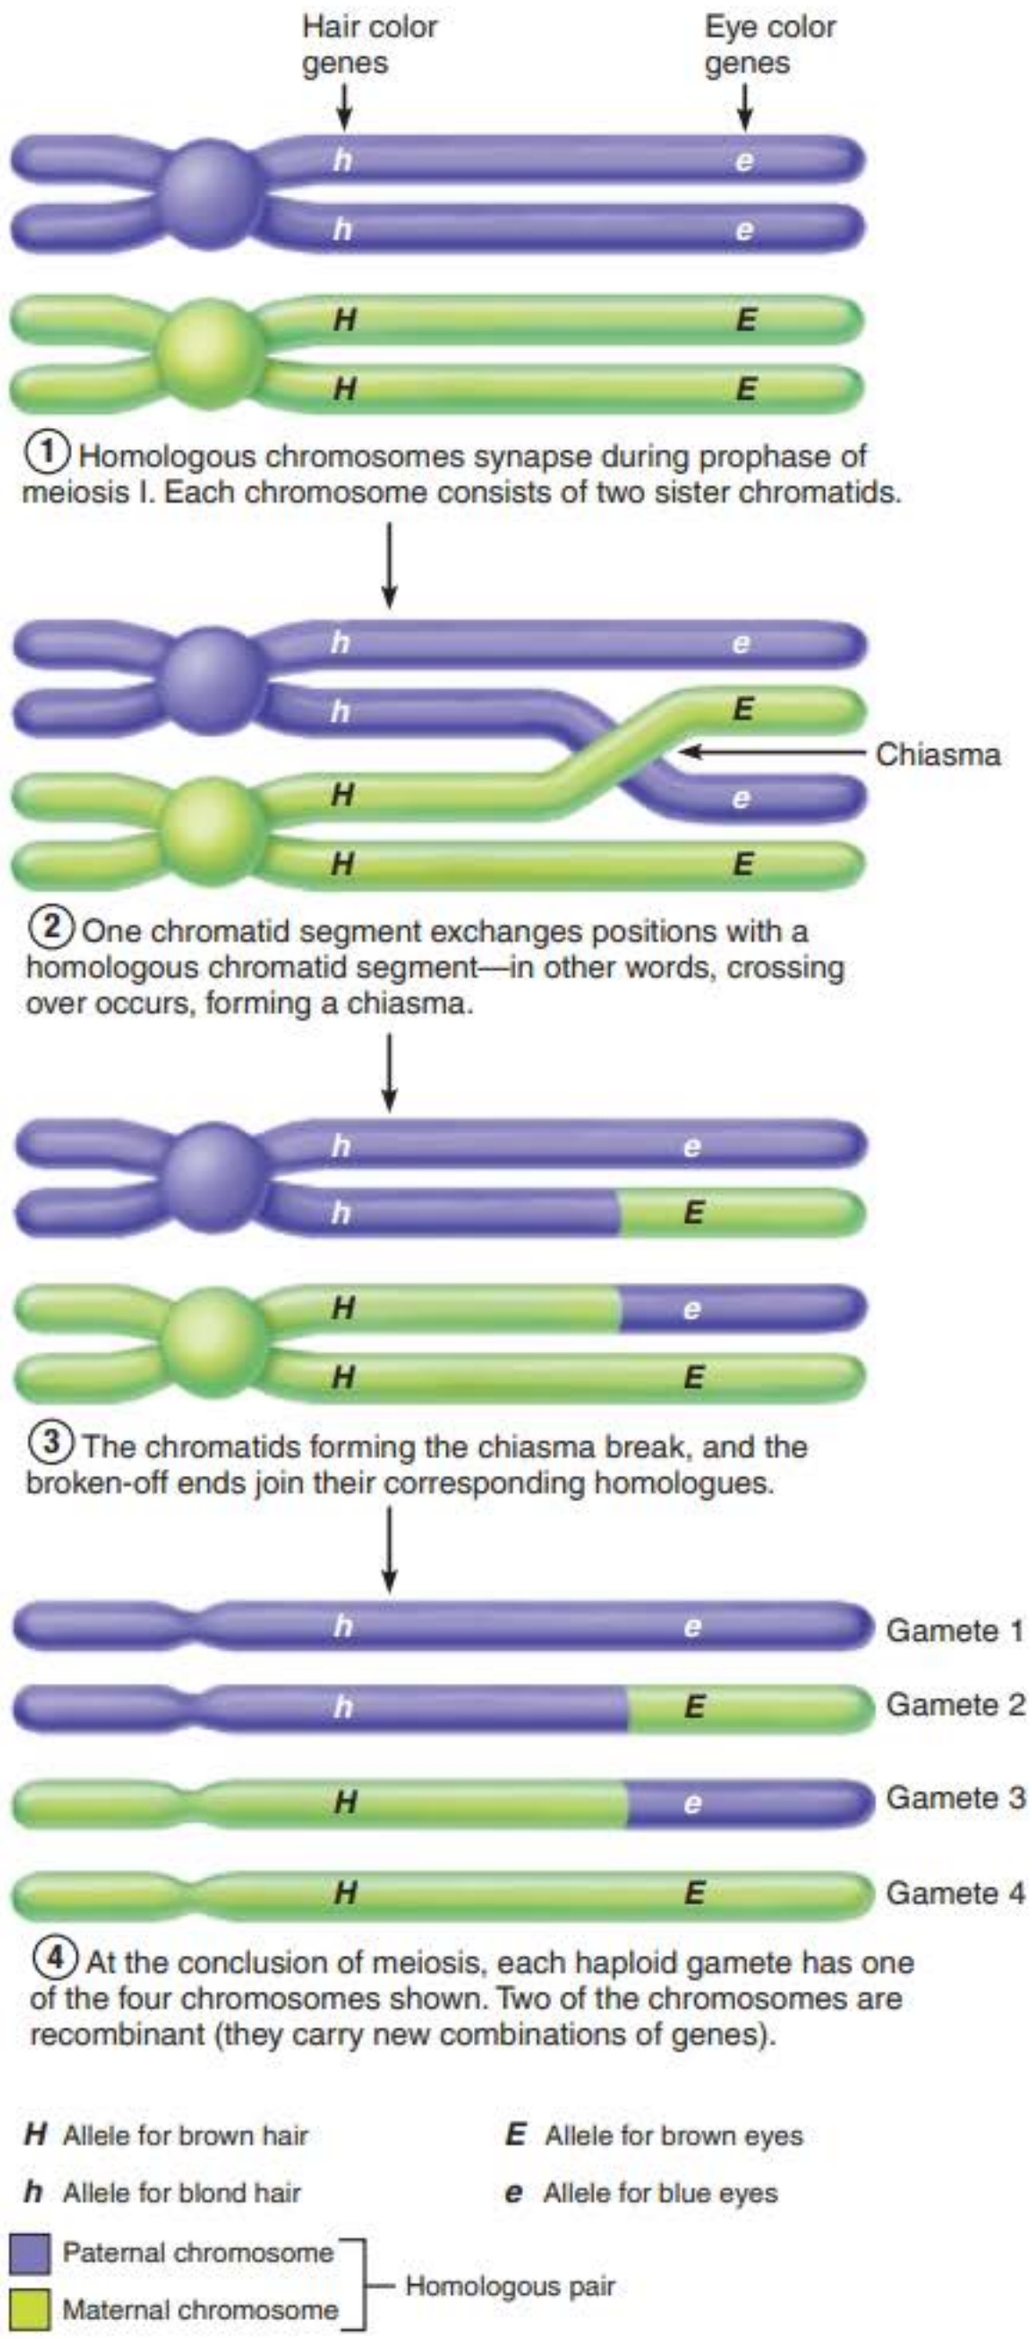

Figure 29.3 Crossing over and genetic recombination. These meiosis I events increase genetic variability in the gametes. For simplicity, only two chromatids are shown taking part in crossing over. Multiple chiasmata result in more complex patterns.

29

and brown eyes and another with alleles for brown hair and blue eyes. As a result of the crossing over, two of the four chromatids present in the tetrad end up with a mixed set of alleles—some maternal and some paternal. This means that when the chromatids segregate, each gamete will receive a unique combination of parental genes.

Because humans have 23 tetrads, with at least one chiasma going on in each of them during meiosis I, the variability resulting from this factor alone is tremendous.

Random Fertilization

At any point in time, gametogenesis is turning out gametes with all variations possible from independent assortment and random crossing over. Fertilization compounds this variety because a single human egg will be fertilized by a single sperm on a totally random basis. If we consider variation resulting only from independent assortment and random fertilization, any offspring represents one out of the more than 72 trillion (8.5 million × 8.5 million) zygotes possible. The additional variation introduced by crossing over increases this number exponentially. Perhaps now you can understand why brothers and sisters are so different, and marvel at how they can also be so alike in many ways.

Check Your Understanding

5. We said that genetic variability is introduced by independent assortment. Just what is assorting independently?
6. How does crossing over increase genetic variability?

For answers, see Answers Appendix.

29.3 Several patterns of inheritance have long been known

Learning Outcomes

- **Compare and contrast dominant-recessive inheritance with incomplete dominance and codominance.**
- **Describe the mechanism of sex-linked inheritance.**
- **Explain how polygene inheritance differs from that resulting from the action of a single pair of alleles.**

A few human phenotypes can be traced to a single gene pair (as we will describe shortly), but most such traits are very limited in nature, or reflect variation in a single enzyme. Most human traits are determined by multiple alleles or by the interaction of several gene pairs.

Dominant-Recessive Inheritance

Dominant-recessive inheritance reflects the interaction of dominant and recessive alleles. A simple diagram, called the **Punnett square**, is used to figure out, for a single trait, the possible gene combinations that would result from the mating of parents of known genotypes (**Figure 29.4**). In the example shown, both parents have normal pigmentation but carry the recessive allele for albinism (*a*), the lack of the pigment melanin (◀ p. 169). This means each parent is heterozygous for this trait and has the genotype *Aa*. The alleles of one parent are written along one side of the Punnett square, and the alleles for the other parent are shown along an adjacent side. The alleles are then combined down and across to determine the possible gene combinations (genotypes) and their expected frequency in the offspring of these two parents.

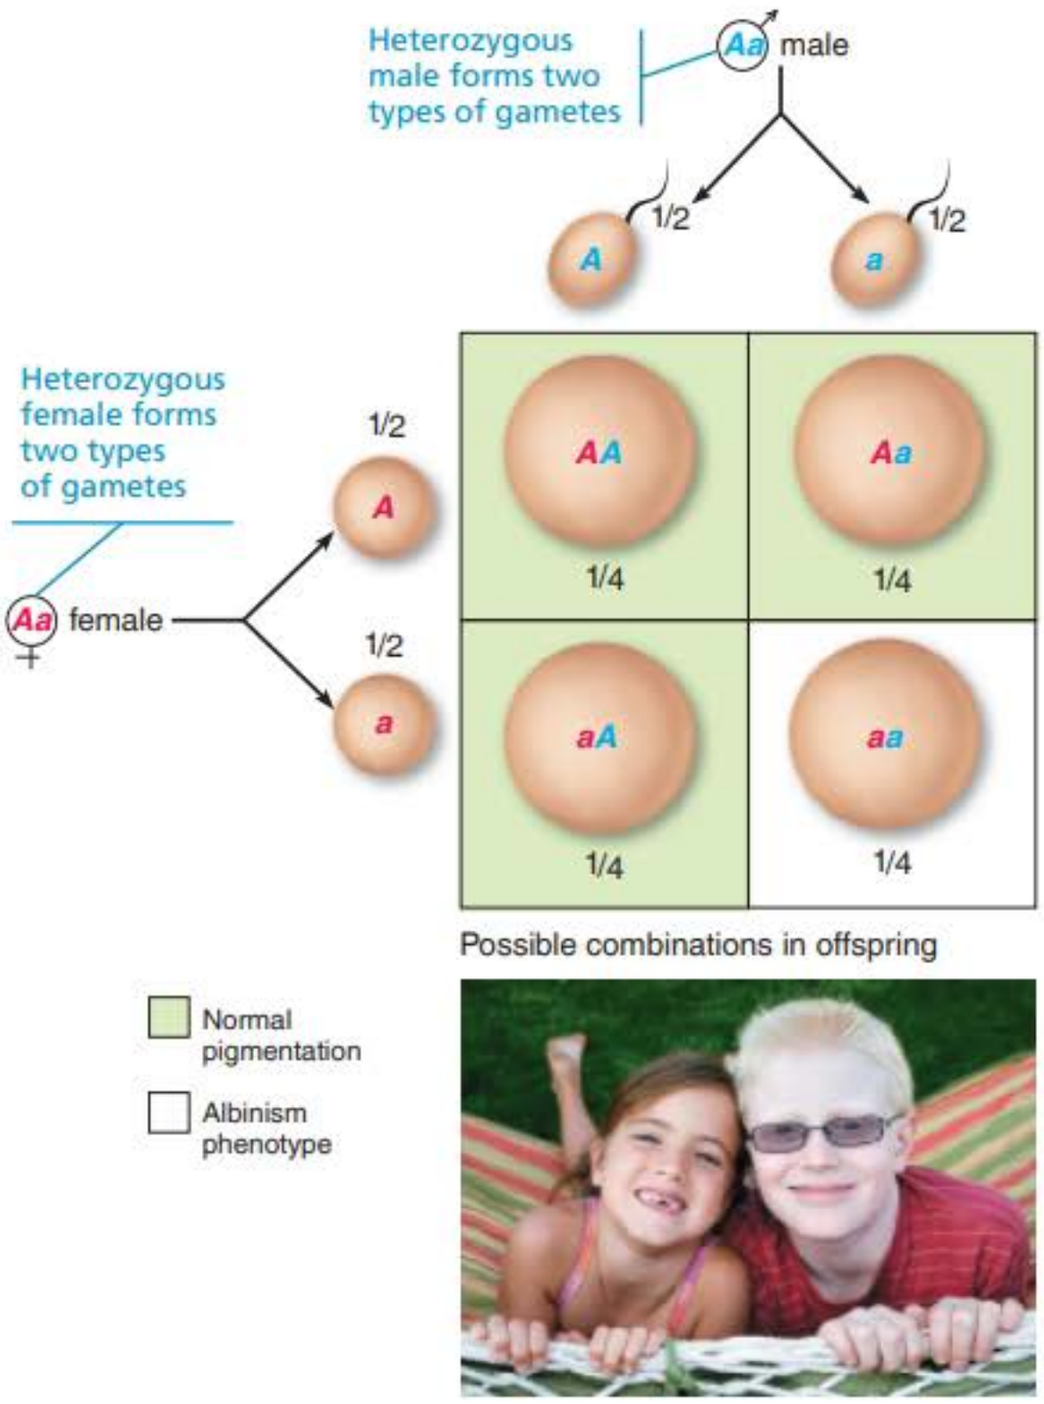

Figure 29.4 Genotype and phenotype probabilities resulting from a mating of two heterozygous parents. The Punnett square shows all possible combinations of a set of alleles in the zygote. In this example, the *A* allele is dominant and determines pigmentation (green background); the *a* allele is recessive. The photo shows a boy with albinism and his normally pigmented sister.

As the completed Punnett square shows, the probability of these parents producing a homozygous dominant child (*AA*) is 25% (1 out of 4); of producing a heterozygous child (*Aa*), 50% (2 out of 4); and of producing a homozygous recessive child, 25% (1 out of 4). The *AA* and *Aa* offspring will have normal pigmentation. Only the *aa* offspring will have albinism.

The Punnett square predicts only the *probability* of a particular genotype (and phenotype). The larger the number of offspring, the greater the likelihood that the ratios will conform to the predicted values—just as the chances of getting heads half the time and tails half the time increase with the number of tosses of a coin. If we toss only twice, we may well get heads both times. Likewise, if the couple in our example had only two children, it would not be surprising if both children had the genotype *Aa*.

Table 29.1 Traits Determined by Simple Dominant-Recessive Inheritance

PHENOTYPE DUE TO EXPRESSION OF:	
DOMINANT GENES (*ZZ* OR *Zz*)	**RECESSIVE GENES (*zz*)**
Syndactyly (webbed digits)	Normal digits
Achondroplasia (heterozygous: dwarfism; homozygous: lethal)	Normal endochondral ossification
Huntington's disease	Absence of Huntington's disease
Normal skin pigmentation	Albinism
Absence of Tay-Sachs disease	Tay-Sachs disease
Absence of cystic fibrosis	Cystic fibrosis

What are the chances of having two children of the same genotype? To determine the probability of two events happening in succession, we must multiply the probabilities of the separate events happening. The probability of getting heads in one coin toss is 1/2, so the probability of getting two heads in a row is $1/2 \times 1/2 = 1/4$. Remember that the production of each child, like each coin toss in a series, is an *independent event* that is not influenced by the production of any other child by the same couple. If you get heads on the first toss, the chance of getting heads the second time is still 1/2. Likewise, if our couple's first child is an *aa*, they still have a 1/4 chance of getting an *aa* the next time.

Dominant Traits

Most easily observable traits in humans (such as eye color and hair color) are controlled by multiple genes and influenced by the environment. Simple dominant-recessive patterns of inheritance are rare. Indeed, many human traits once thought to be determined by single-gene dominant-recessive inheritance (such as freckles, dimples, a widow's peak, double-jointed thumbs, the ability to tongue roll or taste phenylthiocarbamide) don't actually follow this pattern. This pattern of inheritance is most clearly seen in disorders such as those listed in **Table 29.1**.

Disorders caused by dominant genes are uncommon because *lethal dominant genes* are almost always expressed and result in the death of the embryo, fetus, or child. However, in some dominant disorders the person is less impaired or at least survives long enough to reproduce. One example is *Huntington's disease*, a fatal nervous system disease involving degeneration of the basal nuclei (◀ p. 444). It involves a *delayed-action gene* that is expressed when the affected individual is about 40. Offspring of a parent with Huntington's disease have a 50% chance of inheriting the lethal gene. (The parent is heterozygous, because the dominant homozygous condition is lethal to the fetus.) Many children of such parents are, as adults, opting not to become parents themselves.

Recessive Traits

Some examples of recessive inheritance are the more desirable genetic condition. For example, normal endochondral ossification (◀ p. 184) is dictated by recessive alleles, whereas achondroplasia (abnormal endochondral ossification; ◀ p. 195) is prescribed by dominant alleles. However, many if not most genetic disorders are inherited as simple recessive traits. These include conditions as different as *albinism*; *cystic fibrosis*, a condition of excessively thick mucus production that impairs lung and pancreatic functioning (◀ p. 861); and *Tay-Sachs disease*, a disorder of brain lipid metabolism caused by an enzyme deficit that shows itself a few months after birth (◀ p. 87).

Recessive genetic disorders are more frequent than disorders caused by dominant alleles because those who carry a *single* recessive allele for a recessive genetic disorder do not themselves express the disease. However, they can pass the gene on to offspring and so are called *carriers* of the disorder.

Incomplete Dominance

In dominant-recessive inheritance, one allele variant completely masks the other. Some traits, however, exhibit **incomplete dominance**. In such instances, the heterozygote has a phenotype intermediate between those of homozygous dominant and homozygous recessive individuals.

Perhaps the best human example is inheritance of the *sickling gene* (*s*), which causes a substitution of one amino acid in the beta chain of hemoglobin. Hemoglobin molecules containing the abnormal beta chains crystallize when blood oxygen levels are low, causing the erythrocytes to assume a sickle shape (◀ Figure 17.8b, p. 651). Individuals with a double dose of the sickling allele (*ss*) have **sickle-cell anemia** (◀ p. 650), and any condition that lowers their blood oxygen level, such as respiratory difficulty or excessive exercise, can precipitate a *sickle-cell crisis*. The deformed erythrocytes jam up and fragment in small capillaries, causing intense pain.

Individuals heterozygous for the sickling gene (*Ss*) have **sickle-cell trait**. They make both normal and sickling hemoglobin, and as a rule, these individuals are healthy. However, they can suffer a crisis if there is prolonged reduction in blood oxygen levels, as might happen when traveling in high-altitude areas, and they can transmit the sickling gene to their offspring.

Multiple-Allele Inheritance

Although we inherit only two alleles for each gene, some genes exhibit more than two allele forms, leading to a phenomenon called **multiple-allele inheritance**. An example of multiple-allele inheritance in humans is ABO blood types (◀ Table 17.4, p. 664). Three alleles determine the ABO blood types in humans: I^A, I^B, and *i*. Each of us receives two of these. The I^A and I^B alleles are **codominant**, and both are expressed when present, resulting in the AB blood type. The *i* allele is recessive to the other two. Genotypes determining the four possible ABO blood groups are shown in **Table 29.2**.

Table 29.2 ABO Blood Groups

BLOOD GROUP (PHENOTYPE)	GENOTYPE
O	*ii*
A	I^AI^A or I^Ai
B	I^BI^B or I^Bi
AB	I^AI^B

Sex-Linked Inheritance

Inherited traits determined by genes on the sex chromosomes are said to be **sex-linked**. The X and Y sex chromosomes are not homologous in the true sense. The Y, which contains the gene that determines maleness, is much smaller than the X chromosome (**Figure 29.5**). The X bears over 1400 genes, and a disproportionately large number of them code for proteins important to brain function. Because the Y carries only about 200 genes, it lacks many of the genes present on the X. For example, genes coding for certain clotting factors, cone pigments, and even testosterone receptors are present on X but not on Y. A gene found only on the X chromosome is said to be **X-linked**.

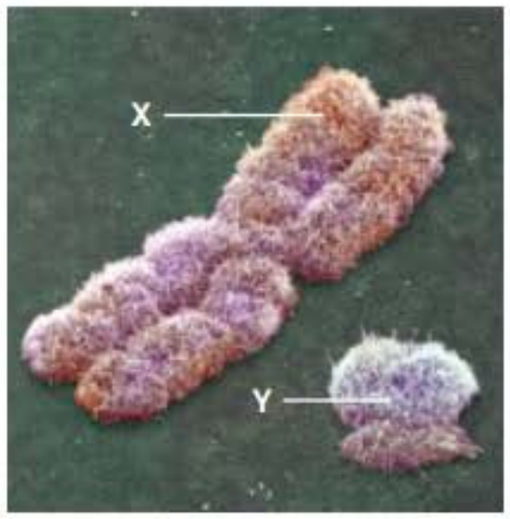

Figure 29.5 Human sex chromosomes. (9100×)

Only relatively short regions at either end of the Y chromosome (corresponding to about 5% of the Y's DNA) code for nonsexual characteristics corresponding to those on the X. Those homologous regions are the only areas that can participate in crossing over with the X.

Two examples of X-linked conditions are hemophilia (◀ p. 662) and red-green color blindness (◀ p. 569). When a male inherits an X-linked recessive allele for one of these conditions, its expression is never masked or damped, because there is no corresponding allele on his Y chromosome. Consequently, the recessive gene is always expressed, even though it is present only in single dose. In contrast, females must have two X-linked recessive alleles to express such a disorder, and as a result, very few females exhibit any X-linked conditions.

X-linked traits are typically passed from mother to son, never from father to son, because males receive no X chromosome from their father. Of course, the mother can also pass the recessive allele to her daughter, but unless the daughter receives another such allele from her father, she will not express the trait (**Figure 29.6**).

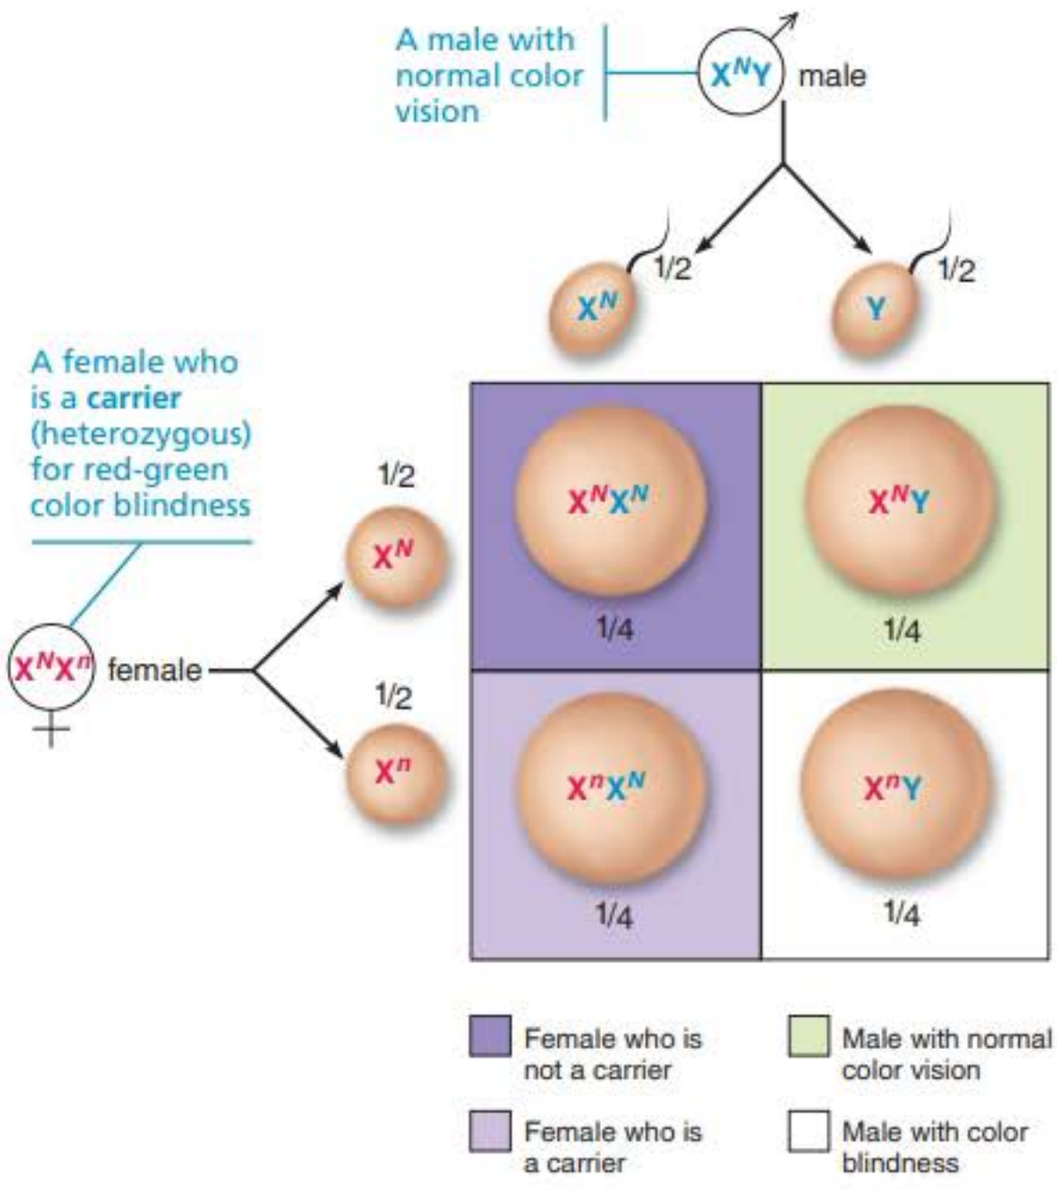

Figure 29.6 Sex-linked inheritance. If a female heterozygous for red-green color blindness and a male with normal color vision have offspring, there is a 50% chance that their sons will be color blind and a 50% chance that their daughters will be carriers. The *N* allele determines normal color vision and the *n* allele is recessive.

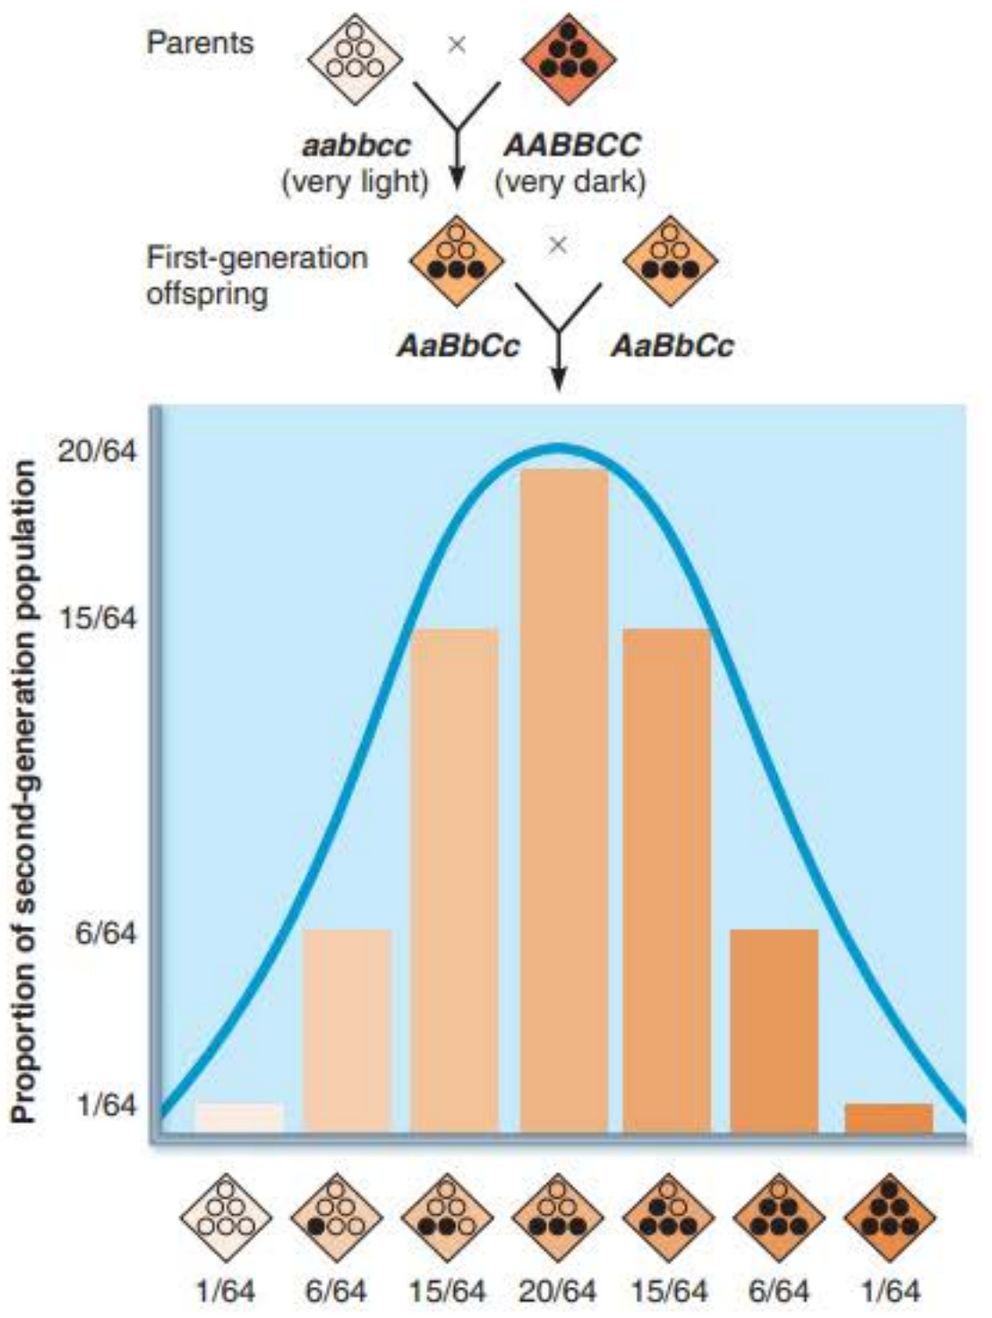

Figure 29.7 Simplified model for polygene inheritance of skin color based on three gene pairs. Alleles for dark skin are incompletely dominant over those for light skin. Each dominant gene (*A, B, C*) contributes 1 "unit" of darkness (indicated by a dark dot) to the phenotypes.

Here the parents are homozygotes at opposite ends of the phenotype range. Each child inherits 3 "units" of darkness (is a heterozygote) and has intermediate pigmentation. When they grow up, if they mate with people with the same alleles, their offspring (second generation) may have a wide variation in pigmentation, as shown by the plotted distribution of skin colors.

Polygene Inheritance

So far, we have considered only traits inherited by mechanisms of classical Mendelian genetics, which are fairly easy to understand, and such traits typically have two, or perhaps three, alternate forms. However, most phenotypes depend on several gene pairs at different locations acting in tandem. Such **polygene inheritance** results in *continuous*, or *quantitative*, phenotypic variation between two extremes and explains many human characteristics. Examples of polygene traits in humans include skin color, height, metabolic rate, and intelligence.

Skin color, for instance, is controlled by at least three separately inherited genes, each existing in two allelic forms: *A, a*; *B, b*; *C, c*. The *A, B*, and *C* alleles confer dark skin pigment, and their effects are additive. The *a, b*, and *c* alleles confer pale skin tone. An individual with an *AABBCC* genotype would be about as dark-skinned as a human can get, while an *aabbcc* person would be very fair. However, when individuals heterozygous for at least one of these gene pairs mate, a broad range of pigmentation is possible in their offspring. Such polygene inheritance results in a distribution of genotypes and phenotypes that, when plotted, yields a bell-shaped curve (**Figure 29.7**).

Check Your Understanding

7. How does incomplete dominance differ from codominance?
8. How can you explain why parents of average height can produce very tall or very short offspring?
9. PREDICT Which lethal allele would you expect to be more widespread in a population—one that is dominant or one that is recessive? Why?
10. DRAW Draw a Punnett square showing the potential offspring of a man with hemophilia and a woman who is a carrier for the same type of X-linked hemophilia. Summarize the results.

For answers, see Answers Appendix.

29.4 Environmental factors may influence or override gene expression

Learning Outcome

- **Provide examples illustrating how gene expression may be modified by environmental factors.**

In many situations environmental factors override or at least influence gene expression. Our genotype (discounting mutations) is as unchanging as a rock, but our phenotype is more like clay. If this were not the case, we would never get a tan, women bodybuilders would never be able to develop bulging muscles, and there would be no hope for treating genetic disorders.

Sometimes, maternal factors such as drugs or pathogens alter normal gene expression during embryonic development. Take, for example, the case of babies in the 1960s whose mothers took the sedative thalidomide to alleviate morning sickness. This drug caused the embryos to develop phenotypes (flipperlike appendages) not directed by their genes. (The same phenotype can also be caused by a genetic mutation.) Such environmentally produced phenotypes that mimic conditions that may be caused by genetic mutations (permanent transmissible changes in the DNA) are called **phenocopies**.

Equally significant are environmental factors that may influence genetic expression after birth, such as the effect of poor infant nutrition on brain growth, general body development, and height. In this way, a person with "tall genes" can be stunted by insufficient nutrition. Furthermore, part of a gene's environment consists of the influence of other genes. For example, hormonal deficits during childhood can lead to abnormal skeletal growth and proportions, as in congenital hypothyroidism, a type of dwarfism resulting from insufficient thyroid hormone secretion.

Check Your Understanding

11. Which of the following factors may alter gene expression? Other genes, measles in a pregnant woman, lack of key nutrients in the diet.

For answers, see Answers Appendix.

29.5 Factors other than nuclear DNA sequence can determine inheritance

Learning Outcomes

- **Describe how RNA-only genes and epigenetic marks affect gene expression.**
- **Describe the basis of extranuclear (mitochondria-based) genetic disorders.**

Mendel's writings underlie mainstream thinking about heredity, but some genetic outcomes do not fit his rules. Among these nontraditional types of inheritance are influences due to RNA-only genes, to chemical groups attached to DNA or histone proteins, and to *extranuclear inheritance* conferred by mitochondrial DNA.

Beyond DNA: Regulation of Gene Expression

Our genome is a biochemical system of awesome complexity, with three basic levels of controls. The protein-coding genes that we have been describing to this point only make up the first level and account for less than 2% of the DNA of a human cell. This is the part of the genome traditionally considered to be a "blueprint" for protein structure.

The second and third layers of information important in directing development lie elsewhere—in the noncoding DNA and even totally outside the DNA sequences. It takes relatively few genes to build a human being. Our complexity is the result of the mechanisms that control the expression of genes, especially during growth and differentiation. So what are these other regulatory systems?

Small Noncoding RNAs

The second layer of control consists of the abundant "RNA-only genes." About 80% of the genome, which was once believed to

be "junk DNA," forms a parallel regulatory system. This system generates a variety of *small noncoding RNAs* (*sncRNAs*): microRNAs, small interfering RNAs (◀ p. 108), and piwi-interacting RNAs. These small RNA molecules are mobile "control freaks" that act in similar ways that generally reduce the expression of particular genes. All of their mechanisms depend on combining with protein enzymes and using complementary RNA-RNA base pairing to identify their targets. Binding of the small RNA–enzyme complex has three possible results:

- Destruction of the target mRNA by dicing it up into smaller fragments
- Inhibition of translation of the target mRNA
- Silencing the gene that codes for the target mRNA by modifying the histone proteins that pack up the DNA coding for that gene (◀ p. 93)

Small RNAs are particularly important during development and in helping us fight off viral infections. They can also protect us from elements of our own DNA that can act as aggressive (jumping) genes called *transposons*, which tend to copy themselves and then insert the copies into distant DNA sites, disabling or hyperactivating genes at those sites.

At present, small RNAs are widely used as research tools to experimentally interfere with the expression of certain genes. This allows researchers to find out what those genes do. Mutations in genes coding for small RNAs have already been linked to conditions as diverse as cancers and schizophrenia. Small RNAs are also on the cutting edge of drug research. Clinical trials are under way using small RNAs to treat a large variety of diseases including macular degeneration, cancers, and various liver diseases.

Epigenetic Marks

Epigenetic marks (*epi* = "over, above") form the third layer of gene controls. Chemical tags such as methyl and acetyl groups bound to DNA segments and to histone proteins (◀ p. 93) determine (mark) whether the DNA is available for transcription (acetylation) or silenced (methylation). This information, stored in the proteins and chemical groups that bind to the DNA, and in the way chromatin is packaged in the cell, is continually changing. Epigenetic marks also account for the inactivation (by methylation) of one of the female's X chromosomes in the early embryo.

Epigenetic marks or lack of them may predispose a cell for transformation from normal to cancerous, and even slight deviations in the epigenetic marks on specific chromosomes can result in devastating human illness.

For most genes, both the maternal and paternal alleles are expressed at the same time. For about 300 genes, this isn't the case and only one of the two parental alleles is expressed in every body cell. The addition of a methyl (—CH_3) group during gamete formation silences one of the alleles and marks it as coming from the mother or the father. This process is called **genomic imprinting**. During gametogenesis, the "old" imprinting tags are stripped away and a new set of tags are added to each gene, marking it as maternal (in ova) or paternal (in sperm).

Mutations of imprinted genes may lead to pathology and the mutated allele can have different effects depending on which parent it comes from. For example, people with Prader-Willi syndrome have mild to moderate intellectual disability, and are short and often obese. People with Angelman syndrome have severe intellectual disability, are unable to speak coherently, laugh uncontrollably, and exhibit jerky, lurching movements as if tied to a puppeteer's strings. The manifestations of these two disorders are very different, but the genetic cause is the same—deletion of a particular region of chromosome 15. If the defective chromosome comes from the father, the result is Prader-Willi syndrome; the mother's defective chromosome confers Angelman syndrome.

Unlike the part of the genome that acts as a blueprint for protein structure, epigenetic marks are more like marks on an Etch a Sketch®—a good "shake" during gametogenesis wipes away the message. However, sometimes that "shake" is insufficient to make the message disappear and the current epigenetic marks are passed on to the next generation (inherited) and cause epigenetic changes to occur there.

In short, protein-coding genes are not the only instructions to which cells refer. RNA matters, and so do the tiny chemical tags that attach to the chromatin.

Extranuclear (Mitochondrial) Inheritance

Although we have focused on the chromosomal basis of inheritance, remember that not all genes are in the cell's nucleus: 37 genes (referred to as mtDNA) are in mitochondria (◀ pp. 83–84). Mitochondrial genes are transmitted to the offspring almost exclusively by the mother because the ovum donates essentially all the cytoplasm in the fertilized egg. Additionally, sperm mitochondrial DNA is selectively destroyed in both the sperm and egg.

A growing list of disorders, all rare, is now being linked to errors (mutations) in mitochondrial genes. Most involve problems with oxidative phosphorylation within the mitochondria, but a few lead to unusual degenerative muscle disorders or neurological problems. Some researchers suggest that Alzheimer's and Parkinson's disease may be among them.

Check Your Understanding

12. What process labels genes as paternal or maternal?

13. What is the source of the genes that confer extranuclear inheritance?

For answers, see Answers Appendix.

29.6 Genetic screening is used to detect genetic disorders CLINICAL

Learning Outcomes

- **List and explain several techniques used to detect or predict genetic diseases.**
- **Describe briefly some approaches of gene therapy.**

Certain congenital abnormalities occur sporadically throughout the population, but can be treated successfully if they are caught at birth. For this reason, all newborns are generally examined and tested for:

- Anatomical disorders [such as developmental dysplasia of the hip (◀ p. 247) and imperforate anus]
- Metabolic diseases [such as phenylketonuria (PKU) (◀ p. 968)]

Genetic screening can be used to detect certain genetic conditions before birth. For example, a woman pregnant after age 35 may wish to know if her baby has trisomy 21, or Down syndrome (see Related Clinical Terms, p. 1135), a chromosome abnormality with a high incidence in children of older mothers. Genetic screening and *genetic counseling* provide information and options for prospective parents not even dreamed of 100 years ago.

Genetic screening and genetic counseling may also be important for adults. For example, adults with a parent who had Huntington's disease may wish to know if they will develop this condition themselves or if they might pass it on to their potential offspring.

Depending on the condition being investigated, screening can occur before conception by carrier recognition, or during fetal testing.

Carrier Recognition

There are two major avenues for identifying carriers of detrimental genes: pedigrees and blood tests. A **pedigree** traces a genetic trait through several generations and helps predict the future (**Figure 29.8**). For prospective parents, a genetic counselor collects phenotype information on as many family members as possible and uses it to construct the pedigree (often called the family tree). By working backward from current individuals and applying the rules of dominant-recessive inheritance, a counselor can deduce the genotypes of the parents and figure out the genotypes of the other individuals in their parents' generation.

Simple blood tests are used to screen for the sickling gene in heterozygotes, and sophisticated *blood chemistry tests* and *DNA probes* can detect the presence of other unexpressed recessive genes. At present, carriers of the Tay-Sachs and cystic fibrosis genes can be identified with such tests.

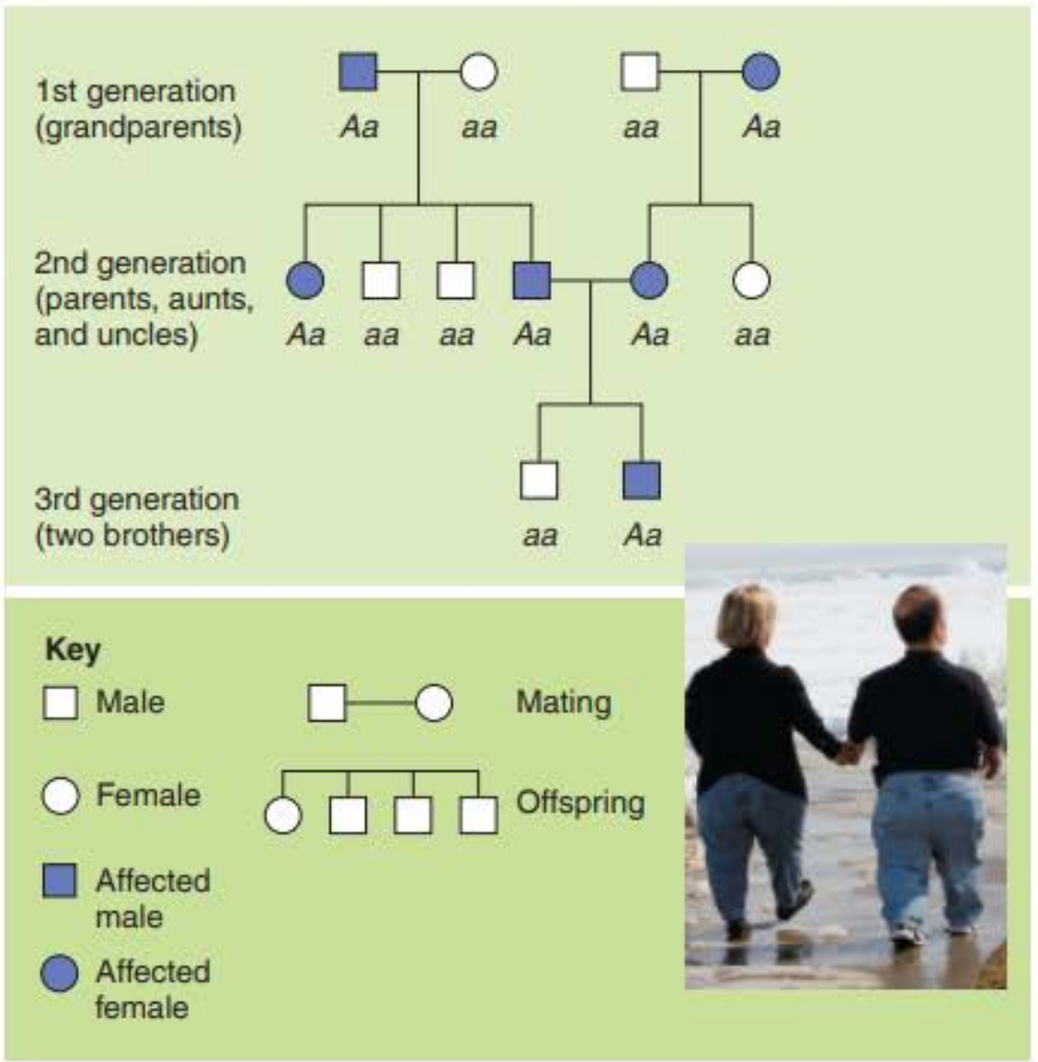

Figure 29.8 Pedigree analysis. This pedigree traces the pattern of inheritance of a dominant allele through three generations. The trait is achondroplasia, a form of dwarfism. All individuals with the dominant allele (*A*) show this trait. Notice that if both parents have achondroplasia (second generation; see photo) their children may or may not be affected. This pattern of inheritance only occurs for dominant alleles. (For this gene, the homozygous condition is lethal.)

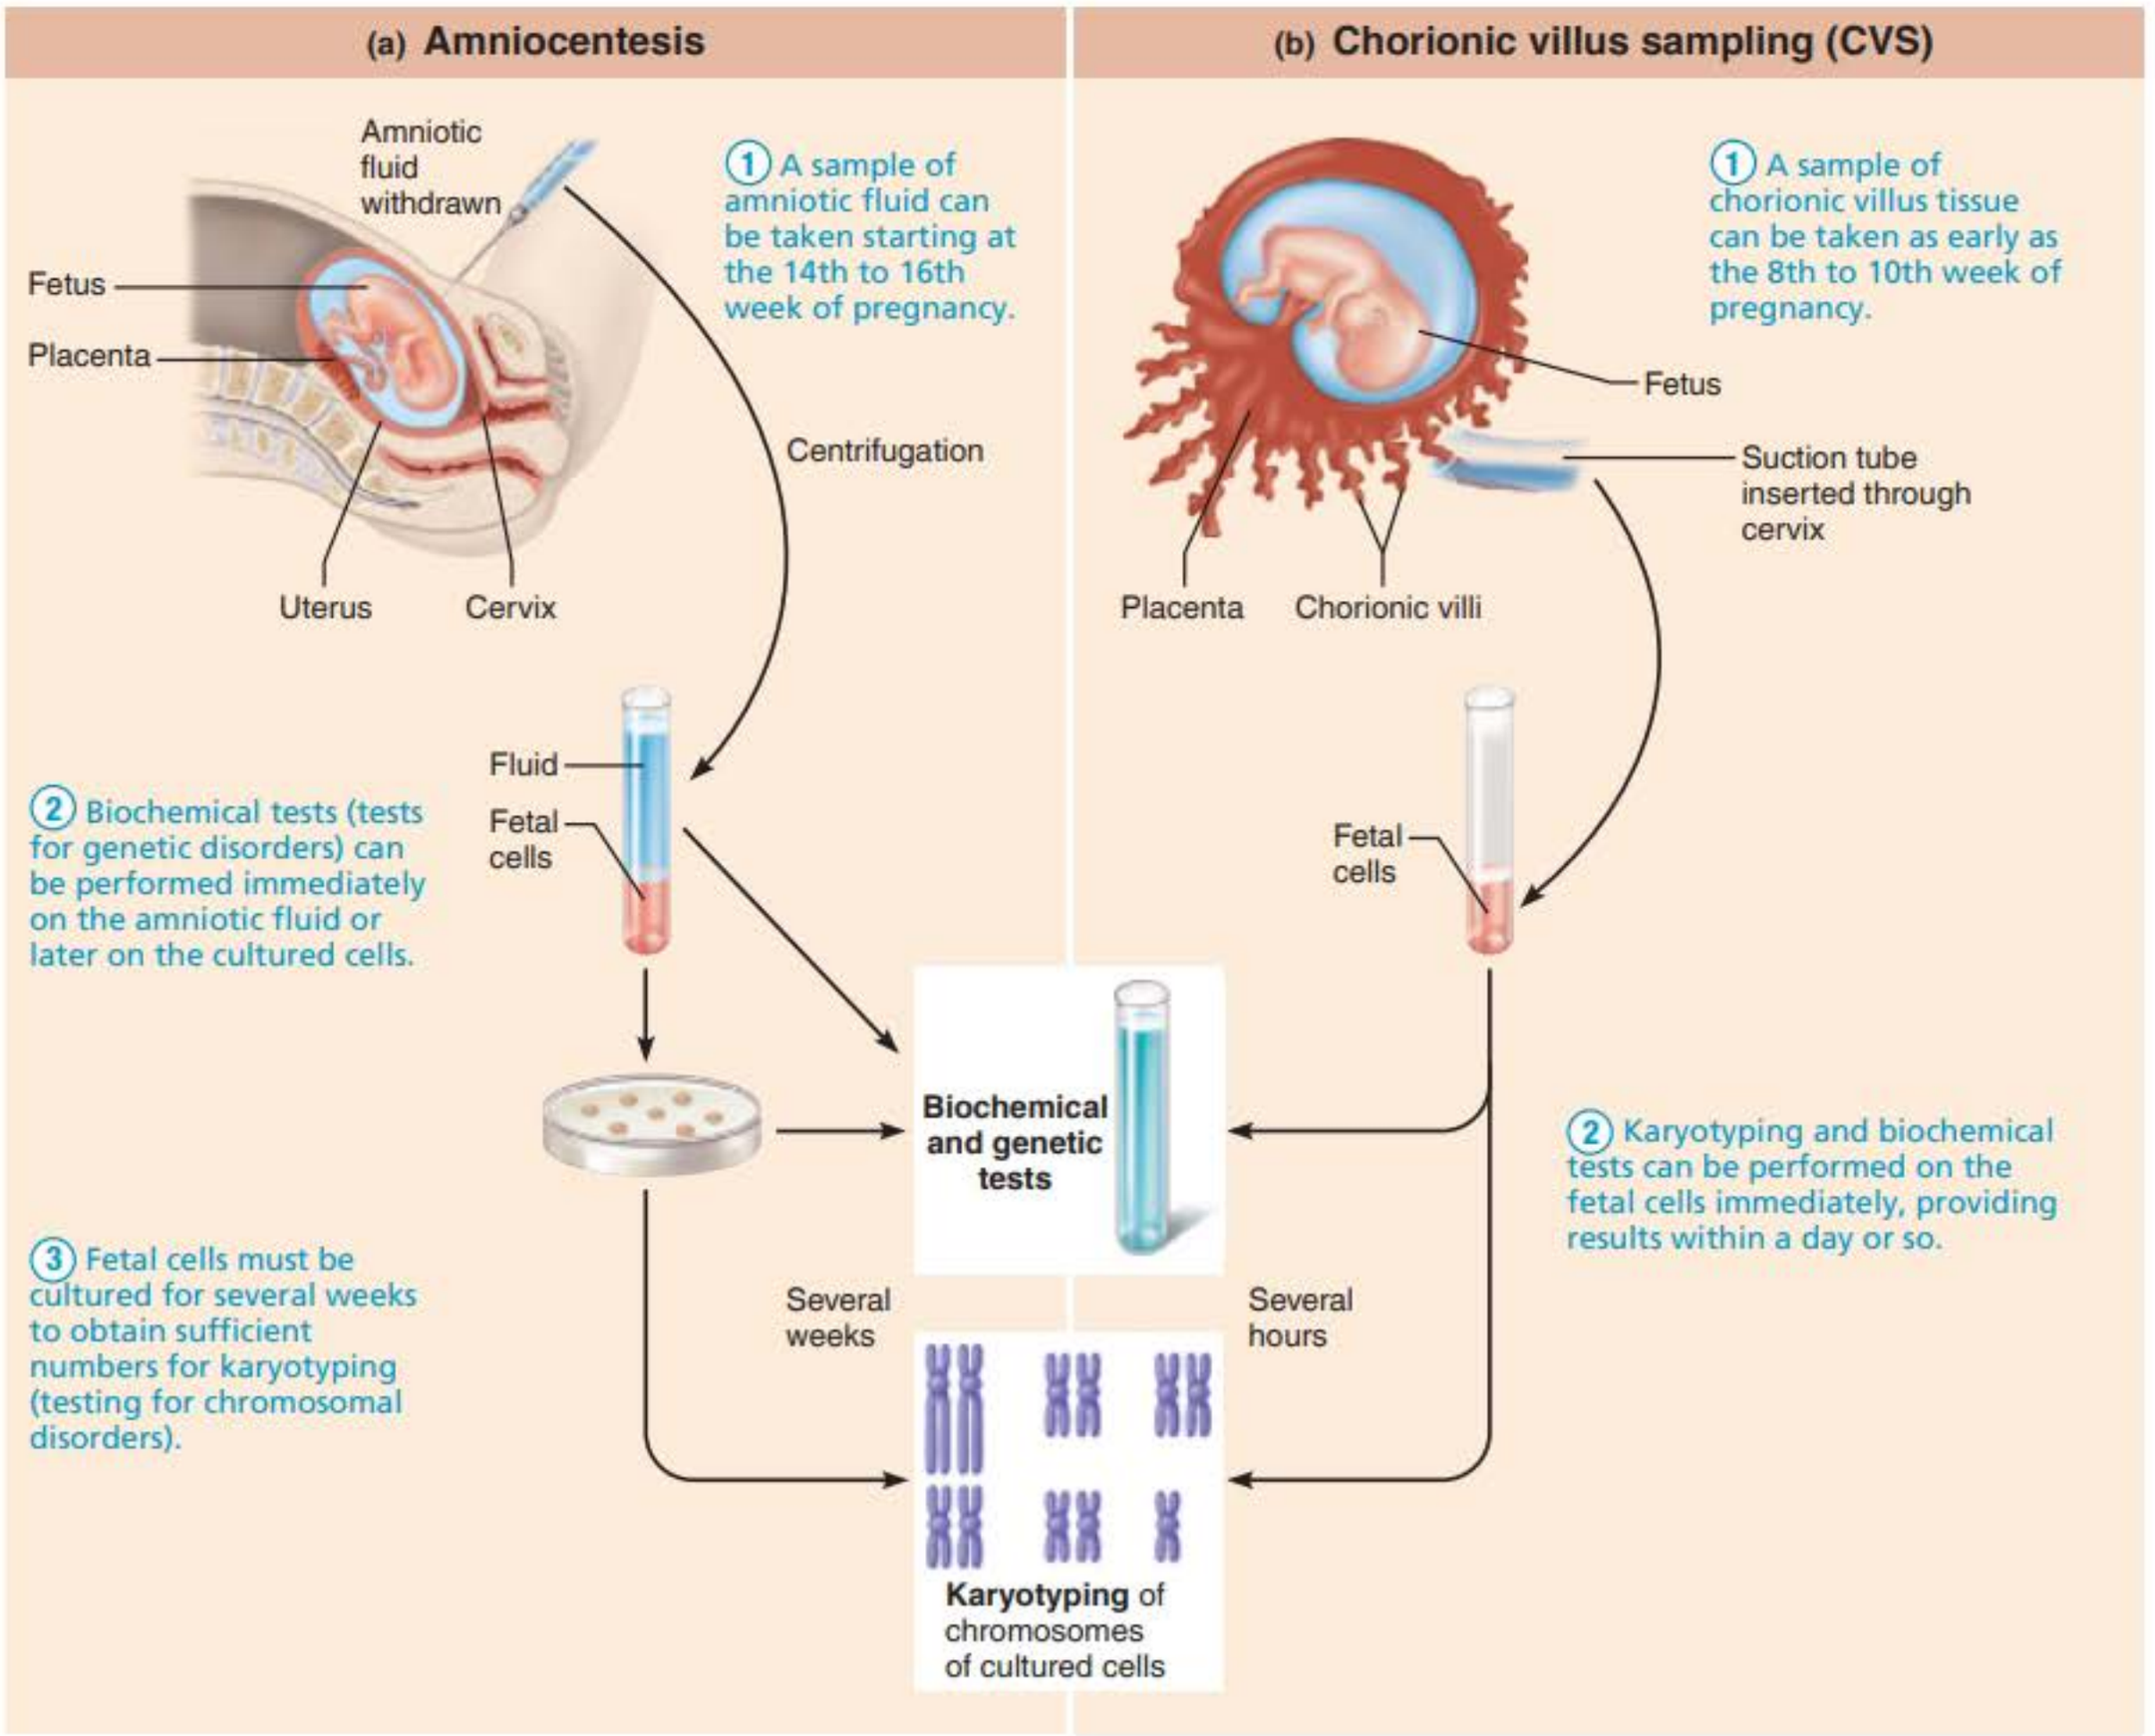

Figure 29.9 **Fetal testing—amniocentesis and chorionic villus sampling.**

29

Fetal Testing

Fetal testing is used when there is a known risk of a genetic disorder. The most common type of fetal testing is **amniocentesis** (am″ne-o-sen-te′sis), in which a wide-bore needle is inserted into the amniotic sac through the mother's abdominal wall, and about 10 ml of fluid is withdrawn (**Figure 29.9a**). Because there is a chance of injuring the fetus before ample amniotic fluid is present, this procedure is not normally done before the 14th week of pregnancy.

The fluid is checked for enzymes and other chemicals that serve as markers for specific diseases, but most tests are done on the sloughed-off fetal cells in the fluid. These cells are cultured in laboratory dishes over a period of several weeks. Then the cells are examined for DNA markers of genetic disease and karyotyped to check for chromosomal abnormalities (see Figure 29.1).

Chorionic villus sampling (CVS) suctions off bits of the chorionic villi from the placenta for examination (Figure 29.9b). A small tube is inserted through the vagina and cervical canal and guided by ultrasound to an area where a piece of placental tissue can be removed. CVS allows testing at 8 weeks but waiting until after the 10th week is usually recommended. Karyotyping can be done almost immediately on the rapidly dividing chorionic cells, much earlier than in amniocentesis.

Both of these procedures are invasive, and they carry with them an inherent risk to both fetus and mother. (For example, increased fetal risk of finger and toe defects is linked to CVS.) These tests are routinely ordered for pregnant women over 35 (because of the higher risk of Down syndrome), but they are performed on younger women when the probability of finding a severe fetal disorder is greater than the probability of doing harm during the procedure.

Advances in DNA sequencing are about to make both of these invasive procedures obsolete. An easily obtained maternal blood sample contains free-floating maternal and fetal DNA released from the placenta. Maternal blood samples are currently being used in the clinic to test for fetal chromosomal abnormalities such as Down syndrome. The same techniques can provide detailed information about the fetus's entire genome, including mutations that increase the likelihood of certain diseases. The technology already exists and is in increasingly wide use.

Human Gene Therapy

As indicated earlier, the ability to sequence and alter DNA has opened an exciting world to scientists investigating gene expression. Advances in diagnosing human genetic diseases have been followed quickly by new applications of gene therapy to alleviate or even cure the disorders, particularly in cases traced to a single defective gene or protein. Advances in genetic engineering using the new CRISPR-Cas9 genome editing technique have greatly facilitated making specific changes to genes. However, delivering the corrected genes to where they are needed is still a daunting task.

One approach (used successfully in treatment of severe combined immunodeficiency syndromes; ◀ p. 811) is to use a modified virus to deliver a functional copy of the affected gene into cells. Another is to inject the "corrected" DNA directly into the patient's cells. Such therapies have had mixed results in treating cystic fibrosis and muscular dystrophy. In addition, genetic engineering processes raise some thorny ethical, religious, and societal questions: Who will pay? Who determines who will be treated with the new therapies? Are we playing God?

Check Your Understanding

14. Which fetal testing procedure depends on analyzing amniotic fluid?
15. APPLY Mr. and Mrs. Lehman have sought genetic counseling. Mrs. Lehman is concerned because she is unexpectedly pregnant and her husband's brother died of Tay-Sachs disease. She can recall no incidence of Tay-Sachs disease in her own family. Do you think biochemical testing should be recommended to detect the deleterious gene in Mrs. Lehman? Explain your answer.
16. MAKE CONNECTIONS What noninvasive imaging procedure is used to determine some aspects of fetal development? (You may want to check *A Closer Look* in Chapter 1, pp. 16–17, for this.)

For answers, see Answers Appendix.

RELATED CLINICAL TERMS

Deletion Chromosomal aberration in which part of a chromosome is lost.

Down syndrome This condition usually reflects the presence of an extra autosome (trisomy of chromosome 21). The child has slightly slanted eyes, flattened facial features, a large tongue, and a tendency toward short stature and stubby fingers. Some, but not all, affected people are intellectually disabled. Down syndrome individuals have mitochondrial defects, which have been associated with neurodegeneration in other disorders. A distinctive feature of Down syndrome is early onset of Alzheimer's disease. The most important risk factor appears to be advanced maternal (or paternal) age.

Mutation (*mutare* = change) A permanent structural change in a gene. The mutation may or may not affect function, depending on the precise site and nature of the alteration.

Nondisjunction Abnormal segregation of chromosomes during meiosis, resulting in gametes receiving two or no copies of a particular parental chromosome. It is more common in female meiosis than in male meiosis. If the abnormal gamete participates in fertilization, the resulting zygote will have an abnormal chromosomal complement (monosomy or trisomy) for that particular chromosome (as in Down syndrome).

CHAPTER SUMMARY

1. Genetics is the study of heredity and mechanisms of gene transmission.

29.1 Genes are the vocabulary of genetics (pp. 1125–1126)

1. A karyotype is a representation of a complete set of chromosomes; the complete genetic complement is the genome. A person's genome consists of two sets of instructions, one from each parent.
2. Genes coding for the same trait and found at the same locus on homologous chromosomes are called alleles.
3. Alleles may be the same or different in expression. When the allele pair is identical, the person is homozygous for that trait; when the alleles differ, the person is heterozygous.
4. The actual genetic makeup of cells is the genotype; phenotype is the manner in which those genes are expressed.

29.2 Genetic variation results from independent assortment, crossing over, and random fertilization (pp. 1126–1128)

1. During meiosis I of gametogenesis, tetrads align randomly on the metaphase plate, and chromatids are randomly distributed to the daughter cells. This is called independent assortment of the homologues. Each gamete receives only one allele of each gene pair.
2. Each different metaphase I alignment produces a different assortment of parental chromosomes in the gametes, and all combinations of maternal and paternal chromosomes are equally possible.

3. During meiosis I, nonsister chromatids of each tetrad cross over at one or more points and exchange corresponding gene segments. The recombinant chromosomes contain new gene combinations, adding to the variability arising from independent assortment.
4. The third source of genetic variation is random fertilization of eggs by sperm.

29.3 Several patterns of inheritance have long been known (pp. 1128–1131)

1. Dominant genes are expressed when present in single or double dose; recessive genes must be present in double dose to be expressed.
2. For traits following the dominant-recessive pattern, the laws of probability predict the outcome of a large number of matings.
3. Genetic disorders more often reflect the homozygous recessive condition than the homozygous dominant or heterozygous condition because dominant genes are expressed and, if they are lethal genes, the pregnancy usually results in miscarriage. Genetic disorders caused by dominant alleles include achondroplasia and Huntington's disease; recessive disorders include cystic fibrosis and Tay-Sachs disease.
4. Carriers are heterozygotes who carry a deleterious recessive gene (but do not express the trait) and have the potential of passing it on to offspring.
5. In incomplete dominance, the heterozygote exhibits a phenotype intermediate between those of the homozygous dominant and recessive individuals. Inheritance of sickle-cell trait is an example of incomplete dominance.
6. Multiple-allele inheritance involves genes that exist in more than two allelic forms in a population. Only two of the alleles are inherited, but on a random basis. Inheritance of ABO blood types is an example of multiple-allele inheritance in which the I^A and I^B alleles are codominant.
7. Traits determined by genes on the X and Y chromosomes are said to be sex-linked. The small Y chromosome lacks most genes present on the X chromosome. Recessive genes located only on the X chromosome are expressed in single dose in males. Examples of X-linked conditions, passed from mother to son, include hemophilia and red-green color blindness.
8. Polygene inheritance occurs when several gene pairs interact to produce phenotypes that vary quantitatively over a broad range. Height, intelligence, and skin pigmentation are examples.

29.4 Environmental factors may influence or override gene expression (p. 1131)

1. Environmental factors may influence the expression of genotype.
2. Maternal factors that cross the placenta may alter expression of fetal genes. Environmentally provoked phenotypes that mimic genetically determined ones are called phenocopies. Nutritional deficits or hormonal imbalances may alter anticipated growth and development during childhood.

29.5 Factors other than nuclear DNA sequence can determine inheritance (pp. 1131–1133)

1. Control of gene expression occurs at three levels: protein-coding genes, small noncoding RNAs, and epigenetic marks. The latter two account for many cases of inherited disease that fail to follow traditional inheritance patterns.
2. Small noncoding RNAs silence genes or prevent their expression, particularly during development or infection by viruses.
3. Epigenetic marks involve attachment of small chemical groups (methyl or acetyl) to DNA or histone proteins. In general, methylation prevents DNA transcription whereas acetylation allows DNA transcription. Genomic imprinting, which involves methylation of certain genes during gametogenesis, confers different effects and phenotypes on maternal and paternal genes. It is reversible, and typically occurs anew each generation.
4. Mitochondrial genes pass to offspring via the ovum and help to determine certain characteristics. Deletions or mutations in mitochondrial genes are responsible for some problems with oxidative phosphorylation and some rare genetic diseases.

29.6 Genetic screening is used to detect genetic disorders (pp. 1133–1135)

1. The likelihood of an individual carrying a deleterious recessive gene may be assessed by constructing a pedigree. Some of these genes can be detected by various blood tests and DNA probes.
2. Amniocentesis is fetal testing based on needle-aspirated samples of amniotic fluid. Fetal cells in the fluid are cultured for several weeks, then examined for chromosomal defects (karyotyped) or for DNA markers of genetic disease. Amniocentesis cannot be performed until the 14th week of pregnancy.
3. Chorionic villus sampling is fetal testing based on a sample of the chorion. This tissue is rapidly mitotic, so karyotyping can be done almost immediately. Samples may be obtained by the 8th week.
4. The ability to sequence and edit DNA has allowed research on diagnosis of genetic disease and on its treatment to surge forward. So far, gene therapy has been particularly useful for correcting single-gene disorders. The most common approach involves transferring a corrected gene via a virus to the affected cells to restore normal function.

REVIEW QUESTIONS

29

To access additional practice questions using your smartphone, tablet, or computer: MasteringA&P® > Study Area > Practice Tests & Quizzes

Level 1 Remember/Understand

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Match each of the following key terms (a–i) with its description below:

Key: **(a)** alleles **(b)** autosomes **(c)** dominant allele **(d)** genotype **(e)** heterozygote **(f)** homozygote **(g)** phenotype **(h)** recessive allele **(i)** sex chromosomes

____ **(1)** genetic makeup
____ **(2)** how genetic makeup is expressed
____ **(3)** chromosomes that dictate most body characteristics
____ **(4)** alternate forms of the same gene
____ **(5)** an individual bearing two alleles that are the same for a particular trait
____ **(6)** an allele that is expressed whether in single or double dose
____ **(7)** an individual bearing two alleles that differ for a particular trait
____ **(8)** an allele that must be present in double dose to be expressed

2. Match the following types of inheritance (key terms a–f) with the descriptions below:

Key: **(a)** dominant-recessive **(d)** polygene
(b) incomplete dominance **(e)** sex-linked
(c) multiple-allele **(f)** extranuclear

____ **(1)** only sons show the trait
____ **(2)** homozygotes and heterozygotes have the same phenotype
____ **(3)** heterozygotes exhibit a phenotype intermediate between those of the homozygotes
____ **(4)** phenotypes of offspring may be more varied than those of the parents
____ **(5)** inheritance of ABO blood types
____ **(6)** inheritance of stature
____ **(7)** reflects activity of mitochondrial DNA

Level 2 Apply/Analyze

3. Describe the important mechanisms that lead to genetic variations in gametes.

4. Suppose that the ability to taste PTC (phenylthiocarbamide) depends on the presence of a dominant gene *T*; nontasters are homozygous for the recessive gene *t*. This would be a case of classical dominant-recessive inheritance. **(a)** Consider a mating between heterozygous parents producing three offspring. What proportion of the offspring are likely to be tasters? What is the chance that all three offspring will be tasters? Nontasters? What is the chance that two will be tasters and one will be a nontaster? **(b)** Consider a mating between *Tt* and *tt* parents. What is the anticipated percentage of tasters? Nontasters? What proportion can be expected to be homozygous recessive? Heterozygous? Homozygous dominant?

5. Most children with cystic fibrosis are born to normal parents. Children with cystic fibrosis are homozygous for the recessive gene (*cc*). What can you conclude about the genotypes of the normal parents?

6. A woman with blood type A has two children. One has type O blood and the other has type B blood. What is the genotype of the mother? What are the genotype and phenotype of the father? What is the genotype of each child?

7. In skin color inheritance, what will be the relative range of pigmentation in offspring arising from the following parental matches? **(a)** *AABBCC* × *aabbcc*, **(b)** *AABBCC* × *AaBbCc*, **(c)** *Aabbcc* × *aabbcc*.

8. Compare and contrast amniocentesis and chorionic villus sampling as to the time at which they can be performed and the techniques used to obtain information on the fetus's genetic status.

9. The Browns are both carriers of the recessive allele that causes the metabolic disorder called phenylketonuria. What is the probability of each of the following occurring? **(a)** All three children will have the disorder. **(b)** None of their three children will have the disorder. **(c)** One or more of their children will have the disorder. **(d)** At least one of their children will be phenotypically normal.

Level 3 Evaluate/Synthesize

10. A color-blind man marries a woman with normal vision. The woman's father was also color-blind. **(a)** What is the chance that their first child will be a color-blind son? A color-blind daughter? **(b)** If they have four children, what is the chance that two will be color-blind sons? (Be careful on this one.)

11. A genetic counselor has been consulted by a couple that is concerned about a dominant form of syndactyly (fused fingers or toes) in the male partner, Paul. Paul has syndactyly, as do his three brothers. His mother, his maternal grandparents, and his paternal grandfather do not have syndactyly, but his father and paternal grandmother do. The counselor constructs a pedigree spanning three generations for Paul's family. Draw this pedigree and show the phenotype and genotype for each person.

CLINICAL CASE STUDY

27-Year-Old with Normal First Pregnancy

Ms. Rodriguez has had a normal pregnancy so far. During one of her regular visits with her doctor, Ms. Rodriguez asks what blood type her baby will have, given that her husband's blood type is type A and hers is type O. Her doctor explains to Ms. Rodriguez that she would need to know more about the blood type of Mr. Rodriguez's parents.

1. Describe the difference between genotype and phenotype. What are the phenotypes and genotypes of Mr. and Ms. Rodriguez?

2. Describe the type of inheritance that is responsible for blood type.

3. ✚ NCLEX-STYLE Mr. Rodriguez's mother has type O blood and his father has type A blood. What does this tell you about Mr. Rodriguez's genotype?
- **a.** He might be either I^AI^A or I^Ai, since his parents had both alleles.
- **b.** He must be I^Ai, because his mother was *ii*.
- **c.** He must be I^AI^A, because his father was I^AI^A.
- **d.** The man who Mr. Rodriguez thinks is his biological father cannot be—the son of type A and type O parents cannot be type A.

4. What is the probability that Ms. Rodriguez's baby will have type O blood? A? B? AB?

5. ✚ NCLEX-STYLE You're talking with Ms. Rodriguez about her baby. Which of her statements indicate a need for further instruction about genetics?
- **a.** "My mother had Huntington's disease, but I've been tested and don't have the bad gene, and no one in my husband's family has had the disease, so luckily my baby won't get it either."
- **b.** "We should talk to all of our relatives and find out if any other diseases run in the family, so we know what to watch out for."
- **c.** "He's sure to be type A if he's a boy, because boys always inherit their father's traits."
- **d.** "Girls are protected from some of those inherited conditions because of their chromosomes."

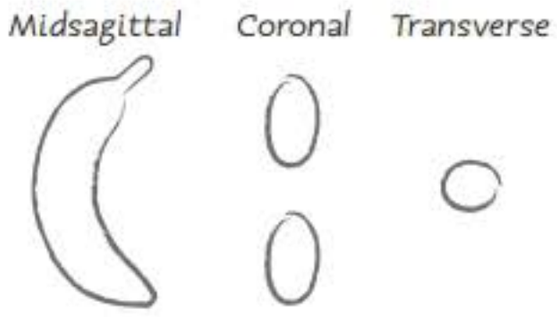
Answers to Check Your Understanding and Level 1 Review Questions

Chapter 1

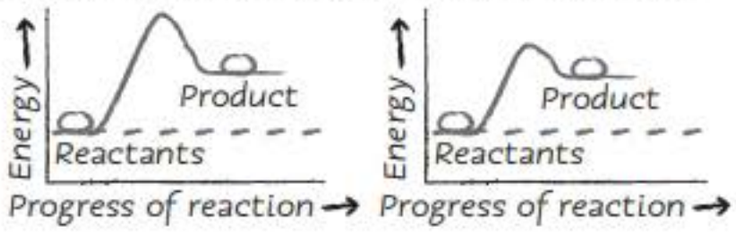
Check Your Understanding 1. The operation or function of a structure is promoted or prevented by its anatomy. For example, oxygen and carbon dioxide are exchanged across the very thin membranes of the lungs but not across the much thicker skin. **2.** Muscle shortening is a topic of physiology. The body location of the lungs is an anatomy topic. **3.** gastritis: inflammation of the stomach; leukocyte: white cell; nephropathy: kidney disease. **4.** Cytologists study the cellular level of organization. **5.** The order in the structural hierarchy is cell, tissue, organ, and organism. **6.** Living organisms can maintain their boundaries, move, respond to environmental changes, digest nutrients, carry out metabolism, dispose of wastes, reproduce, and grow. While inanimate objects may exhibit some of these properties, they do not exhibit all of them. **7.** Metabolism is the term that encompasses all the chemical reactions that occur in body cells. **8.** Boundary "a" is the plasma membrane. Fluid compartment "b" is intracellular fluid. Fluid compartment "c" is interstitial fluid, which is part of the extracellular fluid. **9.** Negative feedback mechanisms allow us to adjust to conditions outside the normal temperature range by causing heat to be lost from the body (in hot conditions) and retained or generated by the body (in cold conditions). **10.** This is a positive feedback mechanism because it enhances the change (formation of a platelet plug) set into motion by the stimulus (damage to the blood vessel). The response ends when the platelet plug has plugged the hole in the blood vessel. **11.** Thirst is part of a negative feedback control system because it prods us to drink, which ends the thirst stimulus and returns body fluid volume to the normal range. **12.** The position in which a person is standing erect with feet slightly separated and palms facing anteriorly. Knowing the anatomical position is important because directional terms refer to the body as if it is in this position. **13.** Axillary region is the armpit. Acromial area is the tip of the shoulder. **14.** A frontal (coronal) section would separate the brain into anterior and posterior parts. **15.** › **16.** Of these organs, only the spinal cord is in the dorsal body cavity. **17.** As mobile organs (heart, lungs, digestive organs) work, friction is greatly reduced by the presence of serous fluid. Serous fluid allows the surrounding serous membranes to glide easily over one another. **18.** He may have appendicitis if the pain is in the lower right quadrant of his abdomen.

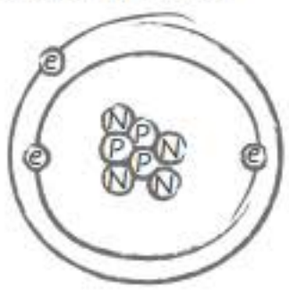


Review Questions 1. c; **2.** a; **3.** e; **4.** a, d; **5.** (a) wrist, (b) hip bone, (c) nose, (d) toes, (e) scalp; **6.** b; **7.** c; **8.** Function (physiology) reflects structure (anatomy); structure will determine and/or influence function. **9.** See Figure 1.4, which provides a summary of all the organ systems of the body. **10.** Five survival factors are: (1) nutrients—the chemical substances used for energy and cell building; (2) oxygen—used in the reactions that produce cellular energy; (3) water—the liquid environment necessary for all chemical reactions; (4) body temperature—to maintain the proper temperature for chemical reactions to proceed; and (5) atmospheric pressure—to allow gas exchange to occur. **11.** Homeostasis is the ability to maintain internal conditions within a narrow set of limits, even in the face of continuous change in the outside world. **12.** A plane refers to an imaginary flat surface, and a section refers to a cut along that imaginary surface. **13.** (a) brachial, (b) femoral, (c) thoracic, (d) digits, (e) patellar. **14.** See Figures 1.12 and 1.13. The figures illustrate the regions and quadrants and list several organs for each.

Chapter 2

Check Your Understanding 1. Foods contain chemical energy. **2.** Electrical energy is the energy used by nerve cells to transmit messages in the body. **3.** Potential energy (PE) is available when we are still. When we exercise, PE is converted to kinetic (working) energy, specifically to mechanical energy. **4.** Besides hydrogen and nitrogen, carbon and oxygen help to make up the bulk of living matter. **5.** › **6.** An iron deficiency would decrease the ability of red blood cells to transport oxygen on hemoglobin molecules. This would result in less oxygen in the blood. **7.** A molecule is 2 or more atoms held together by chemical bonds. **8.** A compound is formed when two or more different kinds of atoms chemically bond together, as in NaCl. Oxygen gas is 2 oxygen atoms (the same kind of atom) bonded together. **9.** Blood is a mixture because its components are not changed by their combination and they can be separated by physical means. **10.** Hydrogen bonds (linking H of one water molecule to O of another) form between water molecules. **11.** Argon's valence shell is full:)2e)8e)8e. For this reason it is nonreactive. **12.** Electrons would spend more time in the vicinity of the more electronegative atom in XY, whereas electrons in XX would orbit both X atoms to an equal extent. **13.** Fats are digested in the small intestine by decomposition reactions. **14.** Biochemical reactions in the body tend to be irreversible because (a) one or more of the products is removed from the reaction site or (b) reactions usually release large amounts of energy that would have to be restored for the reaction to run in reverse. **15.** Decomposition reactions in which foods are broken down for energy are oxidation-reduction (redox) reactions. **16.** Electrolytes are substances that will conduct an electrical current in aqueous solution. **17.** H^+ is responsible for acidity. **18.** You will get a large change in pH if you add a strong acid to a strong base. You will get a smaller change in pH if you add a strong acid to a weak base because the weak base will act as a buffer. **19.** Water is an excellent solvent because of its polarity. As a dipole, it can orient itself to the end of other molecules, causing them to dissociate or go into solution. **20.** Hydrolysis reactions are decomposition reactions in which molecules are broken down to simpler substances by addition of a water molecule to each bond. **21.** Monomers of carbohydrates are called monosaccharides or simple sugars. Glucose is blood sugar. **22.** The animal form of stored carbohydrate is glycogen. **23.** Triglycerides, the major source of stored energy in the body, are composed of three fatty acid chains and a glycerol molecule and are found in fat tissue. Phospholipids consist of two fatty acid chains, glycerol, a charged P-containing group, and a nitrogen-containing group. They are found in all cell membranes and form the basis of those membranes. **24.** An "amino acid" has an amine group (NH_2) and a COOH group that has acidic properties. **25.** The primary structure of proteins is the stringlike chain of amino acids. **26.** The secondary structures of proteins are the alpha helix and the beta-pleated sheet. **27.** › **28.** DNA contains deoxyribose sugar and the bases A, T, G, C. RNA contains ribose sugar and the bases A, U, G, C. **29.** The base pair C-G is less likely to come apart than the base pair A-T because it has three hydrogen bonds holding it together, whereas A-T only has two hydrogen bonds between its bases. (Hydrogen bonds are shown as dotted lines in Figure 2.25b.) **30.** ATP stores energy in smaller packets that are more readily released and transferred (during ATP hydrolysis) than the energy stored in glucose. The use of ATP as an energy source keeps energy waste to a minimum. **31.** When ATP releases energy, it loses a phosphate group and becomes ADP (also energy-rich).



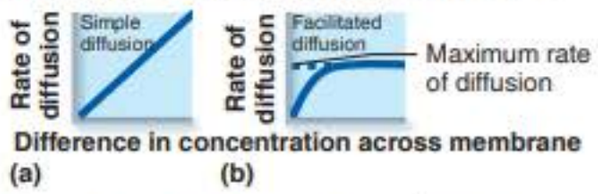


Review Questions 1. d; **2.** d; **3.** a; **4.** b; **5.** d; **6.** a; **7.** c; **8.** d; **9.** d; **10.** a; **11.** b; **12.** Ca, C, H, Fe, N, O, K, Na.

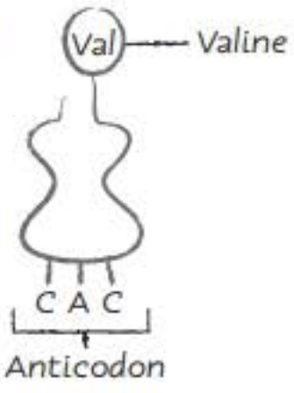
Chapter 3

Check Your Understanding 1. The cell is the smallest unit of life. All organisms are made of one or more cells. Cells only arise from other cells. **2.** The three main parts of a human cell are the plasma membrane, the cytoplasm, and the nucleus. **3.** All cellular membranes consist of a double layer of phospholipids in which proteins are embedded. **4.** Structure (a) is a carbohydrate. Carbohydrates act as identity molecules, helping cells recognize each other. Structure (b) is the steroid cholesterol. Cholesterol stiffens the membrane. Structure (c) is a protein. Proteins are responsible for most specialized membrane functions such as acting as receptors, mediating transport, acting as enzymes, and attaching cells to each other and the extracellular matrix. **5.** The heart has desmosomes (anchoring

junctions) that secure cardiac cells together as the heart pumps, and gap junctions (communicating junctions) that allow ions to flow from cardiac cell to cardiac cell. **6.** Unsaturated phospholipids would make the membrane more fluid. The double bonds cause the fatty acid chains to kink so that they cannot be packed closely, and this makes the membrane more fluid. **7.** Diffusion is driven by kinetic energy of the molecules. **8.** In channel-mediated diffusion, the diffusing substance moves through a channel protein. In carrier-mediated diffusion, the diffusing substance attaches to a carrier protein that moves it across the membrane. **9.** If a cell suddenly became permeable to both Na^+ and Cl^-, then these solutes have become penetrating solutes. As result, the nonpenetrating solutes inside the cell would no longer be balanced by nonpenetrating solutes outside the cell. The cell would swell (and possibly lyse) as Na^+, Cl^-, and water all move into the cell. **10.** Graph (a) represents simple diffusion. In graph (a), there is no maximum rate of diffusion. Notice that the higher the difference in concentration of a substance across the membrane, the higher will be its rate of diffusion. Graph (b) represents facilitated diffusion. There is a maximum rate of diffusion (that is shown by the rate of transport leveling off at higher solute concentrations). › The graphs illustrate the transport property of saturability.



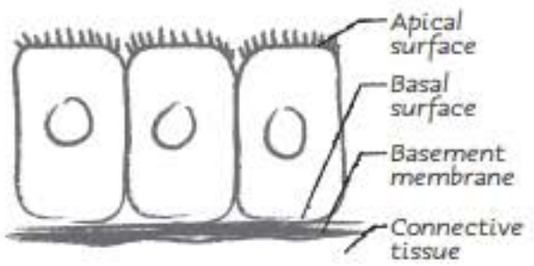
11. The Na^+-K^+ ATPase pumps K^+ into the cell. It expels three Na^+ for every two K^+ it brings in. **12.** The plasma membrane expands as a result of exocytosis. **13.** Phagocytic cells engulf debris, and a smoker's lungs would be laden with carbon particles and other debris from smoke inhalation. **14.** Cholesterol is taken in by receptor-mediated endocytosis. **15.** Diffusion of ions, mainly the diffusion of K^+ from the cell through leakage channels, establishes the resting membrane potential. **16.** In a polarized membrane of a resting cell, the inside is negative relative to its outside. **17.** Signaling chemicals that bind to membrane receptors are called ligands. G protein–coupled receptors direct intracellular events by promoting formation of second messengers. **18.** The lysosomal enzymes digest foreign substances engulfed by the cell, nonuseful or deteriorating organelles, or even the cell itself to prevent the buildup of cellular debris. The enzymes in peroxisomes detoxify harmful chemicals and neutralize free radicals. **19.** Both microfilaments and microtubules are involved in organelle movements within the cell and/or movements of the cell as a whole. **20.** The organelles are: (a) smooth endoplasmic reticulum, (b) microtubule, (c) mitochondria, (d) Golgi apparatus, and (e) rough endoplasmic reticulum. (1)b; (2)c; (3)a,d,e; (4)c; (5)a; (6)d. **21.** The protein is synthesized by a ribosome attached to the rough endoplasmic reticulum. Carbohydrates are attached to the protein in the cisterns of the rough ER, making it a glycoprotein. The glycoprotein is incorporated into a vesicle that migrates from the ER to the Golgi apparatus. Its carbohydrate may be modified or added to within the Golgi. It then exits from the *trans* face of the Golgi as part of a vesicle that migrates to and fuses with the plasma membrane. This membrane fusion results in the carbohydrate of the glycoprotein facing the outer surface of the plasma membrane. **22.** The major function of microvilli is to increase the cell's surface area for absorption of substances. **23.** If a cell loses its nucleus, it is doomed to die because it will be unable to make proteins, which include the enzymes needed for all metabolic reactions. **24.** Nucleoli are the site of synthesis of ribosomal subunits. **25.** Histone proteins provide the means to pack DNA in a compact, orderly way, and they play a role in gene regulation. **26.** DNA is synthesized during the S phase. **27.** Nuclear envelope breaks up, spindle forms, nucleoli disappear, and the chromosomes coil and condense. **28.** The base sequence of the corresponding strand will be GCTTAC. **29.** The A site is the entry site for tRNA at the ribosome. The P site is where the tRNA carrying the growing polypeptide is located. The E site is the tRNA exit site from the ribosome. **30.** DNA provides the coded instructions (is the template) for protein synthesis via the mRNA synthesized on it. **31.** The anticodon CAC binds the codon GUG. This codes for the amino acid valine, as shown in the diagram. › **32.** Ubiquitin attaches to misfolded, damaged, or unneeded proteins, tagging them for destruction by proteasomes. **33.** Apoptosis is a process of programmed cell death which rids the body of cells that are stressed, damaged, old, or no longer needed.



Review Questions 1. d; **2.** a, c; **3.** b; **4.** e; **5.** a; **6.** a; **7.** b; **8.** c; **9.** d; **10.** a; **11.** The extensions found on the cells lining the trachea are cilia. Cilia are extensions of the plasma membrane made by microtubules that extend out from basal bodies. They are used to move mucus with trapped dust particles and bacteria up and away from the lungs.

Chapter 4

Check Your Understanding 1. Fixing tissue preserves it and prevents it from deteriorating. **2.** Heavy metal salts are used to stain tissues viewed by electron microscopes. **3.** Epithelial tissue lines body cavities and covers the body's external surface; thus polarity with one free (apical) surface is a requirement. **4.** Simple epithelia are "built" to provide for efficient absorption and filtration across their thin epithelial barriers. **5.** Pseudostratified epithelia appear to be stratified because their cells' nuclei lie at different distances from the basement membrane. However, all cells rest on the basement membrane. **6.** This gland is a holocrine gland. Holocrine glands have the highest rate of cell division. The secretory cells rupture when they secrete, and so they must be continuously replaced. **7.** › **8.** Connective tissue functions to bind, support, protect, and insulate body organs. In addition, blood acts to transport substances throughout the body. **9.** Reticular, collagen, and elastic fibers are found in the various connective tissues. **10.** Areolar connective tissue, because of its loose weblike nature, is capable of serving as a fluid reservoir. **11.** Dense regular connective tissue is damaged when you lacerate a tendon. **12.** Oxygen and nutrient needs are not being met because the calcified cartilage matrix is too hard to allow them to reach the cells by diffusion. Remember, cartilage is avascular. **13.** Cardiac muscle cells have striations and are branching cells. **14.** Skeletal muscle tissue is voluntary and is the muscle tissue injured when you "pull a muscle" while exercising. **15.** With extended processes, a neuron can conduct electrical signals a great distance within the body. **16.** A mucous membrane consists of both connective tissue and epithelium. It lines body cavities open to the exterior. **17.** The serous membranes called pleurae line the thorax walls and cover the lungs. **18.** These membranes differ from each other in their size, composition, and location. Plasma membranes surround cells and are tiny, made of two layers of phospholipid molecules with embedded proteins. The basement membrane is larger than the plasma membrane and is a layer of extracellular material that lies just outside the basal surface of epithelial cells. Serous and mucous membranes are much larger still. They consist of many cells and, because they consist of two types of tissues, they are considered organs. **19.** Water's high surface tension (due to its hydrogen bonds) makes the layers of serous membrane stick together. **20.** The three main steps of tissue repair are inflammation, organization, and permanent repair via regeneration and fibrosis. **21.** More severe injuries damage and destroy more tissue, requiring greater replacement with scar tissue. **22.** The liver is a gland that is derived from epithelial tissue. Epithelial tissue regenerates well. Nervous tissue in the brain and cardiac muscle exhibit virtually no functional regeneration.



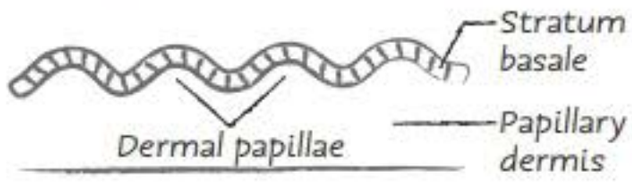
Review Questions 1. (1)a, (2)c, (3)d, (4)b; **2.** c, e; **3.** b; **4.** c; **5.** b; **6.** fibrocyte, chondrocyte, osteocyte; **7.** The extracellular matrix consists of fibers (collagen, elastic, and reticular) and ground substance. Ground substance consists of interstitial fluid, cell adhesion proteins, and proteoglycans. **8.** (a) areolar connective tissue, (b) elastic cartilage, (c) elastic connective tissue, (d) mesenchyme, (e) fibrocartilage, (f) hyaline cartilage, (g) adipose tissue. **9.** Macrophages are cells of the immune system that are involved in overall body defenses. They are phagocytes that engulf and destroy bacteria, dead cells, and other debris.

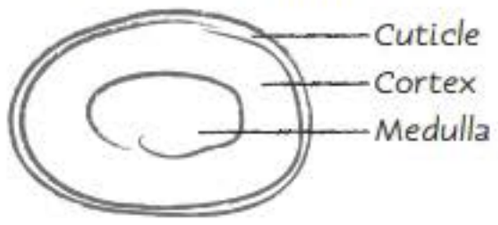
Chapter 5

Check Your Understanding 1. The dermis is connective tissue, which is vascular, so its cells would be better nourished than those of the epidermis, which is avascular epithelium. **2.** Since the sole of the foot has thick skin, the layers from most superficial to deepest would be the stratum corneum, stratum lucidum, stratum granulosum, stratum spinosum, and stratum basale. **3.** The stratum basale undergoes almost continuous mitosis to replace cells lost by abrasion. **4.** The skin

ANSWERS APPENDIX

is subjected to a lot of abrasion and physical trauma. The desmosomes, which are connecting junctions, help to hold the cells together during such stress. The tight junctions help to reduce water movement though the skin. **5.** Some possible answers to this question are: (1) You would either be unable to grow, or there would be big cracks in the stratum corneum as you grew. (2) The thickness of the skin would impede joint movement so it would be hard to move. (3) You would not be able to lose heat through your skin as effectively as you do now. (4) Your skin would be very heavy to carry around after a while. **6.** The papillary dermis consists of areolar connective tissue, and the reticular dermis consists of dense irregular connective tissue. **7.** Because there is no bleeding, the cut has penetrated into the avascular epidermis only. **8.** Because Stefan's wound runs along a cleavage line, it is likely to heal much more cleanly than it would if it ran perpendicular to the cleavage lines. **9.** › **10.** The third pigment that contributes to skin color is hemoglobin, the pigment contained in red blood cells found in blood vessels of the dermis. **11.** Jaundice, a yellow cast to the skin due to the deposit of yellow bile pigments in body tissues, may indicate a liver disorder. **12.** There are no nerves in a hair, so cutting hair is painless. **13.** The parts of the hair labeled a and c are the hair shaft and hair root, respectively. Structures b and d are the arrector pili muscle and the hair papilla, respectively. Arrector pili muscles pull the hair (normally slanted) to the upright position (when cold or scared). Hair papillae contain a knot of capillaries that supplies nutrients to cells of the hair bulb. **14.** › **15.** The lunule of the nail is white because the thick nail matrix that underlies it blocks the rosy color of the dermal blood supply from showing through. **16.** Nails are hard because the keratin they contain is the hard keratin variety. **17.** Sebaceous glands and apocrine glands are associated with the hair follicles. **18.** His autonomic nervous system activated his eccrine sweat glands and caused heat-induced sweating in order to cool the body. **19.** Heat-induced sweating occurs all over the body when we are overheated. A cold sweat is emotionally induced sweating that begins on the palms, soles, and armpits and then spreads to other body areas. Both types of sweating are primarily produced by the eccrine sweat glands. **20.** The palms of the hands and soles of the feet are thick skin areas. It would be dangerous to have oily soles, and oily palms would decrease the ability of the hands to hang onto things. **21.** The low pH of skin secretions (acid mantle) inhibits division of bacteria, and many bacteria are killed by dermcidin in sweat, bactericidal substances in sebum, or natural antibiotics called defensins produced by skin cells. Damaged skin secretes cathelicidins that are effective against a certain strain of strep bacteria. **22.** The epidermal dendritic cells play a role in body immunity. **23.** Sunlight causes the skin to produce a precursor of vitamin D from cholesterol. Vitamin D is essential for absorption of calcium from the diet, and calcium is a major component of bone. **24.** The effector in this case is smooth muscle. **25.** Basal cell carcinoma develops from the youngest epidermal cells. **26.** The ABCD rule helps one to recognize signs of melanoma. **27.** First- and second-degree burns can heal uneventfully by regeneration of epidermal cells as long as infection does not occur. Third-degree burns destroy the entire depth of skin and regeneration is usually not possible. Infection and loss of body fluid and proteins make recovery problematic. **28.** Burns to the face are serious because damage to the respiratory passageways can occur in such burns.

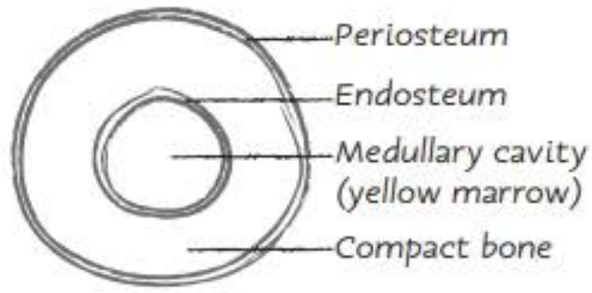




Review Questions 1. a; **2.** c; **3.** d; **4.** d; **5.** b; **6.** b; **7.** c; **8.** b; **9.** a; **10.** d; **11.** b; **12.** First-degree burns damage only the epidermis, second-degree burns damage the epidermis and the upper region of the dermis, and third-degree burns damage the entire thickness of the skin (the entire epidermis and dermis). **13.** Wrinkling is due to the loss of the elasticity of the skin, along with the loss of the subcutaneous tissue, and is hastened by exposure to the sun.

Chapter 6

Check Your Understanding 1. Hyaline cartilage is the most plentiful in the adult body. **2.** The epiglottis and external ear cartilages are flexible elastic cartilage. **3.** Interstitial growth is growth from within. **4.** Skeletal muscles use bones as levers to cause movement of the body and its parts. **5.** Bone matrix stores minerals (calcium and phosphate). Bone marrow cavities serve as sites for triglyceride (fat) storage. **6.** The components of the axial skeleton are the skull, the vertebral column, and the rib cage. **7.** The major function of the axial skeleton is to establish the long axis of the body and to protect structures that it encloses. The general function of the appendicular skeleton is to allow us mobility for propulsion and manipulation of our environment. **8.** The ribs and skull bones are flat bones. **9.** The parts of the bone are the epiphysis (a) and the diaphysis (b). The membranes at c and d are the endosteum and periosteum, respectively. The cartilage at e is articular cartilage, which is hyaline cartilage. This bone is from an adult. You can tell because it does not have an epiphyseal plate anymore (it just has an epiphyseal line). **10.** Because acidic vinegar soaks away a bone's mineral salts, the bone becomes flexible and bends too easily to support weight, so it would not be good at resisting compression. However, its organic components, particularly collagen, would allow it to resist tension. **11.** › **12.** The osteoclast fits this description. The lysosomes would contain the matrix-digesting enzymes. **13.** Bones begin as fibrous membranes or hyaline cartilages. **14.** The cartilage model grows, then breaks down and is replaced by bone. **15.** The primary ossification center in a long bone is in the center of the shaft. The secondary ossification centers are in the epiphyses (bone ends). **16.** The chondrocytes are enlarging and their lacunae are breaking down and leaving holes in the cartilage matrix. **17.** Parathyroid hormone maintains blood calcium levels. **18.** Bone growth increases bone mass, as during childhood or when exceptional stress is placed on the bones. Bone remodeling follows bone growth to maintain the proper proportions of the bone considering stresses placed upon it. **19.** If bone-destroying cells (osteoclasts) are more active than bone-forming cells (osteoblasts), bone mass will decrease. **20.** The bones of astronauts get thinner and weaker because they are deprived of the normal loading stresses that are placed on bones by gravity. Exercise that puts more stress on bones during space flight helps to some extent but cannot substitute for gravity. **21.** In an open fracture, the bone ends are exposed to the external environment. In a closed fracture, the bone ends do not penetrate the external boundary of the skin. **22.** Paget's disease is characterized by excessive deposit of weak, poorly mineralized bone. **23.** Sufficient vitamin D, calcium, and weight-bearing exercise all help to maintain healthy bone density. **24.** Adult rickets is called osteomalacia.

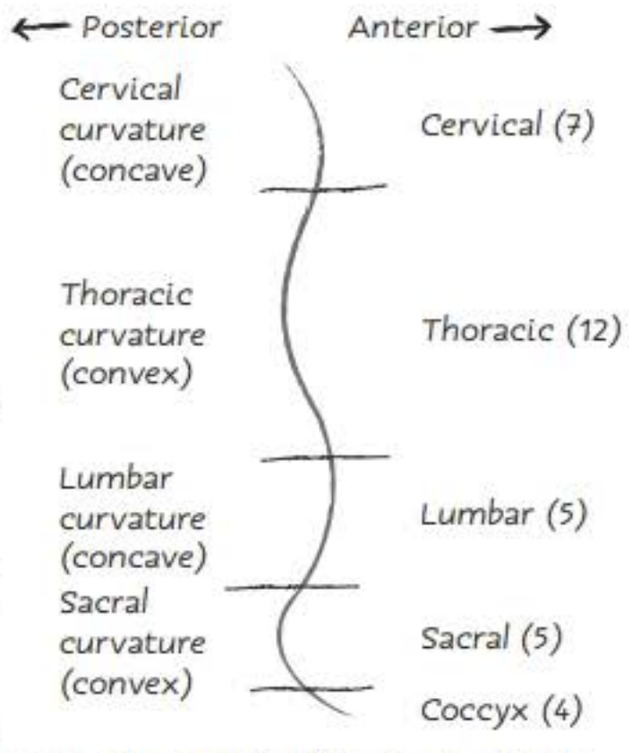


Review Questions 1. e; **2.** d; **3.** b; **4.** d, e; **5.** c; **6.** b; **7.** c; **8.** a; **9.** b; **10.** The steps in endochondral ossification in a long bone are (a) a bone collar forms around the diaphysis of the hyaline cartilage model; (b) cartilage in the center of the diaphysis calcifies and then develops cavities; (c) the periosteal bud invades the internal cavities and spongy bone forms; (d) the diaphysis elongates and a medullary cavity forms. Secondary ossification centers appear in the epiphyses; and (e) the epiphyses ossify.

Chapter 7

Check Your Understanding 1. The maxillae are the keystone bones of the facial skeleton. **2.** The maxillae form the bulk of the orbit floor. The eye is housed in the orbit. **3.** Sutures a and b are the coronal and squamous sutures, respectively. The bones are: (c) sphenoid bone, (d) parietal bone, (e) zygomatic bone, and (f) maxilla. **4.** Eating or talking, because the only freely movable joints of the skull are the temporomandibular joints of the jaw. **5.** Because the hyoid bone is in the neck, a fractured hyoid bone suggests death by strangulation. Alternatively, a forceful blow to the anterior neck could cause a fracture and the person could choke to death. **6.** Most of the skull bones are formed by intramembranous ossification in which bone is formed from embryonic tissue called *mesenchyme*, which contains mesenchymal cells (see also Chapter 4, p. 129). **7.** The fibrocartilage discs contribute to the flexibility of the vertebral column. **8.** A lumbar vertebra is heavier and its massive body is kidney shaped. Its spinous processes are short and project directly back. A thoracic vertebral body is generally heart shaped, its spinous process is long, sharp, and points downward, and its transverse processes have facets for articulating with the ribs. **9.** See the

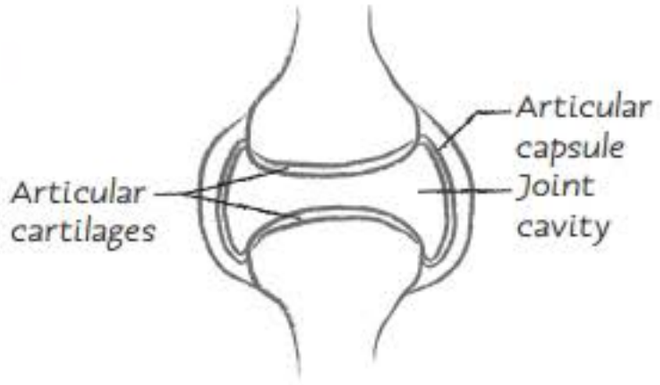
diagram. › The number of vertebrae in each region is stated in parentheses. **10.** A true rib connects to the sternum by its own costal cartilage. A false rib connects to the sternum via costal cartilages of other ribs or not at all. **11.** The tubercle of a rib articulates with the costal facet of the transverse process of the thoracic vertebra that has the same number as the rib. **12.** The thoracic vertebrae also contribute to the thoracic cage. **13.** To determine the number of the rib that was broken, the EMT would first find the sternal angle on the front of the sternum (where the manubrium joins the sternal body). Because it is aligned with the second rib, the sternal angle would help the EMT locate the second rib. From there, she can count ribs to determine which rib is painful when palpated. **14.** Each pectoral girdle is formed by a scapula and a clavicle. **15.** The pectoral girdle attaches to the sternal manubrium of the axial skeleton via the medial end of its clavicle. **16.** A consequence of its flexibility is that it is easily dislocated. **17.** The structures are (a) acromioclavicular joint, (b) coracoid process, (c) manubrium of sternum, (d) body of sternum, and (e) costal cartilage. The rib indicated by (e) is a called a true rib or a vertebrosternal rib. **18.** Together the ulna and humerus form the elbow joint. **19.** The ulna and the radius each have a styloid process distally. **20.** Carpals are found in the proximal region of the palm. They are classified as short bones. **21.** The third bone that forms the hip bone is the ischium. **22.** The pelvic girdle receives the weight of the upper body (trunk, head, and upper limbs) and transmits that weight to the lower limbs. **23.** The regions of the hip bone are (a) ilium, (b) ischium, and (c) pubis. The opening at (d) is the obturator foramen and the socket at (e) is the acetabulum. The head of the femur (thigh bone) articulates with the acetabulum. **24.** A pelvis shaped like a male's would cause problems during childbirth because of its narrower overall shape. A smaller pelvic inlet would impede the infant's entry into the true pelvis at the beginning of labor. The smaller pelvic outlet would impede passage of the baby at birth. In particular, ischial spines that are closer together and point more medially and a coccyx that projects anteriorly and is less movable could cause a problem during the delivery. **25.** The tibia is the second largest bone in the body. **26.** The two bones shown are the tibia and fibula. They are from the right side of the body. The labeled structures are (a) medial condyle, (b) medial malleolus, and (c) head of fibula. **27.** The lateral condyles are not sites of muscle attachment; they are articular surfaces. **28.** Because of their springiness, the foot arches save energy during locomotion. **29.** The two largest tarsals are the talus and the calcaneus, which forms the heel.



Review Questions 1. (1)b, g; (2)h; (3)d; (4)d, f; (5)e; (6)c; (7)a, b, d, h; (8)i; **2.** (1)g, (2)f, (3)b, (4)a, (5)b, (6)c, (7)d, (8)e; **3.** (1)b, (2)c, (3)e, (4)a, (5)h, (6)e, (7)f; **4.** The thoracic and sacral curvatures are called primary curvatures because they are present at birth. The cervical and lumbar curvatures are called secondary curvatures because they develop after birth when the baby learns to lift its head (cervical curvature) and when it learns to walk (lumbar curvature). **5.** The intervertebral discs act as shock absorbers and provide flexibility to the spine, allowing it to flex and extend. **6.** Rib pairs 11 and 12 are called floating ribs (or vertebral ribs) because they are not attached to the sternum anteriorly. **7.** Differences between the male and female pelves include that (1) the female pelvic inlet and outlet are wider, (2) the female pelvis is wider, shallower, and lighter, and (3) and the female ischial spines are farther apart. **8.** Both cleft palate and hip dysplasia are congenital abnormalities affecting skeletal formation. Cleft palate is a condition in which the left and right halves of the palate fail to fuse medially. The resulting opening between the nasal and oral cavities may cause difficulty sucking. Aspiration of food and aspiration pneumonia may result. In developmental dysplasia of the hip, the acetabulum is poorly formed, and the head of the femur may be partially or completely dislocated. Hip dysplasia can lead to degenerative arthritis of the hip joint.

Chapter 8

Check Your Understanding 1. The synarthroses are the least mobile of the joint types. **2.** In general, the more stable a joint, the less mobile it is. **3.** Most fibrous joints are synarthroses (immovable). **4.** *Cranio-* refers to the skull bones (see Chapter 7, p. 201) and *synostosis* refers to ossification of skull bone sutures. Craniosynostosis is a disorder in which the sutures in the skull close prematurely (in babies). Premature closing of sutures prevents the brain from growing normally. **5.** Evan would not have synchondroses at the ends of his femur. By age 25, his epiphyseal plates have fused and become synostoses. **6.** Bursae and tendon sheaths help to reduce friction during joint movement. **7.** The muscle tendons that cross the joint are typically the most important factor in stabilizing synovial joints. **8.** The hinge and pivot joints are uniaxial joints. **9.** The synovial joint categories are (a) ball-and-socket, (b) hinge, (c) pivot, and (d) condylar. **10.** Nick's hip joint was flexed and his knees extended and his thumb was in opposition (to his index finger). **11.** › **12.** The knee and temporomandibular joints have menisci. The elbow and knee each act mainly as a uniaxial hinge. The shoulder depends largely on muscle tendons for stability. **13.** Arthritis means inflammation of the joint. **14.** Lyme disease is caused by spirochete bacteria and transmitted by a tick bite. **15.** RA typically produces pain, swelling, and joint deformations that tend to be bilateral and crippling. OA patients tend to have pain, particularly on arising, which is relieved by gentle exercise, and enlarged bone ends (due to spurs) in affected joints. Affected joints may exhibit crepitus.



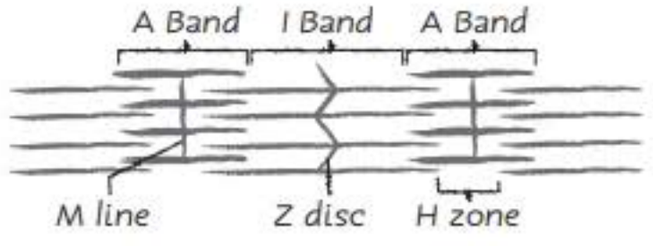
Review Questions 1. (1)c, (2)a, (3)a, (4)b, (5)c, (6)b, (7)b, (8)a, (9)c; **2.** b; **3.** d; **4.** d; **5.** b; **6.** d; **7.** d; **8.** Joints are defined as sites where two or more bones meet. **9.** Nonaxial movements are gliding or slipping movements only; uniaxial movements are in one plane; biaxial movements are in two planes; and multiaxial movements are in or around all three planes or axes. **10.** Uniaxial joints include hinge (elbow) and pivot (atlantoaxial and radioulnar) joints. Biaxial joints include condylar (knuckle) and saddle (thumb) joints. Multiaxial joints are ball-and-socket joints (hip and shoulder). **11.** Sprains and cartilage injuries are particularly problematic because cartilage and ligaments are poorly vascularized and tend to heal very slowly.

Chapter 9

Check Your Understanding

(a) Smooth muscle	(b) Skeletal muscle	(c) Cardiac muscle
Not striated	Striated	Striated
Involuntary	Voluntary	Involuntary
Walls of hollow visceral organs	Attached to skeleton	Heart

1. Striated means "with stripes." **2.** Photomicrograph (a) is smooth muscle, (b) is skeletal muscle, and (c) is cardiac muscle. › **3.** "Epimysium" literally translates to "outside the muscle" and this connective tissue sheath is the outermost muscle sheath, enclosing the entire muscle. **4.** A tendon attaches muscles to bones, whereas a ligament connects bones at joints. **5.** The proteins are (a) troponin, (b) tropomyosin, (c) actin, and (d) myosin. Myosin hydrolyzes ATP, troponin binds Ca^{2+}, and tropomyosin must move out of the way so that cross bridges can form. **6.** In a resting muscle fiber, the SR would have the highest concentration of calcium ions. The mitochondria provide the ATP needed for muscle activity. **7.** › **8.** The levels of organization are: (1) atom: phosphorus atom, (2) molecule: phospholipid



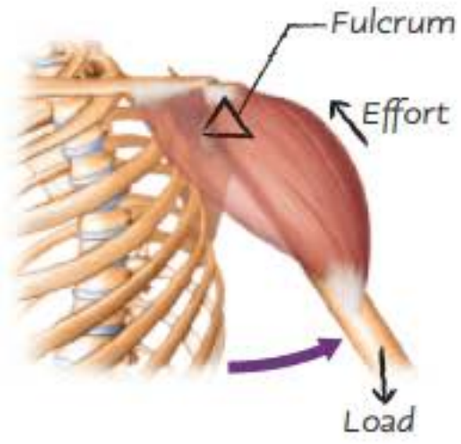
ANSWERS APPENDIX

molecule, (3) organelle: sarcoplasmic reticulum, (4) cell: skeletal muscle fiber, (5) tissue: muscle tissue, (6) organ: the biceps muscle, and (7) organ system: the muscular system. **9.** There are at least four sets of ion channels involved: (1) Voltage-gated Ca^{2+} channels in the axon terminal of the motor neuron are opened by the action potential running down the axon. (2) Chemically gated channels permeable to both Na^+ and K^+ are opened by acetylcholine binding to ACh receptors on the junctional folds of the sarcolemma. (3) Voltage-gated Na^+ and K^+ channels are required for generating and propagating the action potential along the sarcolemma. The end plate potential initiates the action potential by opening the first set of voltage-gated Na^+ channels, and then the action potential itself opens more voltage-gated channels as it moves along the sarcolemma. (4) Ca^{2+} release channels in the terminal cisterns of the SR open to release Ca^{2+} into the cytosol. These channels open because an AP running along the T tubules causes the voltage-sensitive tubule proteins to change shape, and this shape change causes the Ca^{2+} release channels of the SR to open. **10.** The final trigger for contraction is a certain concentration of calcium ions in the cytosol. The initial trigger is depolarization of the sarcolemma. **11.** There are always some myosin cross bridges bound to the actin myofilament during the contraction phase. This prevents backward sliding of the actin filaments. **12.** Without ATP, rigor would occur because the myosin heads could not detach. **13.** A motor unit is an axon of a motor neuron and all the muscle fibers it innervates. **14.** The phases are (a) the latent period, (b) the period of contraction, and (c) the period of relaxation. During the latent period, events of excitation-contraction coupling are occurring. **15.** Immediately after Jacob grabs the bar, his biceps muscles are contracting isometrically. As his body moves upward toward the bar, they are contracting isotonically and concentrically. As he lowers his body toward the mat, the biceps are contracting isotonically and eccentrically. **16.** Chris is breathing heavily because it takes some time for her heart rate and overall metabolism to return to the resting state after exercise. Moreover, she has likely incurred an oxygen debt that requires her to take in extra oxygen, called EPOC, for the restorative processes. Although running can be an aerobic exercise, there is generally some anaerobic respiration that occurs as well—the amount depends on exercise intensity. The weakness Chris feels is likely in part due to muscle fatigue. Muscle fatigue is likely due to a combination of factors in her muscles including increased inorganic phosphate and magnesium, decreased ATP and glycogen, and other ionic imbalances. **17.** Factors that influence muscle contractile force include the frequency of stimulation of muscle fibers, muscle fiber size, the number of muscle fibers stimulated, and the degree of muscle stretch. Factors that influence velocity of contraction include muscle fiber type, load, and the number of motor units contracting. **18.** Fast glycolytic fibers would provide for short periods of intense strength needed to lift and move furniture. **19.** It makes sense that there are no slow glycolytic fibers because glycolysis is a fast but inefficient pathway for generating ATP. Why use such an inefficient pathway if the contraction is just going to be slow anyway (and so use up ATP slowly)? **20.** Aerobic exercise increases muscle endurance, whereas anaerobic exercise (such as high-intensity resistance exercise) increases muscle size and strength. **21.** Both skeletal and smooth muscle fibers are elongated cells, but unlike smooth muscle cells, which are spindle shaped (tapered at both ends), uninucleate, and nonstriated, skeletal muscle cells are very large cylindrical, multinucleate, striated cells. **22.** Calcium binds to troponin on the thin filaments in skeletal muscle cells. In smooth muscle cells, it binds to a cytoplasmic protein called calmodulin. **23.** Hollow organs that have smooth muscle cells helping to form their walls often must temporarily store the organ's contents (urine, food residues, etc.), an ability facilitated by the stress-relaxation response. **24.** Intracellular calcium acts as a second messenger (see Chapter 3, p. 81). In addition, calcium is involved in exocytosis in many different cells just as it is in the motor neuron axon terminal.

Review Questions 1. c; **2.** b; **3.** (1)b, (2)a, (3)b, (4)a, (5)b, (6)a; **4.** c; **5.** a; **6.** a; **7.** d; **8.** a; **9.** (1)a, (2)a, c, (3)b, (4)c, (5)b, (6)b; **10.** a; **11.** c; **12.** c; **13.** c; **14.** b

Chapter 10

Check Your Understanding 1. The antagonists of gluteus medius (a hip abductor) are hip adductors. Hip adductors are located on the medial side of the hip joint. **2.** The adductor brevis is a small muscle that causes adduction (of the thigh); the quadriceps femoris muscle has four heads and follows the course of the femur; the tibialis anterior lies anterior to the tibial bone; and the iliacus overlies the iliac bone. **3.** Of the muscles illustrated in Figure 10.1, the one with the parallel arrangement (sartorius) could shorten to the greatest degree. The stocky bipennate (rectus femoris) and multipennate (deltoid) muscles would be most powerful because they pack in the most fibers. **4.** The patterns of muscle fascicle arrangement are (a) circular, (b) fusiform or parallel (fusiform is a subtype of parallel), (c) convergent, and (d) parallel. **5.** Third-class levers are the fastest levers. **6.** You would want the fulcrum to be closer to the post because this would give you a mechanical advantage. A lever that operates at a mechanical advantage allows the muscle to exert less force than the load being moved. **7.** › The deltoid is part of a third-class lever system, which operates at a mechanical disadvantage. **8.** Mario was using the frontal belly of his epicranius to raise his eyebrows and an orbicularis oculi muscle to wink at Sarah. **9.** The deltoid has a broad origin. When only its anterior fibers contract, it flexes and medially rotates the arm. When only its posterior fibers contract, it extends and laterally rotates the arm. **10.** The opponens pollicis does not have an insertion on the bones of the thumb. **11.** To make a sad clown's face you would contract your platysma, depressor anguli oris, and depressor labii inferioris muscles. **12.** The muscles that cross the knee also reinforce the joint by providing increased stability. **13.** The muscles for intramuscular injections are (a) deltoid, (b) gluteus medius, and (c) vastus lateralis. The vastus lateralis is a common injection site in infants because they have poorly developed buttock and arm muscles.

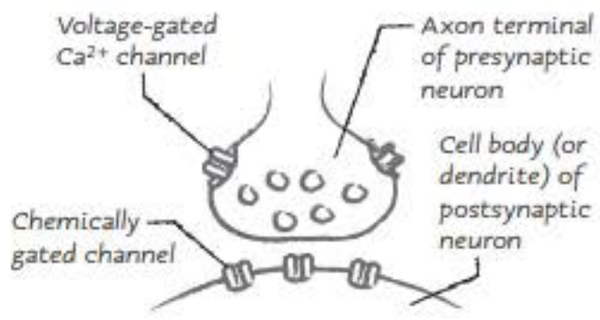


Review Questions 1. c; **2.** c; **3.** (1)e, (2)c, (3)g, (4)f, (5)d; **4.** a; **5.** c; **6.** d; **7.** c; **8.** c; **9.** b; **10.** b; **11.** a; **12.** a, b; **13.** a; **14.** The pharyngeal constrictor muscles propel food through the pharynx to the esophagus. **15.** To nod your head "yes," the sternocleidomastoid muscles contract simultaneously. Acting on one side only, the sternocleidomastoid and splenius muscles allow you to shake your head "no." **16.** (a) The extensor carpi radialis longus and brevis are strong hand extensors and abductors. (b) The forearm muscle that can flex the distal interphalangeal joints is the flexor digitorum profundus.

Chapter 11

Check Your Understanding 1. Integration involves processing and interpreting sensory information, and making a decision about motor output. Integration occurs primarily in the CNS. **2.** (a) This "full stomach" feeling would be relayed by the sensory (afferent) division of the PNS (via its visceral afferent fibers). (b) The somatic nervous system, which is part of the motor (efferent) division of the PNS, controls movement of skeletal muscle. (c) The autonomic nervous system, which is part of the motor (efferent) division of the PNS, controls the heart rate. **3.** Astrocytes control the extracellular environment around neuron cell bodies in the CNS, whereas satellite cells perform this function in the PNS. **4.** Oligodendrocytes and Schwann cells form myelin sheaths in the CNS and PNS, respectively. **5.** A nucleus within the brain is a cluster of neuron cell bodies, whereas the nucleus within each neuron is a large organelle that acts as the control center of the cell. **6.** In the CNS, a myelin sheath is formed by oligodendrocytes that wrap their plasma membranes around the axon. The myelin sheath protects and electrically insulates axons and increases the speed of transmission of nerve impulses. **7.** The neuron is a unipolar (or pseudounipolar) neuron that acts as a sensory neuron. The parts of this neuron are (a) receptive endings, (b) peripheral process (part of the axon), (c) cell body, and (d) axon terminals. **8.** Burning a finger will first activate unipolar (pseudounipolar) neurons that are sensory (afferent) neurons. The impulse to move your finger away from the heat will be carried by multipolar neurons that are motor (efferent) neurons. **9.** A nerve fiber is a long axon, an extension of the cell. In connective tissue, fibers are extracellular proteins that provide support. In muscle tissue, a muscle fiber is a muscle cell. **10.** The concentration gradient and the electrical gradient—together

called the electrochemical gradient—determine the direction in which ions flow through an open membrane channel. **11.** There are more leakage channels for K^+ than for any other cation. **12.** The resting membrane potential depends on both the concentration gradients of K^+ and Na^+ across the membrane and the permeability of the membrane to K^+ and Na^+. An increase in the extracellular K^+ concentration will decrease the concentration gradient for K^+ and this will decrease the resting membrane potential of neurons and muscle cells. In other words, the inside of these cells will become less negative (be depolarized). **13.** The size of a graded potential is determined by the strength of a stimulus. **14.** The graded potential at the junctional folds of the sarcolemma is called an end plate potential (EPP). It triggers an action potential in the adjacent sarcolemma. **15.** Action potentials are larger than graded potentials and travel farther. Graded potentials generally initiate action potentials. **16.** An action potential is regenerated anew at each membrane patch. **17.** Conduction of action potentials is faster in myelinated axons because myelin allows the axon membrane between myelin sheath gaps to change its voltage rapidly, and allows current to flow only at the widely spaced gaps. **18.** If a second stimulus occurs before the end of the absolute refractory period, no AP can occur because sodium channels are still inactivated. **19.** The x axis indicates time measured in milliseconds (ms). The y axis indicates membrane potential (which is the difference in voltage between the inside and outside of the cell) in millivolts (mV). Phase (a) is depolarization, which is due to an increase in permeability to Na^+. Phase (b) is repolarization, which is due to both a decrease in permeability to Na^+ and an increase in permeability to K^+. Phase (c) is hyperpolarization, which is due to delayed closure of K^+ channels, which means that the membrane is still more permeable to K^+ than it is at rest. **20.** › As shown in the diagram, voltage-gated ion (Ca^{2+}) channels are found in the presynaptic axon terminal.



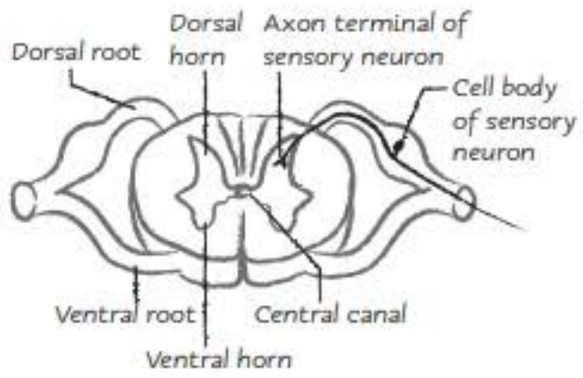
They open when an action potential reaches the axon terminal. Chemically gated ion channels are found in the postsynaptic membrane and open when neurotransmitter binds to the receptor protein. **21.** At an electrical synapse, neurons are joined by gap junctions. **22.** IPSPs result from the flow of either K^+ or Cl^- through chemically gated channels. EPSPs result from the flow of both Na^+ and K^+ through chemically gated channels. **23.** Temporal summation is summation in time of graded potentials occurring in quick succession at the postsynaptic membrane. It can result from EPSPs arising from just one synapse. Spatial summation is summation in space—a postsynaptic neuron is stimulated by a large number of terminals at the same time. **24.** ACh interacts with more than one specific receptor type, and this explains how it can excite at some synapses and inhibit at others. **25.** Cyclic AMP (cAMP) is called a second messenger because it relays the message between the first messenger (the original chemical messenger) outside of the cell and effector molecules that will ultimately bring about the desired response within the cell. **26.** Reverberating circuits and parallel after-discharge circuits both result in prolonged output. **27.** The pattern of neural processing is serial processing. The response is a reflex arc. **28.** The pattern of neural processing is parallel processing.

Review Questions 1. b; **2.** (1)d, (2)b, (3)f, (4)c, (5)a; **3.** c; **4.** c; **5.** b; **6.** d; **7.** c; **8.** c; **9.** a; **10.** (1)d, (2)b, (3)a, (4)c; **11.** (a) Myelin is a whitish, fatty, phospholipid-containing insulating material (essentially the wrapped plasma membranes of oligodendrocytes or Schwann cells). (b) CNS myelin sheaths are formed by extensions of oligodendrocytes and lack an outer collar of perinuclear cytoplasm. Each oligodendrocyte can myelinate several (up to 60) axons. PNS myelin sheaths are formed by Schwann cells. One Schwann cell is dedicated to wrapping one internode region and the myelin sheaths have an outer collar of perinuclear cytoplasm. **12.** The CNS interprets a stimulus as strong when the frequency, or rate, of action potentials arriving at the CNS is high. Conversely, a low frequency of action potentials indicates a weaker stimulus. **13.** When the professor discusses group A fibers, she is referring to fibers that have a large diameter, thick myelin sheaths, and rapid conduction. Group B fibers are lightly myelinated, have intermediate diameters, and have slower conduction velocity. The absolute refractory period is the period of time during which a neuron cannot generate an action potential in response to another stimulus (no matter how large) because the voltage-gated sodium channels are either still open or are inactivated. When the professor refers to myelin sheath gaps, she is referring to part of an axon that is not covered by a myelin sheath. These gaps occur between Schwann cells or adjacent processes of oligodendrocytes and are about 1 mm apart. **14.** During the first developmental stage, neurons proliferate; during the second stage, neurons migrate to proper position; during the third stage, neurons connect to other neurons.

Chapter 12

Check Your Understanding 1. The third ventricle is surrounded by the diencephalon. **2.** The cerebral hemispheres and the cerebellum have an outside layer of gray matter in addition to central gray matter and its surrounding white matter. **3.** Convolutions increase the surface area of the cortex, which allows more neurons to occupy the limited space within the skull. **4.** The central sulcus separates primary motor areas from somatosensory areas. **5.** Motor functions on the left side of the body are controlled by the right hemisphere of the brain because motor tracts from the right hemisphere cross over (in the medulla oblongata) to the left side of the spinal cord to go to the left side of the body. **6.** Commissural fibers (which form commissures) allow the cerebral hemispheres to "talk to each other." **7.** The caudate nucleus, putamen, and globus pallidus together form the basal nuclei. **8.** Virtually all inputs ascending to the cerebral cortex synapse in the thalamus en route. **9.** The hypothalamus oversees the autonomic nervous system. **10.** The pyramids of the medulla are the corticospinal (pyramidal) tracts, the large voluntary motor tracts descending from the motor cortex. The result of decussation (crossing over) is that each side of the motor cortex controls the opposite side of the body. **11.** The cerebral peduncles and the colliculi are associated with the midbrain. **12.** There are many possible answers to this question—here are a few: Structurally, the cerebellum and cerebrum are similar in that they both have a thin outer cortex of gray matter, internal white matter, and deep gray matter nuclei. Also, both have body maps (homunculi) and large fiber tracts connecting them to the brain stem. Both receive sensory input and influence motor output. A major difference is that the cerebellum is almost entirely concerned with motor output, whereas the cerebrum has much broader responsibilities. Also, while a cerebral hemisphere controls the opposite side of the body, a cerebellar hemisphere controls the same side of the body. **13.** Kayla would likely have problems with executing smooth, coordinated movements. This would affect her balance so she might fall over when walking or running, and might have trouble keeping up with her peers. Her motor tone would also likely be decreased so her limbs might seem "floppy." **14.** The hypothalamus is part of the limbic system and also an autonomic (visceral) control center. **15.** Taylor is increasing the amount of sensory stimuli she receives, which will be relayed to the reticular activating system, which, in turn, will increase activation of the cerebral cortex. **16.** Transfer of memory from STM to LTM is enhanced by (1) rehearsal, (2) association (tying "new" information to "old" information), and (3) a heightened emotional state (for example, alert, motivated, surprised, or aroused). **17.** Delta waves are typically seen in deep sleep in normal adults. **18.** Drowsiness (or lethargy) and stupor are stages of consciousness between alertness and coma. **19.** Most skeletal muscles are actively inhibited during REM sleep. **20.** CSF, formed by the choroid plexuses as a filtrate of blood plasma, is a watery "broth" similar in composition to plasma. It protects the brain and spinal cord from blows and other trauma, helps nourish the brain, and carries chemical signals from one part of the brain to another. **21.** The structures are (a) dural venous sinus (if you said superior sagittal sinus, that's also correct), (b) arachnoid granulation, (c) dura mater, (d) arachnoid mater, and (e) pia mater. Arachnoid granulations absorb CSF into venous blood. You would find CSF in the subarachnoid space between structures (d) and (e). The two parts of the dura mater are the superficial periosteal layer next to the bone and the deeper meningeal layer. **22.** A TIA is a temporary loss of blood supply to brain tissue, and it differs from a stroke in that the resulting impairment is fully reversible. **23.** Mrs. Lee might have Parkinson's disease. **24.** The nerves serving the limbs arise in the cervical and lumbar enlargements of the spinal cord. **25.** A loss of motor function is called paralysis. Lower limb paralysis could be caused by a spinal cord injury in the thoracic region (between T_1 and L_1). If the spinal cord is transected,

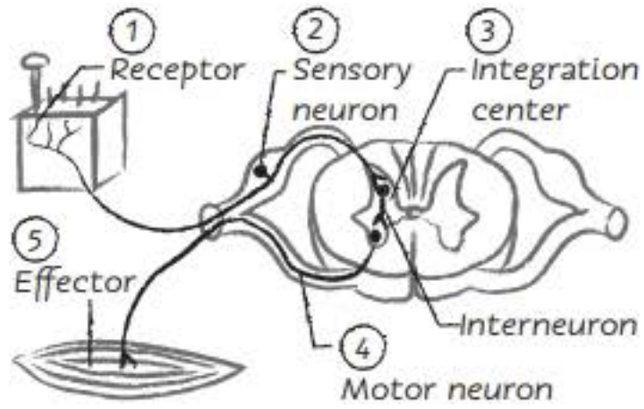
the result is paraplegia. If the cord is only bruised, he may regain function in the limbs. **26.** See the labeled diagram. › Make sure that the sensory neuron you drew has a unipolar shape (there should be a clear "T-shaped junction" of the axon attached to the cell body with the central and peripheral axons; see also p. 397). The central canal contains CSF. **27.** In the spinothalamic pathway, the cell bodies of first-order sensory neurons are outside the spinal cord in a ganglion, cell bodies of second-order sensory neurons are in the dorsal horn of the spinal cord, and cell bodies of third-order sensory neurons are in the thalamus. (See also Figure 12.34b.) **28.** The pyramidal cells controlling left big toe movement are in the right primary motor cortex in the frontal lobe. They synapse with the cell bodies of ventral horn neurons in the spinal cord. **29.** A nerve is a bundle of axons in the PNS, whereas a tract is a bundle of axons in the CNS. A nucleus is a collection of neuron cell bodies in the CNS, whereas a ganglion is a collection of neuron cell bodies in the PNS.



Review Questions 1. a; **2.** d; **3.** c; **4.** (1)d, (2)f, (3)e, (4)g, (5)b, (6)f, (7)i, (8)a; **5.** c; **6.** a; **7.** d; **8.** (a) The basal nuclei help to coordinate and control motor activity. They initiate slow and sustained movement. (b) The striatum is formed by the caudate nucleus and the putamen. (c) The caudate nucleus arches over the diencephalon. **9.** (a) The reticular formation extends through the central core of the medulla, pons, and midbrain. (b) RAS means reticular activating system, which is our cortical arousal mechanism. It helps to keep the cerebral cortex alert while filtering out unimportant inputs. **10.** The CNS is protected by the bony cranium, the meninges, the cerebrospinal fluid, and the blood brain barrier. **11.** The blood brain barrier is primarily the endothelial cells of the capillaries, which are joined by particularly impermeable tight junctions. This characteristic makes them highly selective, ensuring that only certain substances can gain access to neural tissue.

Chapter 13

Check Your Understanding 1. In addition to nerves, the PNS also consists of sensory receptors, motor endings, and ganglia. **2.** Nociceptors respond to painful stimuli. They are exteroceptors that are nonencapsulated (free nerve endings). **3.** Amber is likely to suffer from numerous undetected injuries. These could lead to infection (and possibly amputation). **4.** The sensory structures are as follows: (a) epithelial tactile complexes, which detect light pressure; (b) tactile corpuscle, which also detects light pressure (usually on hairless skin); (c) lamellar corpuscle, which detects deep pressure, stretch, and vibration; (d) bulbous corpuscle, which detects deep pressure and stretch; (e) free nerve endings, which detect pain and temperature; and (f) hair follicle receptor, which detects hair movement. **5.** The three levels of sensory integration are receptor level, circuit level, and perceptual level. **6.** Phasic receptors adapt, whereas tonic receptors exhibit little or no adaptation. Pain receptors are tonic so that we are reminded to protect the injured body part. **7.** Hot and cold are conveyed by different sensory receptors that are parts of separate "labeled lines." Cool and cold are two different intensities of the same stimulus, detected by frequency coding—the frequency of APs would be higher for a cold stimulus than for a cool one. Action potentials arising in the fingers and foot arrive at different locations in the somatosensory cortex via their own "labeled lines" and in this way the cortex can determine their origin. **8.** Ganglia are collections of neuron cell bodies in the PNS. **9.** Nerves also contain connective tissue, blood vessels, lymphatic vessels, and the myelin surrounding the axons. **10.** Schwann cells, macrophages, and the neurons themselves were all important in healing the nerve. **11.** The oculomotor (III), trochlear (IV), and abducens (VI) nerves control eye movements. Sticking out your tongue involves the hypoglossal nerve (XII). The vagus nerve (X) influences heart rate and digestive activity. The accessory nerve (XI) innervates the trapezius muscle, which is involved in shoulder shrugging. **12.** Roots lie medial to spinal nerves, whereas rami lie lateral to spinal nerves. Dorsal roots are purely sensory, whereas dorsal rami carry both motor and sensory fibers. **13.** The ventral rami were C_3–C_5, the nerve plexus was the cervical plexus, and the major nerve was the phrenic nerve. The phrenic nerve is the sole motor nerve supply to the diaphragm, the primary muscle for respiration. **14.** Varicosities are the series of knoblike swellings that are the axon endings of autonomic motor neurons. You would find them on axon endings serving smooth muscle or glands. **15.** The cerebellum and basal nuclei, which form the precommand level of motor control, plan and coordinate complex motor activities. **16.** The effector (muscle or gland) brings about the response. **17.** See the labeled diagram. › Make sure that in your drawing (as in the diagram), the cell body of the sensory neuron is in the dorsal root ganglion, the cell body of the interneuron is in the dorsal horn, and the cell body of the motor neuron is in the ventral horn.

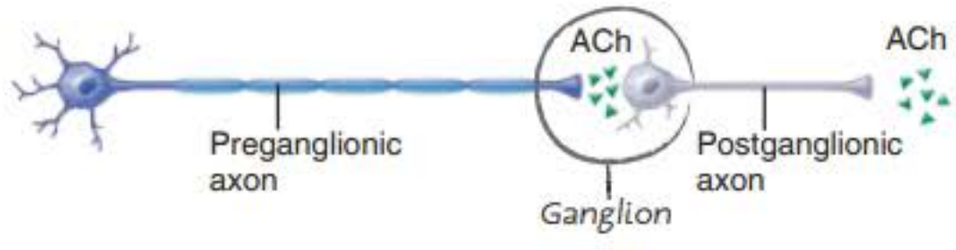


18. The stretch reflex is important for maintaining muscle tone and adjusting it reflexively by causing muscle contraction in response to increased muscle length (stretch). It maintains posture. The flexor or withdrawal reflex is initiated by a painful stimulus and causes automatic withdrawal of the painful body part from the stimulus. It is protective. **19.** This response is called Babinski's sign and it indicates damage to the corticospinal tract or primary motor cortex. **20.** The spinothalamic pathway carries pain signals to the somatosensory cortex in the parietal lobe. The pyramidal pathways carry voluntary motor information and would be involved in inhibiting the flexor reflex.

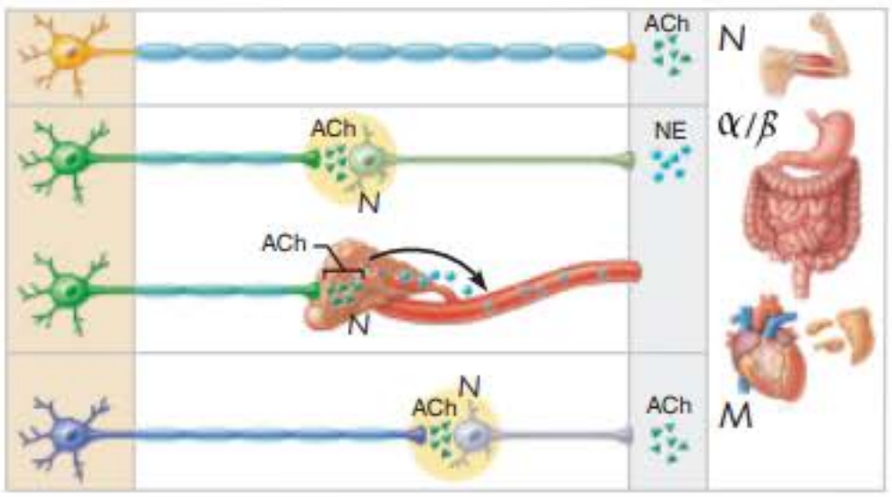
Review Questions 1. b; **2.** c; **3.** d; **4.** c; **5.** e; **6.** (1)d, (2)c, (3)f, (4)b, (5)e, (6)a; **7.** (1)f, (2)i, (3)b, (4)g, h, (5)e, (6)i, (7)c, (8)k, (9)l, (10)c, d, f, k; **8.** (1)b 6; (2)d 8; (3)c 2; (4)c 5; (5)a 4; (6)a 3, 9; (7)a 7; (8)a 7; (9)d 1; (10)a 3, 4, 7, 9; **9.** c; **10.** c; **11.** The PNS includes all nervous tissue outside the CNS, and consists of the sensory receptors that detect specific stimuli, the peripheral nerves (cranial and spinal) that conduct impulses to and from the CNS, the ganglia that contain synapses or cell bodies outside the CNS, and motor nerve endings that innervate effector organs. **12.** (a) A plexus is a network. A *nerve* plexus is a branching nerve network formed by ventral rami from several spinal nerves. (b) The cervical plexus originates from the ventral rami of C_1 to C_4 (and some C_5) spinal nerves; the brachial plexus originates from the ventral rami of C_5 to T_1; the lumbar plexus originates from the ventral rami of L_1 to L_4; and the sacral plexus originates from L_4 to S_4. **13.** Ipsilateral reflexes involve a reflex initiated on and affecting the same side of the body; contralateral reflexes involve a reflex that is initiated on one side of the body and affects the other side.

Chapter 14

Check Your Understanding 1. The effectors of the autonomic nervous system are cardiac muscle, smooth muscle, and glands. **2.** The somatic motor system relays instructions to muscles more quickly because it involves only one motor neuron, whereas the ANS uses a two-neuron chain. Moreover, axons of somatic motor neurons are typically heavily myelinated, whereas preganglionic autonomic axons are lightly myelinated and postganglionic axons are nonmyelinated. **3.** Dorsal root ganglia also contain neuron cell bodies. These cell bodies belong to neurons that are structurally classified as unipolar (pseudounipolar) and functionally classified as sensory neurons (first-order sensory neurons in this case). **4.** While you relax in the sun on the beach, the parasympathetic branch of the ANS would probably predominate. When you perceive danger (as in a shark), the sympathetic branch of the ANS predominates. **5.** Cell bodies of preganglionic parasympathetic neurons that innervate the head are in the brain stem. Cell bodies of postganglionic parasympathetic neurons innervated by the vagus nerve are in ganglia found mostly in the walls of visceral organs. **6.** › Ganglia of



parasympathetic neurons are terminal ganglia. If you said "intramural ganglion" you are partly right—most but not all terminal ganglia are intramural ganglia (depending on whether they are in the wall of the target organ). **7.** "Short preganglionic fibers," "origin from thoracolumbar region of spinal cord," "collateral ganglia," and "innervates adrenal medulla" are all characteristic of the sympathetic nervous system. Terminal ganglia are found in the parasympathetic nervous system. **8.** The major differences are (1) the ANS has visceral afferents rather than somatic afferents, (2) the ANS has a two-neuron efferent chain, whereas the somatic nervous system has one, and (3) the effectors of the ANS are smooth muscles, cardiac muscle, and glands, whereas the effectors of the somatic nervous system are skeletal muscles. **9.** You would find nicotinic receptors on skeletal muscle and the hormone-producing cells of the adrenal medulla, but not on smooth muscle or glands. Virtually all types of receptors (including nicotinic receptors) are also found in the CNS (see Table 11.4 on pp. 421–422). **10.** › As shown in the diagram, nicotinic receptors are located on skeletal muscle

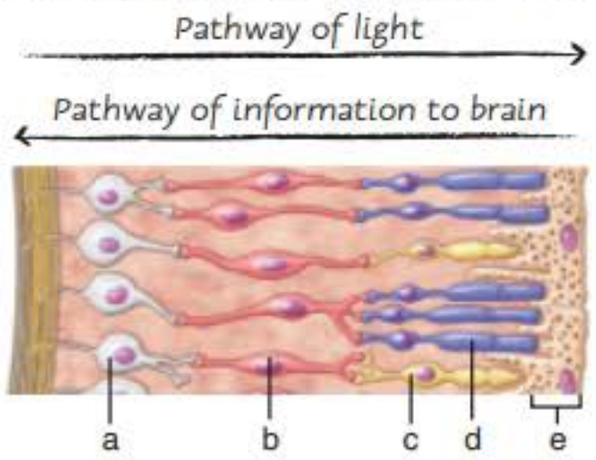


(in the junctional folds of the sarcolemma), on postganglionic neurons (cell bodies and dendrites), and on the secretory cells of the adrenal medulla. Muscarinic receptors are located on the plasma membrane of target organs that respond to acetylcholine, whereas α and β receptors are found on the plasma membrane of target organs that respond to norepinephrine (and epinephrine). **11.** The parasympathetic nervous system increases digestive activity and decreases heart rate. The sympathetic nervous system increases blood pressure, dilates bronchioles, stimulates the adrenal medulla to release its hormones, and causes ejaculation. **12.** The main integration center of the ANS is the hypothalamus, although the most direct influence is through the brain stem reticular formation and the reflex centers in the pons and medulla oblongata. **13.** Jackson's doctor may have prescribed a beta-blocker because Jackson has hypertension. (Chronic stress is a factor in causing hypertension.) The beta-blocker will decrease blood pressure by blocking beta-adrenergic receptors in the heart, thereby decreasing heart rate and force of contraction, and by decreasing renin release from the kidneys.

Review Questions 1. d; **2.** (1)S, (2)P, (3)P, (4)S, (5)S, (6)P, (7)P, (8)S, (9)P, (10)S, (11)P, (12)S; **3.** c; **4.** a; **5.** All preganglionic fibers of the ANS secrete ACh. In addition, all postganglionic fibers of the parasympathetic nervous system secrete ACh, as do some postganglionic sympathetic fibers (e.g., those serving sweat glands). Only postganglionic sympathetic fibers secrete norepinephrine. **6.** The cell bodies of visceral sensory neurons are in the dorsal root ganglia and in the sensory ganglia of cranial nerves.

Chapter 15

Check Your Understanding 1. Tears (lacrimal fluid) are a dilute saline secretion that contains mucus, antibodies, and lysozyme. They are secreted by the lacrimal glands. **2.** The blind spot of the eye is the optic disc. It is the part of the retina where the optic nerve exits the eye, and it is "blind" because it is a region of the retina that lacks photoreceptors. **3.** › The cells and layers are: (a) ganglion cell; (b) bipolar cell; (c) cone; (d) rod; and (e) pigmented layer. The choroid is superficial to the



pigmented layer. **4.** Light passes through the cornea, aqueous humor, lens, vitreous humor, ganglion cells, and bipolar cells before it reaches the photoreceptors. **5.** The near point moves farther away as you age because the lens becomes less flexible (presbyopia), so that it is unable to assume the more rounded shape required for near vision. **6.** The ciliary muscles and sphincter pupillae of the iris relax for distant vision. (If you said the medial rectus muscles also relax, this is true, but remember that the rectus muscles are extrinsic eye muscles, not intrinsic.) To see whether you labeled the ciliary muscle and the iris correctly on the diagram, refer to Figure 15.8. **7.** › **8.** Massive activation of the sympathetic

Parasympathetic activation → *Ciliary muscle contracts* → *Ciliary zonule relaxes* → *Lens bulges to more convex shape* → *↓ in lens focal length allows close vision*

nervous system occurs in extreme situations eliciting a "fight-or-flight" response. During these extreme situations, relaxation of the ciliary muscle adjusts your eye for distant vision and stimulation of the dilator pupillae dilates your pupil, allowing more light to enter. These actions allow you to survey the entire threatening scene (helping you decide where to run, for example). **9.** The following are characteristics of cones: "vision in bright light," "color vision," and "higher acuity." The following are characteristics of rods: "only one type of visual pigment," "most abundant in the periphery of the retina," "many feed into one ganglion cell," and "higher sensitivity." **10.** Breakdown of the retinal-opsin combination is called bleaching of the pigment. It occurs with exposure to light. **11.** A tumor in the right visual cortex would affect the left visual field. A tumor compressing the right optic nerve would affect both the left and right visual fields from the right eye only. **12.** The cilia of these receptor cells greatly increase the surface area for sensory receptors. **13.** The five taste modalities are sweet, sour, bitter, salty, and umami. The fungiform, vallate, and foliate papillae contain taste buds. **14.** The tympanic membrane separates the external from the middle ear. The oval and round windows separate the middle from the inner ear. **15.** The basilar membrane allows us to differentiate sounds of different pitch. **16.** The round window acts as the "pressure valve" that allows fluid to move in the cochlea. **17.** High-frequency sounds do not enter the cochlea. You can think of this in two ways: mechanically and logically. Mechanically, the ossicles and tympanic membrane cannot move rapidly enough to transmit these high-frequency sounds, so they reflect off the tympanic membrane. The other way to think about it is that the highest-frequency sounds we can hear map to the part of the basilar membrane that is nearest to the oval window. Logically, even higher-frequency sounds would map to the other (lateral) side of the oval window where there are no sensory cells and so these sounds cannot be heard. **18.** Influx of Na^+ ions is responsible for depolarization in most cells. K^+ and Ca^{2+} ions cause depolarization in hair cells. K^+ moves into hair cells (rather than out) because the extracellular fluid is endolymph, which is rich in K^+. As a result, the electrochemical gradient drives K^+ into these cells. **19.** You would not be able to locate the origin of a sound if the brain stem did not receive input from both ears. **20.** Drawing (a) shows the position of the otolith membrane in the saccule of a person in an elevator that just began to rise. This will cause an increase in action potential frequency in the nerve fibers from this saccule because the hair cells are bending toward the kinocilium. **21.** The following apply to a macula: "contains otoliths," "responds to linear acceleration and deceleration," and "inside a saccule." The following apply to a crista ampullaris: "inside a semicircular canal," "has a cupula," "responds to rotational acceleration and deceleration." **22.** The "fullness" in Mohammed's ears is likely due to an accumulation of fluid in the middle ear as a result of his upper respiratory infection ("cold") spreading into his ear. He has a form of conduction deafness.

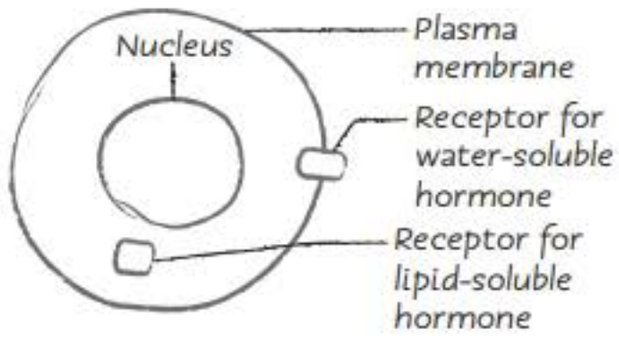
Review Questions 1. c; **2.** d; **3.** a; **4.** c; **5.** a; **6.** b; **7.** b; **8.** d; **9.** d; **10.** b; **11.** c; **12.** d; **13.** b; **14.** c; **15.** Rods operate mostly in dim light and provide noncolor vision with relatively low acuity. Cones provide high-acuity color vision in bright light. For other differences between rods and cones, see Table 15.1 on p. 569. **16.** Taste is served by cranial nerves VII (facial), IX (glossopharyngeal), and X (vagus).

Chapter 16

Check Your Understanding 1. The endocrine system is more closely associated with growth and development, and its responses tend to be long-lasting, whereas nervous system responses tend to be rapid and discrete. **2.** The thyroid and parathyroid glands are found in the neck. **3.** Hormones are released into the blood

ANSWERS APPENDIX

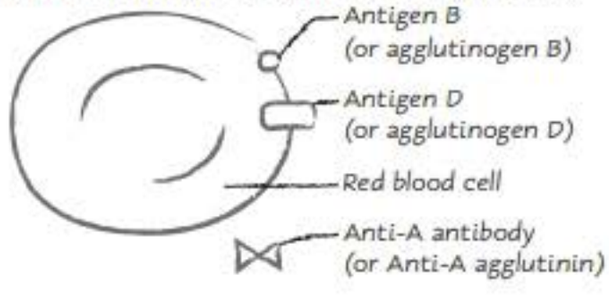
and transported throughout the body, whereas paracrines act locally, generally within the same tissue. **4.** Gland (a) is an exocrine gland and gland (b) is an endocrine gland. In gland (a), you can see the duct that is characteristic of exocrine glands. The duct conveys glandular secretions either out of the body onto the skin or into a hollow organ. Endocrine glands, on the other hand, do not have ducts and instead secrete hormones into the blood. Notice the prominent blood vessels around gland (b). See also Figure 4.5 on p. 123. **5.** Steroid hormones are synthesized on the membrane of the smooth endoplasmic reticulum. Peptide hormones are synthesized on rough endoplasmic reticulum. Peptide hormones can be stored in vesicles and released by exocytosis. **6.** Steroids are all lipid soluble. Thyroid hormones are the only amino acid–based hormones that are lipid soluble. **7.** › As shown in the drawing, receptors for water-soluble hormones are in the plasma membrane, whereas receptors for lipid-soluble hormones are inside the cell. They can be in the cytoplasm (as shown here) or inside the nucleus. Plasma membrane receptors for water-soluble hormones are coupled most often via regulatory molecules called G proteins to intracellular second messengers. Intracellular receptors for lipid-soluble hormones directly activate genes and stimulate synthesis of specific proteins. **8.** Hormone release can be triggered by humoral, neural, or hormonal stimuli. **9.** Lipid-soluble hormones have longer half-lives, meaning that they stay in the blood longer. (They are not as readily excreted by the kidneys because they are bound to plasma proteins, and most need to be metabolized by the liver before they can be excreted.) **10.** The hypothalamus communicates with the anterior pituitary via hormones released into a special portal system of blood vessels. In contrast, it communicates with the posterior pituitary via action potentials traveling down axons that connect the hypothalamus to the posterior pituitary. **11.** Drinking alcoholic beverages inhibits ADH secretion from the posterior pituitary and causes copious urine output and dehydration. The dehydration causes the hangover effects. **12.** LH and FSH are tropic hormones that act on the gonads, TSH is a tropic hormone that acts on the thyroid, and ACTH is a tropic hormone that acts on the adrenal cortex. (If you said growth hormone, that's also a good answer, as GH causing the liver to release IGFs might also be considered a tropic effect.) **13.** T_4 has four bound iodine atoms, and T_3 has three. T_4 is the major hormone secreted, but T_3 is more potent. T_4 is referred to as thyroxine. **14.** Thyroid hormone must be carried through blood by plasma proteins because it is lipid soluble and so does not readily dissolve in blood, which is mostly water. The receptors for TSH (thyroid-stimulating hormone) are located on the plasma membrane of the thyroid follicular cells (on the sides facing away from the colloid). (Recall that TSH is a water-soluble hormone from the anterior pituitary.) **15.** Thyroid hormone increases basal metabolic rate (and heat production) in the body. Parathyroid hormone increases blood Ca^{2+} levels in a variety of ways. Calcitonin at high (pharmacological) levels has a Ca^{2+}-lowering, bone-sparing effect. (At normal blood levels its effects in humans are negligible.) **16.** Thyroid follicular cells release thyroid hormone, parathyroid cells in the parathyroid gland release parathyroid hormone, and parafollicular (C) cells in the thyroid gland release calcitonin. **17.** Glucocorticoids are stress hormones that, among many effects, increase blood glucose. Mineralocorticoids increase blood Na^+ (and blood pressure) and decrease blood K^+. Gonadocorticoids are male and female sex hormones that are thought to have a variety of effects (for example, contribute to onset of puberty, sex drive in women, pubic and axillary hair development in women). **18.** The two major stimuli for aldosterone release are (1) a decrease in blood volume or blood pressure, which triggers the renin-angiotensin-aldosterone mechanism, and (2) an increase in plasma K^+ levels. The major stimulus for cortisol secretion is ACTH from the anterior pituitary. ACTH release, in turn, is controlled by CRH from the hypothalamus. CRH release follows a diurnal (day-night) rhythm and is increased in response to various stressors, as well as by hypoglycemia and fever. **19.** The adrenal cortex (a) releases steroid hormones. The adrenal medulla (b) and anterior pituitary (c) and posterior pituitary (d) all release amino acid–based hormones. ACTH from the anterior pituitary acts to cause release of steroid hormones from the adrenal cortex. Both the adrenal medulla (b) and posterior pituitary (d) are composed of nervous tissue rather than the glandular tissue (a type of epithelial tissue) that other glands are made of. **20.** Melatonin is used by some individuals as a sleep aid, particularly to counter jet lag. **21.** The heart produces atrial natriuretic peptide (ANP). ANP decreases blood volume and blood pressure by increasing the kidneys' production of salty urine. **22.** The major function of vitamin D_3, produced in inactive form by the skin, is to increase intestinal absorption of calcium. **23.** Diabetes mellitus is due to a lack of insulin production or action, whereas diabetes insipidus is due to a lack of ADH. Both conditions are characterized by production of copious amounts of urine. You would find glucose in the urine of a patient with diabetes mellitus, but not in the urine of a patient with diabetes insipidus. **24.** The gonadal hormones are steroid hormones. A major endocrine gland that also secretes steroid hormones is the adrenal cortex.



Review Questions 1. b; **2.** a; **3.** c; **4.** d; **5.** (1)c, (2)a and b, (3)f, (4)d, (5)e, (6)g, (7)a, (8)h, (9)b and e, (10)a; **6.** d; **7.** c; **8.** b; **9.** d; **10.** b; **11.** d; **12.** b; **13.** Hormones are chemical messengers secreted by cells into the extracellular fluid. They travel through the blood and regulate the metabolic function of other cells in the body. **14.** Atrial natriuretic peptide is a hormone released by cardiac muscle cells. Antidiuretic hormone, oxytocin, epinephrine, and norepinephrine are all hormones that are released by neurons.

Chapter 17

Check Your Understanding 1. Blood can prevent blood loss by forming clots when a blood vessel is damaged. Blood can prevent infection because it contains antimicrobial proteins and white blood cells. **2.** The hematocrit is the percentage of blood that is occupied by erythrocytes. It is normally about 45%. **3.** Plasma proteins perform many key functions in the blood (see Table 17.1). One key function is to maintain the correct osmotic pressure in the blood. Without the osmotic pressure of plasma proteins "pulling" water molecules into the bloodstream, more water enters the tissues. Your patient may have tissue swelling (called edema) due to water leaking out of the blood. In addition, some of the plasma proteins synthesized by the liver (e.g., fibrinogen) are clotting proteins, so your patient may bleed more readily in response to only minor injuries. While you might expect to see problems due to the loss of the carrier function of many plasma proteins, this doesn't generally lead to easily observable signs and symptoms. **4.** Each hemoglobin molecule can transport four O_2. The heme portion of the hemoglobin binds the O_2. **5.** The kidneys' synthesis of erythropoietin is compromised in advanced kidney disease, so RBC production decreases, causing anemia. **6.** The cells are (a) lymphocyte, (b) eosinophil, (c) monocyte, (d) basophil, (e) neutrophil. (1) Neutrophils (e) are and monocytes (c) become important phagocytes. (2) Eosinophils (b), basophils (d), and neutrophils (e) are granulocytes. (3) Lymphocytes (a) are abundant in lymph nodes and in the spleen. (4) The granule contents of basophils (d) are similar to those of mast cells. **7.** Amos's red bone marrow is spewing out many abnormal white blood cells, which are crowding out the production of normal bone marrow elements. The lack of normal white blood cells allows the infections, the low number of platelets fails to stop bleeding, and the lack of erythrocytes is anemia. **8.** Microglial cells can become phagocytes in the brain. **9.** A megakaryocyte is a cell that produces platelets. Its name means "big nucleus cell." **10.** The three steps of hemostasis are vascular spasm, platelet plug formation, and coagulation. **11.** Prothrombin activator catalyzes the conversion of prothrombin to thrombin. Thrombin catalyzes the conversion of fibrinogen to fibrin. Prothrombin is an inactive precursor, whereas thrombin acts as an enzyme. Fibrinogen is water soluble, whereas fibrin is not. Most factors are inactive in blood before activation and become enzymes upon activation. (There are exceptions, such as fibrinogen and calcium.) **12.** Thrombocytopenia (platelet deficiency) results in failure to plug the countless small tears in blood vessels, and so manifests as small purple spots (petechiae). Hemophilia A results from the absence of clotting factor VIII. **13.** Nigel has anti-B antibodies in his blood and type A agglutinogens (antigens) on his RBCs. He can donate blood to an AB recipient, but he should not receive blood from an AB donor because his anti-B antibodies will cause a transfusion reaction. **14.** See the drawing. › As shown, the

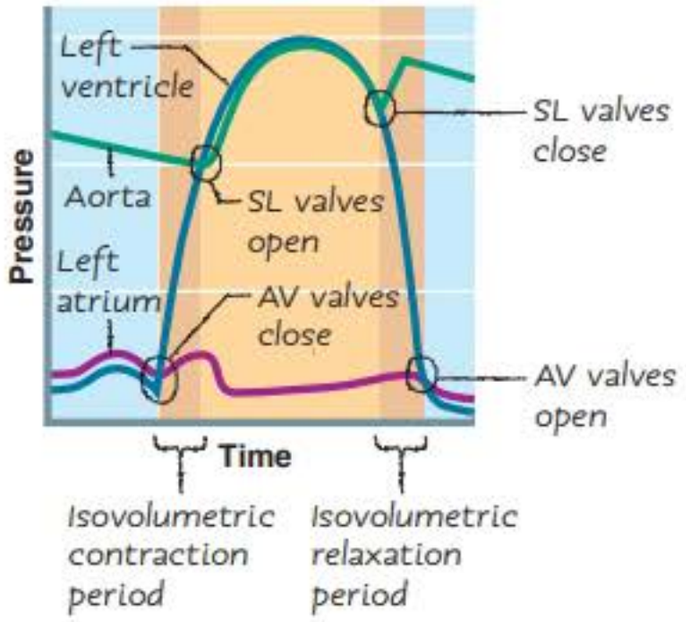


antigens (agglutinogens) are in the plasma membrane and the antibody (agglutinin) is in the plasma (outside of the RBC). The presence of agglutinogen D is Rh^+. Note that the shapes of the antigens and antibody are only representative. You would be correct to use any shape to represent them (as long as the anti-A antibody does not match the shape of antigen B). **15.** If Emily has a bacterial meningitis, a differential WBC count would likely reveal an increase in neutrophils because neutrophils are a major body defense against bacteria.

Review Questions 1. c; **2.** c; **3.** d; **4.** b; **5.** d; **6.** a; **7.** a; **8.** b; **9.** c; **10.** d; **11.** (a) The three major categories of formed elements are leukocytes, erythrocytes, and platelets. (b) The least numerous of the formed elements are the leukocytes. (c) The buffy coat in a hematocrit tube consists of the leukocytes and platelets. **12.** (a) A transfusion reaction includes agglutination of donor RBCs, blockage of small blood vessels, and lysis of RBCs. It occurs after transfusion of mismatched blood as a result of the recipient's plasma antibodies attacking the donor's RBCs. (b) Consequences of a transfusion reaction include loss of oxygen-carrying capacity, fever, chills, low blood pressure, rapid heartbeat, nausea, vomiting, and kidney failure.

Chapter 18

Check Your Understanding 1. The mediastinum is the medial cavity of the thorax within which the heart, great vessels, thymus, and parts of the trachea, bronchi, and esophagus are found. **2.** The layers of the heart wall are the endocardium, the myocardium, and the epicardium. The epicardium is also called the visceral layer of the serous pericardium. This is surrounded by the parietal layer of the serous pericardium and the fibrous pericardium. **3.** The serous fluid decreases friction caused by movement of the layers against one another. **4.** The structures are (a) aorta, (b) pulmonary trunk, (c) left atrium, (d) right atrium, (e) left ventricle, (f) right ventricle, (g) inferior vena cava. The right atrium (d) receives oxygen-poor blood. The left ventricle (e) pumps blood into the systemic circulation. The pulmonary trunk (b) transports blood toward the lungs. **5.** The papillary muscles and chordae tendineae keep the AV valve flaps from everting into the atria as the ventricles contract. **6.** The mitral (left atrioventricular) valve has two cusps. **7.** The right side of the heart acts as the pulmonary pump, whereas the left acts as the systemic pump. **8.** (a) True. The left ventricle wall is thicker than the right. (b) True. The left ventricle pumps blood at much higher pressure than the right ventricle because the left ventricle supplies the whole body, whereas the right ventricle supplies only the lungs. (c) False. Each ventricle pumps the same amount of blood with each beat. If this were not true, blood would back up in either the systemic or pulmonary circulation (because the two ventricles are in series). **9.** The branches of the right coronary artery are the right marginal artery and the posterior interventricular artery. **10.** (a) The refractory period is almost as long as the contraction in cardiac muscle. (b) The source of Ca^{2+} for the contraction is only SR in skeletal muscle. (c) Both skeletal muscle and cardiac muscle have troponin. (d) Only skeletal muscle has triads. **11.** Structure (a) shows cardiac muscle and structure (b) shows skeletal muscle. You can tell that both of these structures are parts of striated (and not smooth) muscle fibers because they have sarcomeres. You can tell that (b) is skeletal muscle because it has terminal cisterns next to each of the T tubules, whereas (a) does not. Also, the T tubules in cardiac muscle (a) are aligned with the Z discs, whereas in skeletal muscle (b), they are at the A-I junctions. **12.** Cardiac muscle cannot go into tetany because the absolute refractory period is almost as long as the contraction. **13.** (a) The QRS wave occurs during ventricular depolarization. (b) The T wave of the ECG occurs during ventricular repolarization. (c) The P-R interval of the ECG occurs during atrial depolarization and the conduction of the action potential through the rest of the intrinsic conduction system. **14.** It is not necessary for the intrinsic conduction system to contact each individual cardiac myocyte. This is because cardiac myocytes are connected to each other by gap junctions and so are depolarized when an adjacent myocyte depolarizes. The subendocardial conducting network excites ventricular muscle fibers. The depolarization wave travels upward from the apex toward the atria. **15.** (b) Represents an action potential (AP) in a contractile cardiac muscle cell, (a) represents an AP in a skeletal muscle cell, and (c) represents an AP in cardiac pacemaker cells. The depolarization phase is due to Na^+ influx in skeletal muscle and contractile cardiac muscle cells, and it is due to Ca^{2+} entry in cardiac pacemaker cells. K^+ efflux is responsible for the repolarization in all action potentials. **16.** The second heart sound is associated with the closing of the semilunar valves. **17.** The murmur of mitral insufficiency occurs during ventricular systole (because this is when the valve should be closed, and the murmur is due to blood leaking through the incompletely closed valve into the atrium). **18.** › **19.** Exercise activates the sympathetic nervous system. Sympathetic nervous system activity increases heart rate. It also directly increases ventricular contractility, thereby increasing Josh's stroke volume. **20.** If the heart is beating very rapidly, the amount of time for ventricular filling between contractions is decreased. This decreases the end diastolic volume, decreases the stroke volume, and therefore decreases the cardiac output.



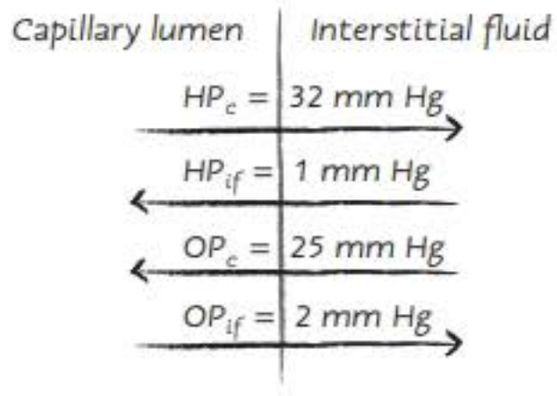
Review Questions 1. a; **2.** c; **3.** b; **4.** c; **5.** b; **6.** b; **7.** c; **8.** b; **9.** The heart is located within the mediastinum. It lies anterior to the vertebral column and posterior to the sternum. About 2/3 of the heart lies to the left of the midsternal line. **10.** The longer refractory period of cardiac muscle is desirable because it prevents the heart from going into prolonged or tetanic contractions, which would stop its pumping action. **11.** See Figure 18.16. The P wave results from depolarization of the atria. The QRS complex results from ventricular depolarization and precedes ventricular contraction. The T wave is caused by ventricular repolarization and precedes ventricular relaxation. **12.** The cardiac cycle includes all events associated with the flow of blood through the heart during one complete heartbeat. One cycle includes a period of (1) ventricular filling (in mid-to-late diastole), (2) isovolumetric contraction, (3) ventricular ejection, and (4) isovolumetric relaxation (in early diastole). (For a more detailed description of what happens in each of these periods, see p. 693.) **13.** Cardiac output is the amount of blood pumped out of each ventricle in 1 minute. It can be calculated using the following equation: cardiac output = heart rate × stroke volume. **14.** The synonyms are: (a) atrioventricular groove = coronary sulcus, (b) tricuspid valve = right AV valve, (c) bicuspid valve = left AV valve or mitral valve, (d) atrioventricular bundle = bundle of His.

Chapter 19

Check Your Understanding 1. The sympathetic nervous system innervates blood vessels. The sympathetic nerves innervate the tunica media. The effector cells in the tunica media are smooth muscle cells. **2.** When vascular smooth muscle contracts, the diameter of the blood vessel becomes smaller. This is called vasoconstriction. **3.** Elastic arteries play a major role in dampening the pulsatile pressure of heart contractions. Dilation or constriction of arterioles determines blood flow to individual capillary beds. Muscular arteries have the thickest tunica media relative to their lumen size. **4.** If you were doing calf raises, your capillary bed would be in the condition depicted in part (a). The capillaries would be flushed with blood to ensure that the working calf muscles could receive the needed nutrients and dispose of their metabolic wastes. **5.** Valves prevent blood from flowing backwards in veins. They are formed from folds of the tunica intima. **6.** In the systemic circuit, veins contain more blood than arteries (see Figure 19.6). **7.** Veins have more anastomoses than arteries. **8.** The three factors that determine resistance are blood viscosity, vessel length, and vessel diameter. Vessel diameter is physiologically most important. **9.** The rate of flow will decrease 81-fold from its original flow ($3 \times 3 \times 3 \times 3 = 81$). **10.** Vessel (c) would have the greatest blood flow and vessel (a) would have the least blood

ANSWERS APPENDIX

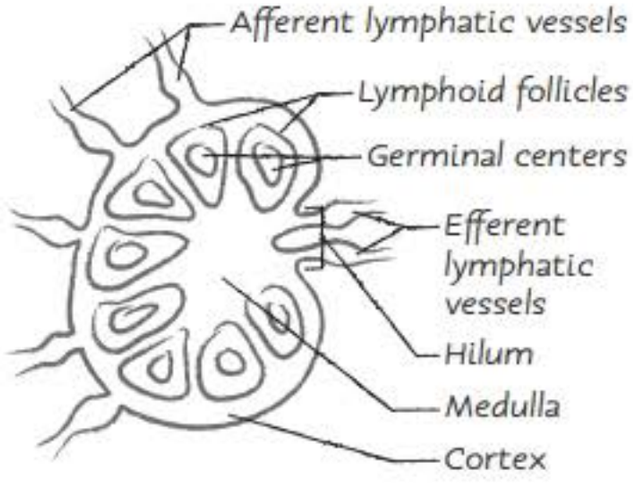
flow. This is because flow increases as resistance decreases ($F = \Delta P/TPR$), and resistance varies directly with length and inversely with diameter. Vessel (c) has the largest diameter and so would have a lower resistance than vessel (b) (which has the same length, but a smaller diameter). Vessel (a) is the longest and so would have a higher resistance than (b) (which has the same diameter, but a shorter length). **11.** (a) The largest pressure drop occurs in the arterioles (because they have the largest resistance). (b) The capillaries are the first vessels that do not have a difference in pressure between systole and diastole. This is good because pressure fluctuations might rupture fragile capillaries. In addition, smooth flow is ideal for exchange at capillaries. (c) About 15–17 mm Hg is left at the start of the venules to get blood back to the heart. Factors that help blood return to the heart include venous valves, the muscular pump, the respiratory pump, and sympathetic venoconstriction. **12.** Cole's pulse pressure is 60 mm Hg. His mean arterial pressure is 80 + 60/3 = 100 mm Hg. **13.** When you first stand up, mean arterial pressure (MAP) temporarily decreases and this is sensed by aortic and carotid baroreceptors. Medullary cardiac and vasomotor center reflexes increase sympathetic and decrease parasympathetic outflow to the heart. Heart rate and contractility increase, increasing cardiac output and therefore MAP. Further, sympathetic constriction of arterioles increases total peripheral resistance, also increasing MAP. (In addition, increased constriction of veins increases venous return, which increases end diastolic volume, increasing stroke volume, and therefore cardiac output and MAP.) See also Figure 19.11 (bottom). **14.** The kidneys help maintain MAP by influencing blood volume. In renal artery obstruction, the blood pressure in the kidney is lower than in the rest of the body (because it is downstream from the obstruction). Low renal blood pressure triggers both direct and indirect renal mechanisms to increase blood pressure by increasing blood volume. This can cause hypertension (called "secondary hypertension" because it is secondary to a defined cause—in this case the renal artery obstruction). **15.** Bob is in vascular shock due to anaphylaxis, a systemic allergic reaction to his medication. His blood pressure is low because of widespread vasodilation triggered by the massive release of histamine. Bob's rapid heart rate is a result of the baroreceptor reflex triggered by his low blood pressure. This activates the sympathetic nervous system, increasing heart rate, in an attempt to restore blood pressure. **16.** Diuretics cause a decrease in blood volume (because more fluid is lost in urine), decreasing cardiac output, which decreases blood pressure. Beta-blockers block beta-adrenergic receptors. Their antihypertensive effects are primarily due to their action in the heart, where they decrease contractility (and therefore stroke volume) and heart rate, resulting in lower cardiac output. Ca^{2+} channel blockers decrease Ca^{2+} entry into arteriolar smooth muscle, decreasing its contraction (causing vasodilation) and resulting in decreased total peripheral resistance. By acting on Ca^{2+} channels in the heart, these drugs may also decrease contractility and heart rate. **17.** In a bicycle race, autoregulation by intrinsic metabolic controls causes arteriolar smooth muscle in your legs to relax, dilating the vessels and supplying more O_2 and nutrients to the exercising muscles. **18.** Extrinsic mechanisms, primarily the sympathetic nervous system, prevent blood pressure from plummeting by constricting arterioles elsewhere (such as the gut and kidneys). In addition, cardiac output increases, which also helps maintain MAP. **19.** › The net filtration pressure (NFP) at this point in the capillary is 8 mm Hg (34 mm Hg – 26 mm Hg). This is a net outward pressure, which tells us that this point in the capillary is near the arterial end of the capillary. **20.** (a) An increase in interstitial fluid osmotic pressure (OP_{if}) would tend to pull more fluid out of capillaries (causing localized swelling, or edema). (b) An increase of OP_{if} to 10 mm Hg would increase the outward pressure on both the arteriolar and venous ends of the capillary. The NFP at the venous end would become 1 mm Hg (27 mm Hg – 26 mm Hg). (c) Fluid would flow out of the venous end of the capillary rather than in. **21.** In heart failure, the heart is no longer able to pump blood adequately (see p. 700). As a result, blood backs up into the veins and capillary beds and the hydrostatic pressure in the capillaries increases, causing edema. **22.** The external carotid arteries supply most of the tissues of the head except for the brain and orbits. **23.** The cerebral arterial circle (circle of Willis) is the arterial anastomosis at the base of the cerebrum. **24.** The four unpaired arteries that emerge from the abdominal aorta are the celiac trunk, the superior and inferior mesenteric arteries, and the median sacral artery. **25.** You would palpate the popliteal artery behind the knee, the posterior tibial artery behind the medial malleolus of the tibia, and the dorsalis pedis artery on the foot. (See also Figure 19.8.) **26.** The vertebral arteries help supply the brain, but the vertebral veins do not drain much blood from the brain. **27.** The internal jugular veins drain the dural venous sinuses. Each internal jugular vein joins a subclavian vein to form a brachiocephalic vein. **28.** Capillary bed (a) is in the digestive organs and capillary bed (c) is in the liver. The liver capillaries are sinusoid capillaries. The blood vessel names are hepatic portal vein (b), hepatic vein (d), and inferior vena cava (e). **29.** The leg veins that often become varicosed are the great and small saphenous veins. **30.** In Chapter 16 (The Endocrine System), you learned about the hypophyseal portal system (see Focus Figure 16.1 on p. 611).



Review Questions 1. d; **2.** d; **3.** c; **4.** e; **5.** d; **6.** c; **7.** b; **8.** b; **9.** a; **10.** (1)b, e, g; (2)c; (3)i; (4)f, h; (5)d; **11.** c

Chapter 20

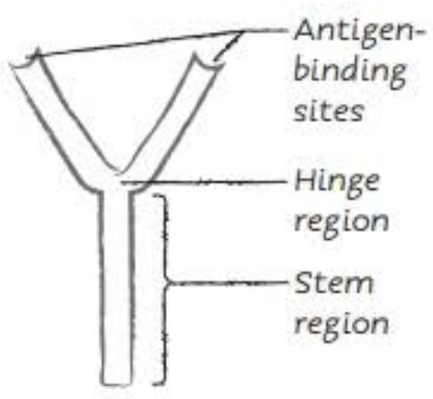
Check Your Understanding 1. Lymph is the fluid inside lymphatic vessels. It enters lymphatic vessels from interstitial fluid. Interstitial fluid, in turn, is a filtrate of blood plasma. **2.** The right lymphatic duct receives lymph from the right upper arm and the right side of the head and thorax. The thoracic duct drains lymph from the rest of the body. **3.** Lymph movement is driven by the contraction of adjacent skeletal muscles, pressure changes in the thorax during breathing, the pulsations of nearby arteries, and contraction of smooth muscle in the lymphatic vessel walls. (Valves in lymphatic vessels prevent backflow of lymph.) **4.** The blocked lymphatic vessels in Mr. Thomas's left leg no longer return excess tissue fluid or proteins to the bloodstream. The lack of fluid return from the tissues into the blood will result in a higher interstitial fluid hydrostatic pressure. This is an inward pressure, and will tend to help limit the edema. However, the lack of proteins being returned from the interstitial fluid to the blood will result in a higher interstitial fluid osmotic pressure, which will tend to pull more fluid into the tissue. **5.** The primary lymphoid organs are the red bone marrow and thymus. Primary lymphoid organs are special because they are the organs where lymphocytes originate and mature. **6.** Red bone marrow in adults is found in the cavities between trabeculae of spongy bones in the flat bones of the skull, the sternum, ribs, clavicles, scapulae, hip bones, and vertebrae. In addition it is found in the heads of the femur and humerus. **7.** Lymphoid follicles are solid, spherical bodies consisting of tightly packed reticular fibers and lymphoid cells, often with a lighter-staining central region. They are regions where B cells predominate. **8.** Having fewer efferents causes lymph to accumulate in lymph nodes, allowing more time for its cleansing. **9.** › **10.** The spleen cleanses the blood, recycles breakdown products of RBCs, stores iron, stores platelets and monocytes, and is thought to be a site of erythrocyte production in the fetus. **11.** The structures are: (a) capsule and (b) trabecula. Region (d) is red pulp and so it is the site of red blood cell destruction and also the site that has splenic cords and splenic sinusoids. Region (c) is white pulp and so it is the region composed mostly of lymphocytes. **12.** The splenic artery arises from the celiac trunk. The splenic vein empties into the hepatic portal vein. **13.** MALT (mucosa-associated lymphoid tissue) is lymphoid tissue found in the mucosa of the digestive, respiratory, and genitourinary tracts. It includes tonsils, Peyer's patches, and the appendix. **14.** B cells mature in the bone marrow.



Review Questions 1. c; **2.** c; **3.** a, d; **4.** c; **5.** a; **6.** b; **7.** a; **8.** b; **9.** d

Chapter 21

Check Your Understanding 1. The innate defense system is always ready to respond immediately, whereas it takes considerable time to mount the adaptive defense system. The innate defenses consist of surface barriers and internal defenses, whereas the adaptive defenses consist of humoral and cellular immunity, which rely on B and T lymphocytes. **2.** Surface barriers (the skin and mucous membranes) constitute the first line of defense. **3.** Opsonization is the process of making pathogens more susceptible to phagocytosis by decorating their surface with molecules that phagocytes can bind. Antibodies and complement proteins are examples of molecules that act as opsonins. **4.** Our own cells are killed by NK cells when they have been infected by viruses or when they have become cancerous. **5.** Redness, heat, swelling, and pain are the cardinal signs of inflammation. Redness and local heat are both caused by vasodilation of arterioles, which increases the flow of blood (warmed by the body core) to the affected area. The swelling (edema) is due to the release of histamine and other chemical mediators of inflammation, which increase capillary permeability. This increased permeability allows proteins to leak into the interstitial fluid (IF), increasing the IF osmotic pressure and drawing more fluid out of blood vessels and into the tissues, thereby causing swelling. The pain is due to two things: (1) the actions of certain chemical mediators (kinins and prostaglandins) on nerve endings, and (2) the swelling, which can compress free nerve endings. **6.** A mutation in the gene that codes for interferon would make Julian particularly susceptible to viruses. **7.** Four key characteristics of adaptive immunity are that it involves B and T lymphocytes, it is specific, it is systemic, and it has memory. **8.** A complete antigen has both immunogenicity and reactivity, whereas a hapten has reactivity but not immunogenicity. **9.** Self-antigens, particularly MHC proteins, mark a cell as self. **10.** Development of immunocompetence of a B or T cell is signaled by the appearance on its surface of specific and unique receptors for an antigen. In the case of a B cell, this receptor is a membrane-bound antibody. (In T cells, it is simply called the T cell receptor.) **11.** Dendritic cells, macrophages, and B cells can all act as APCs. Dendritic cells are most important for T cell activation. **12.** In clonal selection, the antigen does the selecting. What is being selected is a particular clone of B or T cells that has antigen receptors corresponding to that antigen. **13.** The T cell that would survive is (c), one that recognizes MHC but not self-antigen. **14.** The secondary response to an antigen is faster than the primary response because the immune system has already been "primed" and has memory cells that are specific for that particular antigen. **15.** An IgM antibody is shown at right. (You can tell because it consists of five Y-shaped parts—that is, it is a pentamer.) IgG antibody is most abundant in blood. IgM is secreted first in a primary immune response. IgA is most abundant in secretions. **16.** Antibodies can bring about destruction of pathogen via "PLAN"—**p**hagocytosis, **l**ysis (via complement), **a**gglutination, or **n**eutralization. **17.** Vaccinations protect by providing the initial encounter to an antigen—the primary response to that antigen. As a result, when the pathogen for that illness is encountered again, the pathogen elicits the much faster, more powerful secondary response, which is generally effective enough to prevent clinical illness. **18.** › The stem region determines the class of antibody. **19.** Plasma cells make large amounts of antibodies—proteins that are exported from the cell. Rough endoplasmic reticulum is the site where proteins that are exported are synthesized. Ribosomes, the Golgi apparatus, and secretory vesicles are also required for protein synthesis and export, and so would also be abundant in these cells. **20.** Class II MHC proteins display exogenous antigens. Class II MHC proteins are recognized by CD4 T cells. APCs display class II MHC proteins. **21.** Helper T cells are central to both humoral and cellular immunity because they are required for activation of both cytotoxic T cells and most B cells. **22.** (a) Immune cells that secrete proteins that form a pore are cytotoxic T cells and NK cells. In this case, perforins are the proteins that form the pore. (b) Complement proteins are plasma proteins that can form a pore [which is called a membrane attack complex (MAC)]. Specifically, in complement-mediated cell lysis, MAC complexes cause a target cell (usually a bacterium) to become leaky. This allows water to enter and cytoplasmic contents to exit the cell, killing the cell. In contrast, cytotoxic T cells and NK cells kill their targets (usually virus-infected cells) by releasing perforins and granzymes onto the identified target cell. Perforins form a pore in the target cell membrane, and granzymes enter through this pore, activating enzymes that trigger apoptosis (cell suicide). **23.** The cell being activated is a CD4 cell and so could become either a helper T cell or a regulatory T cell. **24.** HIV is particularly hard for the immune system to defeat because (1) it destroys helper T cells, which are key players in adaptive immunity and (2) it has a high mutation rate and so it can avoid detection by the immune system by changing its surface antigens. **25.** Binding of an allergen onto specific IgE antibodies attached to mast cells triggers the mast cells to release histamine.

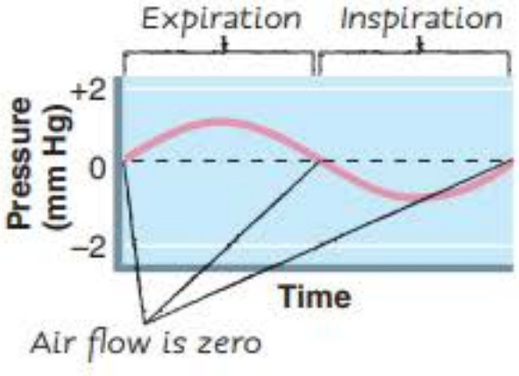


Review Questions 1. c; **2.** a; **3.** d; **4.** a; **5.** d; **6.** b; **7.** c; **8.** d; **9.** d; **10.** (1)b, g; (2)d, i; (3)a, e; (4)a, e, f, h; (5)e, h; (6)c, f, g; **11.** d; **12.** The antibody classes and their likely locations in the body are: IgM—attached to B cell plasma membrane as a monomer and in plasma as a pentamer; IgA—dimers found in secretions such as saliva, tears, intestinal juice, and milk; IgD—attached to B cell plasma membrane as a monomer; IgG—in plasma; IgE—attached to mast cells in skin, mucosae of the gastrointestinal and respiratory tracts, and tonsils.

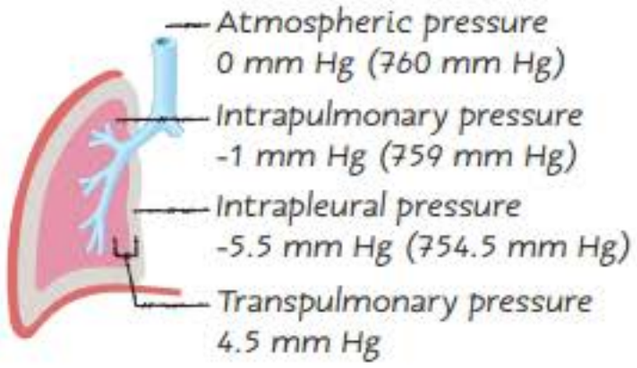
Chapter 22

Check Your Understanding 1. The structures that air passes by are the nasal cavity (nares, nasal vestibule, nasal conchae), nasopharynx, oropharynx, and laryngopharynx. **2.** The nasal cavity contains both respiratory mucosa and olfactory mucosa. **3.** › **4.** The epiglottis seals the larynx when we swallow. **5.** The incomplete, C-shaped cartilage rings of the trachea allow it to expand and contract and yet keep it from collapsing. **6.** The many tiny alveoli together have a large surface area. This and the thinness of their respiratory membranes make them ideal for gas exchange. **7.** The peanut was most likely in the right main bronchus because it is wider and more vertical than the left. **8.** The two circulations of the lungs are the pulmonary circulation, which delivers deoxygenated blood to the lungs for oxygenation and returns oxygenated blood to the heart, and the bronchial circulation, which provides systemic (oxygenated) blood to lung tissue. **9.** Angiotensin converting enzyme is found in the plasma membrane of lung capillary endothelial cells. This is a good location for it because all of the blood in the body passes through the lung capillaries about once every minute. Angiotensin converting enzyme is part of the renin-angiotensin-aldosterone hormone cascade, which increases blood pressure. **10.** The driving force for pulmonary ventilation is a pressure gradient created by changes in the thoracic volume. **11.** The partial vacuum (negative pressure) inside the pleural cavity is caused by the opposing forces acting on the visceral and parietal pleurae. The visceral pleurae are pulled inward by the lungs' natural tendency to recoil and the surface tension of the alveolar fluid. The parietal pleurae are pulled outward by the elasticity of the chest wall. If air enters the pleural cavity, the lung on that side will collapse. This condition is called pneumothorax. **12.** A lack of surfactant increases surface tension in the alveoli and causes them to collapse between breaths. (In other words, it markedly decreases lung compliance.) **13.** › Intrapulmonary pressure increases during expiration and decreases during inspiration. When intrapulmonary pressure is zero relative to atmospheric pressure, air flow is zero. This occurs at the three points labeled in the graph, which are between inspiration and expiration. After air flow stops, it changes direction.

	Conducts	Epithelium	Tonsils
Nasopharynx	Air	Pseudostratified ciliated columnar	Pharyngeal Tubal
Oropharynx	Air and food	Stratified squamous	Palatine Lingual
Laryngopharynx	Air and food	Stratified squamous	— (none)



14. › **15.** Slow, deep breaths ventilate the alveoli more effectively because a smaller fraction of the tidal volume of each breath is spent moving air into and out of the dead space. **16.** Respiratory capacities are combinations of two or more respiratory volumes.

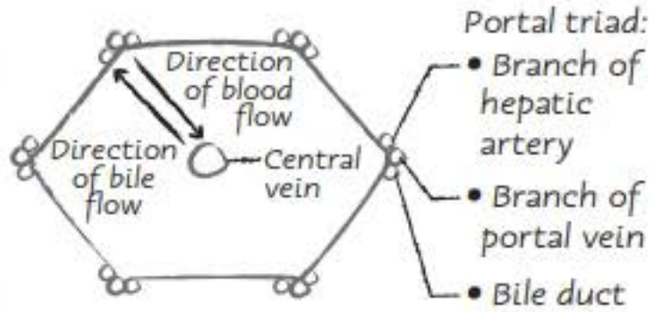


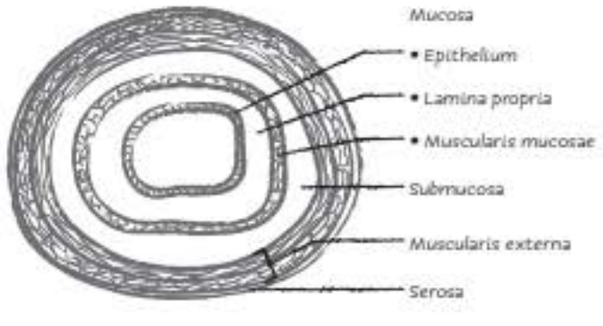
17. The difference in P_{O_2} between inspired air and alveolar air can be explained by (1) the gas exchange occurring in the lungs (O_2 continuously diffuses out of the alveoli into the blood), (2) the humidification of inspired air (which adds water molecules that dilute the O_2 molecules), and (3) the mixing of newly inspired air with gases already present in the alveoli. **18.** The arterioles leading into the O_2-enriched alveoli would be dilated. This response allows matching of blood flow to availability of oxygen. **19.** In a sealed container, the air and water would be at equilibrium. Therefore, the partial pressures of CO_2 and O_2 (P_{CO_2} and P_{O_2}) will be the same in the water as in the air: 100 mm Hg each. More CO_2 than O_2 molecules will be dissolved in the water (even though they are at the same partial pressure) because CO_2 is much more soluble than O_2 in water. **20.** About 70% of CO_2 is transported as bicarbonate ion (HCO_3^-) in plasma. Just over 20% is transported bound to hemoglobin in the RBCs, and 7–10% is dissolved in plasma. **21.** As blood CO_2 increases, blood pH decreases. This is because CO_2 combines with water to form carbonic acid. (However, the change in pH in blood for a given increase in CO_2 is minimized by other buffer systems.) **22.** The shift shown in graph (b) would allow more oxygen delivery to the tissues. Conditions that would cause the curve to shift this way are increased temperature, increased P_{CO_2}, decreased pH, or an increase in BPG levels. **23.** The ventral respiratory group of the medulla (VRG) is thought to be the rhythm-generating area. **24.** CO_2 in blood normally provides the most powerful stimulus to breathe. Central chemoreceptors are most important in this response (see Figure 22.28). **25.** Long-term adjustments to altitude include an increase in erythropoiesis, resulting in a higher hematocrit; an increase in BPG, which decreases Hb affinity for oxygen; and an increase in minute respiratory volume. **26.** The injured soccer player's P_{CO_2} is low. (Recall that normal P_{CO_2} = 40 mm Hg.) The low P_{CO_2} reveals that this is hyperventilation and not hyperpnea (which is not accompanied by changes in blood CO_2 levels). **27.** The obstruction in asthma is reversible, and acute exacerbations are typically followed by symptom-free periods. In contrast, the obstruction in chronic bronchitis is generally not reversible. **28.** Because Mr. Singh's alveoli are poorly ventilated, the local P_{O_2} around those alveoli would be low. This low P_{O_2} would cause the pulmonary arterioles to constrict (due to ventilation-perfusion coupling), increasing resistance and thereby increasing pulmonary blood pressure. In the long term, pulmonary hypertension can cause right heart failure (see *cor pulmonale* in Chapter 18 *Related Clinical Terms* on p. 702). When one side of the heart fails, pressure increases upstream of the failing pump—in this case in the systemic capillaries. This causes peripheral edema, which would be noticeable in the extremities such as the feet and ankles (see p. 700).

Review Questions 1. b; **2.** a and c; **3.** c; **4.** c; **5.** b; **6.** d; **7.** d; **8.** b; **9.** c; **10.** b

Chapter 23

Check Your Understanding 1. The esophagus is found in the thorax. Three alimentary canal organs found in the abdominal cavity include the stomach, small intestine, and large intestine. **2.** The usual site of ingestion is the mouth. **3.** The process of absorption moves nutrients into the body. **4.** The visceral peritoneum is the outermost layer of the digestive organ; the parietal peritoneum is the serous membrane covering the wall of the abdominal cavity. **5.** The pancreas is retroperitoneal. **6.** The hepatic portal circulation is the venous portion of the splanchnic circulation. **7.** › **8.** The muscularis externa is unitary smooth muscle. Characteristics of unitary smooth muscle that make it well suited for this location are that it is electrically coupled by gap junctions and so contracts as a unit, is arranged in longitudinal and circular sheets, and exhibits rhythmic spontaneous action potentials. **9.** Reflexes associated with the GI tract promote muscle contraction and secretion of digestive juices or hormones. **10.** The term "gut brain" refers to the enteric nervous system, the web of neurons closely associated with the digestive organs. **11.** He should temporarily refrain from eating because the parasympathetic nervous system stimulates digestive activities. **12.** The palate forms the roof of the mouth. The hard palate supported by bone is anterior to the soft palate (no bony support). **13.** The tongue is important for taste and for speech, particularly for uttering consonants. **14.** Antimicrobial substances found in saliva include lysozyme, defensins, and IgA antibodies. **15.** Enamel is harder than bone. Pulp consists of nervous tissue and blood vessels. **16.** The glands are (a) parotid gland, (b) sublingual gland, and (c) submandibular gland. The duct of the submandibular gland opens at the base of the lingual frenulum. The duct of the parotid gland pierces the buccinator muscle. **17.** The pharynx is part of the digestive and respiratory systems. **18.** The esophageal muscularis externa undergoes a transformation along its length from skeletal muscle superiorly to smooth muscle near the stomach. **19.** The esophagus is merely a chute for food passage and is subjected to a good deal of abrasion, which a stratified squamous epithelium can withstand. The stomach mucosa is a secretory mucosa served well by a simple columnar epithelium. **20.** During swallowing the larynx rises and the epiglottis covers its lumen so that foodstuffs are diverted into the esophagus posteriorly. **21.** Peristaltic contractions become more and more powerful as they approach the pylorus. Only a small squirt of liquid chyme is allowed through the pyloric sphincter before this sphincter closes as part of the peristaltic wave. Once the pyloric sphincter is closed, solids in the stomach are propelled back into the stomach (a movement called retropulsion) while being pummeled and ground together. **22.** The chief cells produce pepsinogen, which is the inactive enzyme pepsin, and the parietal cells secrete HCl needed to activate pepsinogen. **23.** The three phases of gastric secretion are the cephalic, gastric, and intestinal phases. **24.** The presence of food in the duodenum inhibits gastric activity by triggering the enterogastric reflex and the secretion of enterogastrones (hormones). **25.** The enterohepatic circulation is an important recycling mechanism for retaining bile salts needed for fat absorption. **26.** Pancreatic acini produce the exocrine products of the pancreas (digestive enzymes and bicarbonate-rich juice). The islets produce pancreatic hormones, most importantly insulin and glucagon. **27.** Fluid in the pancreatic duct is bicarbonate-rich, enzyme-rich pancreatic juice. Fluid in the cystic and bile ducts is bile. **28.** CCK is secreted in response to the entry into the duodenum of chyme rich in protein and fat. It causes the pancreatic acini to secrete digestive enzymes, stimulates the gallbladder to contract, and relaxes the hepatopancreatic sphincter. **29.** › **30.** All of these modifications increase the surface area of the small intestine. **31.** Brush border enzymes are enzymes associated with the microvilli of the enterocytes of the small intestine mucosa. **32.** Distension of stomach walls enhances stomach secretory activity. Distension of the walls of the small intestine reduces stomach secretory activity (to give the small intestine time to carry out its digestive and absorptive activities). **33.** Segmentation is the most common motility pattern after a meal. Segmentation mixes chyme with digestive enzymes and exposes the products of this digestion to the absorptive epithelium where brush border enzymes complete digestion and where absorption occurs. **34.** MMC is the migrating motor complex, a pattern of peristalsis seen in the small intestine that moves the last remnants of a meal plus bacteria and other debris into the large intestine. MMC is important to prevent the overgrowth of bacteria in the small intestine. **35.** Mass movements and haustral contractions occur in the large intestine. Mass movements are long, slow, powerful contractions that move over large areas of the colon three or four times a day, forcing the contents toward the rectum. Haustral contractions are a special type of segmentation. **36.** Activation of stretch receptors in the rectal walls initiates the defecation reflex. **37.** Enteric bacteria synthesize B vitamins and some of the vitamin K the liver needs to synthesize clotting proteins. **38.** To be absorbed, nutrients pass through the apical



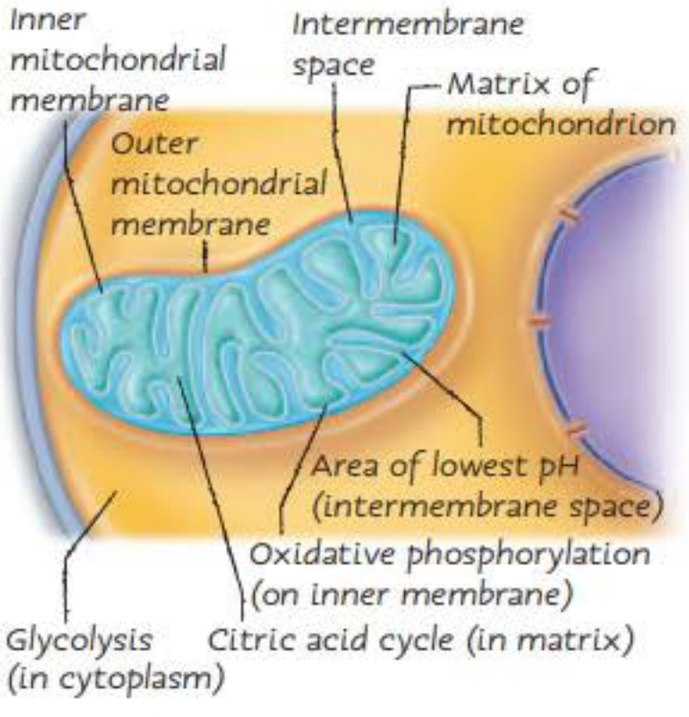


and then the basolateral membranes of enterocytes. **39.** Capillaries that receive absorbed nutrients are in the lamina propria of the mucosa of the small intestine. **40.** Amylase is to starch as lipase is to fats. **41.** Lack of bile salts would dramatically decrease both digestion and absorption of fats and fat-soluble vitamins. Without bile salts, you would expect the patient to have fatty stools. The patient might exhibit signs of weight loss and malnutrition. (In children this would be seen as lack of growth and failure to thrive.) The patient may also exhibit signs of deficiency of fat-soluble vitamins (see Table 24.2).

Review Questions 1. c; **2.** d; **3.** d; **4.** b; **5.** b; **6.** a; **7.** b; **8.** c; **9.** c; **10.** a; **11.** The six functional activities of the digestive system are ingestion, propulsion, mechanical breakdown, digestion, absorption, and defecation. **12.** (a) The normal number of permanent teeth is 32. The normal number of deciduous teeth is 20. (b) Enamel covers a tooth crown, whereas cement covers its root. (c) Dentin forms the bulk of a tooth. (d) Pulp is found in the central cavity of a tooth. It consists of connective tissue containing blood vessels and nerve fibers.

Chapter 24

Check Your Understanding 1. The five major nutrients are carbohydrates, proteins, fats, minerals, and vitamins. **2.** Cellulose provides fiber, which helps in elimination. **3.** Triglycerides are used for ATP synthesis, body insulation and protective padding, and to help the body absorb fat-soluble vitamins. Cholesterol is the basis of our steroid hormones and bile salts, and stabilizes cellular membranes. **4.** Beans (legumes) and grains (wheat) are good sources of protein, but neither is a complete one. However, together they provide all the essential amino acids. **5.** Vitamins serve as the basis for coenzymes, which work with enzymes to accomplish metabolic reactions. **6.** Iodine is essential for thyroxine synthesis. Calcium in the form of bone salts is needed to make bones hard. Iron is needed to make functional hemoglobin. **7.** Vitamin B_{12} needs intrinsic factor synthesized by parietal cells to be absorbed by the intestine. Vitamin B_{12} is absorbed in the ileum, and its lack causes pernicious anemia. **8.** A redox reaction is a combination of an oxidation and a reduction reaction. As one substance is oxidized, another is reduced. **9.** Some of the energy released during catabolism is captured in the bonds of ATP, which provides the energy needed to carry out the constructive activities of anabolism. **10.** The energy released during the oxidation of food fuels is used to pump protons across the inner mitochondrial membrane. **11.** In substrate-level phosphorylation, high-energy phosphate groups are transferred directly from phosphorylated intermediates to ADP to form ATP. In oxidative phosphorylation, electron transport proteins forming part of the inner mitochondrial membrane use energy released during oxidation of glucose to create a steep gradient for protons across this membrane. Then as protons flow back through the membrane, gradient energy is captured to attach phosphate to ADP. **12.** If oxygen and pyruvic acid are not available, glycolysis will stop because the supply of NAD^+ is limited and glycolysis can continue only if the reduced coenzymes ($NADH + H^+$) formed during glycolysis are relieved of their extra hydrogen. **13.** Oxidation (via removal of H) is common in the citric acid cycle; it is indicated by the reduction of a coenzyme (either NAD^+ or FAD). Decarboxylations are also common, and are indicated by the removal of CO_2 from the cycle. **14.** Glycogenolysis is the reaction in which glycogen is broken down to its glucose monomers. **15.** › Note that the area with the lowest pH is the area with the most protons (H^+). **16.** Glycerol, a breakdown product of fat metabolism, enters glycolysis. **17.** Acetyl CoA is the central molecule of fat metabolism. **18.** The products of beta oxidation are acetyl CoA (acetic acid + coenzyme A), $NADH^+ + H^+$, and $FADH_2$. **19.** The liver uses keto acids drained off the citric acid cycle and amino groups (from other nonessential amino acids) as substrates to make the nonessential amino acids that the body needs. **20.** The ammonia removed from amino acids is combined with carbon dioxide to form urea, which is then eliminated by the kidneys. **21.** The three organs or tissues that regulate the directions of interconversions in the nutrient pools are the liver, skeletal muscles, and adipose tissues. **22.** Anabolic reactions and energy storage typify the absorptive state. Catabolic reactions (to increase blood sugar levels) such as lipolysis and glycogenolysis, and glucose sparing occur in the postabsorptive state. **23.** The main antagonist of glucagon is insulin. **24.** A rise in amino acid levels in blood increases both insulin and glucagon release. **25.** High HDL levels would be preferable because the cholesterol these particles transport is destined for the liver and elimination from the body. **26.** Trans fats are oils that have been hydrogenated (with H atoms). They are unhealthy because they cause LDLs to increase and HDLs to decrease—exactly the opposite of what is desirable. **27.** Among short-term stimuli influencing feeding behavior are neural signals from the digestive tract, nutrient signals related to energy stores, and GI tract hormones (CCK, insulin, glucagon, and ghrelin). **28.** Leptin is the most important long-term regulator of feeding behavior. **29.** As you can see in Figure 24.25, the ventromedial nucleus (VMN) is part of the satiety (appetite suppression) pathway. If the VMN is destroyed, the balance between this satiety pathway and the hunger pathway would be lost and the patient would never feel full and would very likely gain weight. **30.** Of the factors listed, breathing and kidney function contribute to BMR. **31.** Samantha is suffering from hypersecretion of thyroid hormone, which makes her feel restless and warm (because it raises her BMR) and gives her insomnia. The presence of autoantibodies suggests that she has Graves' disease (see p. 620), a condition in which antibodies bind to receptors for TSH (mimicking TSH) and stimulate continuous thyroid hormone release. **32.** The body's core is the organs within the skull and the thoracic and abdominal cavities. **33.** Andrea's body temperature is rising as heat-promoting mechanisms (shivering, chills) are activated. Something (an infection?) has caused the hypothalamic thermostat to be set to a higher level (fever) temporarily. **34.** In conduction, heat is transferred directly from one object to another (a hot surface to your palm). In convection, air warmed by body heat is continually removed (warm air rises) and replaced by cooler air (cool air falls), which in turn will absorb heat radiating from the body.

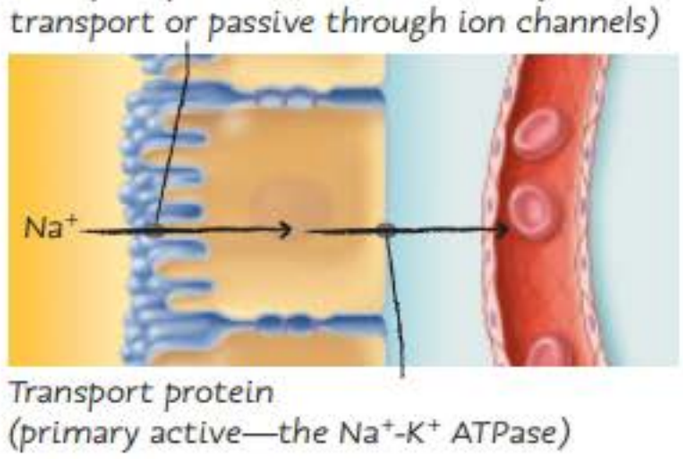


Review Questions 1. a; **2.** c; **3.** b; **4.** d; **5.** b; **6.** c; **7.** a; **8.** d; **9.** d; **10.** b; **11.** d; **12.** a

Chapter 25

Check Your Understanding 1. The lower part of his rib cage and the perirenal fat capsule protect his kidneys from blows. **2.** The layers of supportive tissue around each kidney are the fibrous capsule, the perirenal fat capsule, and the renal fascia. The parietal peritoneum overlies the anterior renal fascia. **3.** The renal pelvis, which has extensions called calyces, is continuous with the ureter. **4.** Filtrate is formed in the glomerular capsule and then passes through the proximal convoluted tubule (PCT), the descending and ascending limbs of the nephron loop, and the distal convoluted tubule (DCT). **5.** The structural differences are (1) juxtamedullary nephrons have long nephron loops (with long thin segments) and renal corpuscles that are near the cortex-medulla junction, whereas cortical nephrons have short nephron loops and renal corpuscles that lie more superficially in the cortex; (2) efferent arterioles of juxtamedullary nephrons supply vasa recta, while efferent arterioles of cortical nephrons supply peritubular capillaries. **6.** The glomerular capillaries are fenestrated capillaries. (See Figure 19.3 on p. 711 to refresh your memory of capillary types.) Their function is to filter large amounts of plasma into the glomerular capsule. **7.** The structures shown are (a) glomerular capsule, (b) efferent arteriole, (c) vasa recta, (d) proximal convoluted tubule (PCT), (e) collecting duct, and (f) nephron loop (ascending thin limb). **8.** Excretion is a means of removing wastes from the body, whereas tubular secretion is the process of selectively moving substances from the blood into the filtrate. While secretion often leads to excretion, this is not always the case because something could be secreted in the proximal tubules and yet reabsorbed distally. **9.** Intrinsic controls serve to maintain a nearly constant GFR in spite of changes in systemic blood pressure. Extrinsic controls

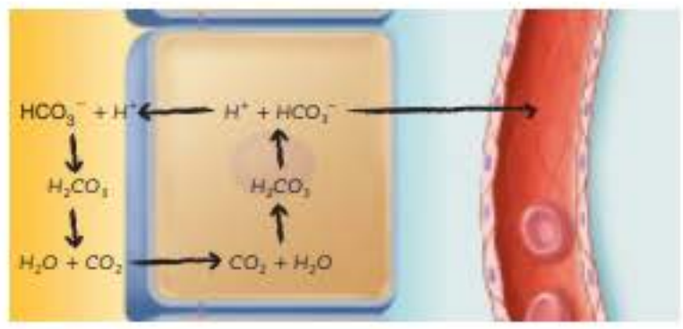
serve to maintain systemic blood pressure. **10.** Hydrostatic pressure in the glomerular capillaries (HP_{gc}) is regulated by intrinsic and extrinsic controls of GFR. **11.** Net filtration pressure is 5 mm Hg [50 mm Hg – (25 mm Hg + 20 mm Hg)]. **12.** The majority of reabsorption occurs in the proximal convoluted tubule. **13.** The reabsorption of Na^+ by primary active transport drives reabsorption of amino acids and glucose by secondary active transport. It also drives passive reabsorption of chloride, and reabsorption of water by osmosis. The reabsorption of water leaves behind other solutes, which become more concentrated and can therefore be reabsorbed by diffusion. **14.** › **15.** In primary active transport, the energy for the process is provided directly by ATP. In secondary active transport, the energy for the process is provided by the Na^+ concentration gradient established by active pumping of Na^+ occurring elsewhere in the cell. As Na^+ moves down its own concentration gradient, it drives the movement of another substance (e.g., glucose) against that substance's concentration gradient. **16.** H^+, K^+, NH_4^+, creatinine, urea, and uric acid are all substances that are secreted into the kidney tubules. **17.** The descending limb of the nephron loop is permeable to water and impermeable to NaCl. The ascending limb is impermeable to water and permeable to NaCl. **18.** ADH is released from the posterior pituitary in response to hyperosmotic extracellular fluid (as sensed by hypothalamic osmoreceptors). ADH causes insertion of aquaporins into the apical membranes of the principal cells of the collecting ducts. **19.** The three major nitrogenous wastes excreted in urine are urea, creatinine, and uric acid. **20.** The normal renal clearance value for amino acids is zero. You would expect this because amino acids are valuable as nutrients and as the building blocks for protein synthesis, so it would not be good to lose them in the urine. **21.** A kidney stone blocking the ureter would interfere with urine flow to the bladder. The pain would occur in waves that coincide with the peristaltic contractions of the smooth muscle of the ureter. **22.** The trigone is a smooth triangular region at the base of the bladder. Its borders are defined by the openings for the ureters and the urethra. **23.** The prostatic urethra, the intermediate part of the urethra, and the spongy urethra are the three regions of the male urethra. **24.** The detrusor contracts in response to increased firing of parasympathetic nerves. **25.** In both cases (micturition and defecation) the external sphincters are skeletal muscle under voluntary control, and the internal sphincters are smooth muscle controlled by the autonomic nervous system.



Review Questions 1. d; **2.** b; **3.** c; **4.** d; **5.** c; **6.** b; **7.** a; **8.** c; **9.** b; **10.** A perirenal fat capsule surrounds each kidney and cushions it against blows. **11.** Micturition is the act of emptying the bladder. The micturition reflex is activated when stretch receptors sense stretch of the bladder wall. This causes firing of afferent neurons, which excite parasympathetic (and inhibit sympathetic) efferent neurons in the sacral spinal cord. Parasympathetic activation causes the detrusor muscle to contract. In addition, the afferent impulses from stretch receptors inhibit somatic motor neurons, which allows the external urethral sphincter to open. Together, these responses allow micturition.

Chapter 26

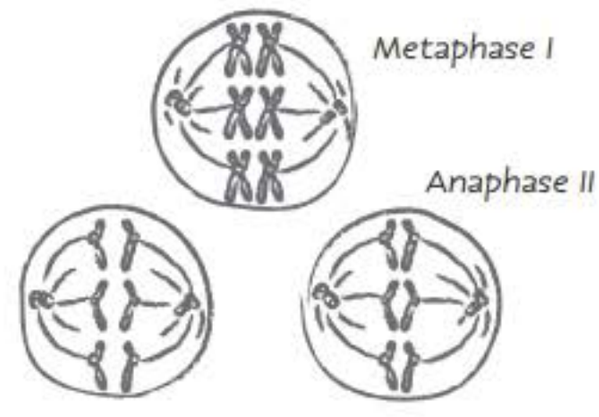
Check Your Understanding 1. You have more intracellular than extracellular fluid and more interstitial fluid than plasma. **2.** Na^+ is the major cation in the ECF and K^+ is the major cation in the ICF. The intracellular counterparts to extracellular Cl^- are HPO_4^{2-} and protein anions. **3.** If you eat salty pretzels, your extracellular fluid volume will expand even if you don't ingest fluids. This is because water will flow by osmosis from the intracellular fluid to the extracellular fluid. **4.** An increase in osmolality of the plasma is most important for triggering thirst. This change is sensed by osmoreceptors in the hypothalamus. **5.** ADH cannot add water—it can only conserve what is already there. In order to reduce an increase in osmolality of body fluids, the thirst mechanism is required. **6.** (a) A decrease in plasma proteins causes edema. (b) Copious sweating causes dehydration. (c) Using ecstasy (together with drinking lots of fluids) could cause hypotonic hydration because ecstasy promotes ADH secretion, which interferes with the body's ability to get rid of extra water. **7.** Arrow 2 in the proximal convoluted tubule shows the site where most Ca^{2+} is reabsorbed. Arrow 5 corresponds to Na^+ reabsorption in the collecting duct, which is regulated by aldosterone. Arrow 4 corresponds to K^+ secretion in the collecting duct, which is regulated by aldosterone. **8.** The major regulator of calcium in the blood is parathyroid hormone. Hypercalcemia decreases excitability of neurons and muscle cells and may cause life-threatening cardiac arrhythmias. Hypocalcemia increases excitability and causes muscle tetany. **9.** Insufficient aldosterone would cause Nathan's plasma Na^+ to be decreased and his plasma K^+ to be elevated. The decrease in plasma Na^+ would cause a decrease in blood pressure, because plasma Na^+ is directly related to blood volume, which is a major determinant of blood pressure. **10.** Acidemia is an arterial pH below 7.35 and alkalemia is a pH above 7.45. **11.** The three major chemical buffer systems of the body are the bicarbonate buffer system, the phosphate buffer system, and the protein buffer system. The most important intracellular buffer is the protein buffer system. **12.** Joanne's ventilation would be increased. The acidosis caused by the accumulated ketone bodies will stimulate the peripheral chemoreceptors, and this will cause more CO_2 to be "blown off" in an attempt to restore pH to normal. **13.** The most important urinary buffer of H^+ is the phosphate buffer system. **14.** The tubule and collecting duct cells generate new HCO_3^- either by excreting ammonium ions (NH_4^+) or by excreting buffered H^+ ions. **15.** › **16.** In both renal tubule cells and parietal cells, (a) the enzyme carbonic anhydrase is key, and (b) blood concentration of HCO_3^- increases. **17.** Key features of an uncompensated metabolic alkalosis are an increase in blood pH and an increase in blood HCO_3^-. Key features of an uncompensated respiratory acidosis are a decrease in blood pH and an increase in blood P_{CO_2}. **18.** The kidneys compensate for respiratory acidosis by excreting more H^+ and generating new HCO_3^- to buffer the acidosis.



Review Questions 1. a; **2.** c; **3.** b; **4.** a and b; **5.** h, i; **6.** c, g; **7.** a, e; **8.** b; **9.** a, b; **10.** j; **11.** b, d; **12.** c; **13.** The body fluid compartments are: (1) intracellular fluid (ICF), which is the fluid inside cells, about 25 liters; (2) extracellular fluid (ECF), which is all of the fluid outside cells, about 15 liters. The ECF can be further divided into (a) plasma, which is the fluid part of blood, about 3 liters, and (b) interstitial fluid (IF), which is the fluid that surrounds and bathes the cells in tissues and is about 12 liters.

Chapter 27

Check Your Understanding 1. The HPG axis is the hormonal interrelationship between the hypothalamus, anterior pituitary, and gonads that regulates the production of gametes and sex hormones. **2.** Meiosis reduces the chromosomal count from $2n$ to n and introduces variability. **3.** › **4.** The seminiferous tubules act as the sperm factories. **5.** When the ambient temperature is cold, the associated muscles contract, bringing the testes close to the warm body wall. When temperature is high, the associated muscles relax, allowing the testes to hang away from the body wall. The pampiniform venous plexus absorbs heat from the arterial blood, cooling the blood before it enters the testes. **6.** Balancing his laptop on his lap for two hours a day might affect Carlos's fertility by increasing the temperature inside his scrotum. Increased testicular

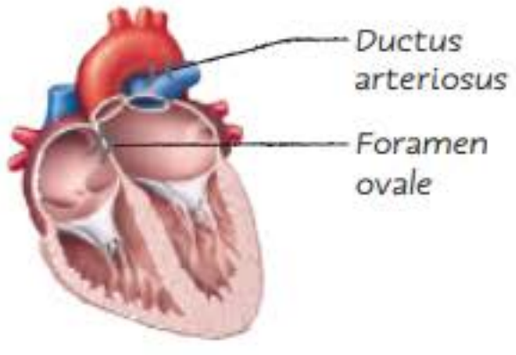


temperatures decrease fertility. **7.** The organs of the male duct system in order from the epididymis to the body exterior are the ductus deferens, ejaculatory duct, prostatic urethra, intermediate part of the urethra, and spongy urethra. The ductus deferens runs from the scrotum into the pelvic cavity. **8.** These stereocilia pass nutrients to the sperm and absorb excess testicular fluid. **9.** The corpora cavernosa allow the penis to become stiff so that it can enter the female vagina to deliver sperm. **10.** The male perineum is the external region where the penis and scrotum are suspended. **11.** The bulbo-urethral glands (c) secrete primarily mucus. The seminal glands (a) produce the largest fraction of semen volume. The prostate (b) is at the junction of the ejaculatory duct and urethra. **12.** Semen is sperm plus the secretions of the male accessory glands. **13.** Arthur probably has benign prostatic hyperplasia (BPH). (Recall that that prostate cancer is usually symptomless, whereas BPH is characterized by difficult urination.) **14.** Erection is the stiffening of the penis that occurs when blood floods the cavernous tissue and is also prevented from leaving the penis. It is caused by the parasympathetic division of the autonomic nervous system. **15.** Resolution is a period of muscular and psychological relaxation that follows orgasm. It results as the sympathetic nervous system causes constriction of the internal pudendal arteries, reducing blood flow to the penis, and activates small muscles that force blood out of the penis. **16.** The sperm head is the compacted DNA-containing nucleus. The acrosome that caps the head is a lysosome-like sac of enzymes. The midpiece contains the energy-producing mitochondria. The tail, a flagellum, is the propulsive structure. **17.** Sustentocytes provide nutrients and essential developmental signals to the developing sperm and form the blood testis barrier that prevents sperm antigens from escaping into the blood. Interstitial endocrine cells secrete testosterone. **18.** Both cilia and flagella use the motor protein dynein for movement (see p. 90). Cilia line both the upper and lower respiratory tract, and so Caleb might have recurrent episodes of sinusitis, bronchitis, or pneumonia (as a result of the inability of his cilia to efficiently move the mucus that clears infectious organisms from his respiratory tract). (Cilia also line the middle ear and so patients with defective dynein often have chronic otitis media and may present with hearing problems.) **19.** Follicle-stimulating hormone indirectly stimulates spermatogenesis by prompting the sustentocytes to secrete androgen-binding protein. Androgen-binding protein keeps the concentration of testosterone high in the vicinity of the spermatogenic cells, which directly stimulates spermatogenesis. **20.** Secondary sex characteristics of males include appearance of pubic, axillary, and facial hair, deepening of the voice, increased oiliness of the skin, and increased size (length and mass) of the bones and skeletal muscles. **21.** Testosterone has negative feedback effects on GnRH release from the hypothalamus and on gonadotropin release from the anterior pituitary. So if testosterone blood levels are high, blood levels of GnRH, FSH, and LH would be low. **22.** The female's internal genitalia include the ovaries and duct system (uterine tubes, uterus, and vagina). **23.** The ovaries produce the female gametes and secrete female sex hormones (estrogens and progesterone). **24.** Women are more at risk for PID than men because the duct system of women is incomplete—there is no physical connection between the ovary and the uterine tubes, which are open to the pelvic cavity. In men, the duct system is continuous from the testes to the body exterior. **25.** The waving action of the fimbriae and currents created by the beating cilia help to direct the ovulated oocytes into the uterine tube. **26.** The labeled structures are (a) ampulla of uterine tube, (b) fimbriae of the uterine tube, (c) ovary, (d) ovarian ligament, (e) endometrium of uterus, (f) cervix, and (g) vagina. The usual site of fertilization is the uterine tube (a). The endometrium of the uterus (e) has spiral arteries. **27.** The greater vestibular glands are the female homologue of the male bulbo-urethral glands. **28.** Both the penis and clitoris are hooded by a skin fold and are largely erectile tissue. However, the clitoris lacks a corpus spongiosum containing a urethra, so the urinary and reproductive systems are completely separate in females. **29.** Developmentally, the mammary glands are modified sweat glands. **30.** The glandular portion of the breast usually develops about midway through a pregnancy. **31.** The products of meiosis in females are 2 or 3 nonfunctional polar bodies (tiny haploid cells with essentially no cytoplasm) and 1 haploid ovum (functional gamete). Meiosis in males yields 4 functional gametes, the haploid sperm. **32.** The antrum is the fluid-filled cavity of a vesicular follicle. **33.** From left to right, the three follicles indicated in Figure 27.16 on p. 1061 are (1) a vesicular (antral) follicle, (2) a secondary follicle, and (3) a primary follicle. (Fixing and staining makes the fluid inside the first, vesicular follicle appear cloudy. The primary and primordial follicles are quite tiny in this photomicrograph, so don't worry if you weren't sure whether the last one was a primary or primordial follicle.) **34.** Identical twins develop from separation of a very young embryo (the result of fertilization of a single oocyte by a single sperm) into two parts. Fraternal twins develop when different oocytes are fertilized by different sperm. **35.** In the luteal phase, the follicle from which an oocyte has been ovulated develops into a corpus luteum, which then secretes progesterone (and some estrogens). **36.** Leptin is important in advising the brain of the girl's readiness (relative to energy stores) for puberty. **37.** LH prompts ovulation. **38.** Estrogens exert positive feedback on the anterior pituitary that leads to a burstlike release of LH. **39.** Estrogens are responsible for the secondary sex characteristics of females. **40.** Estrogens promote epiphyseal closure in both males and females. Long bones stop growing in length when the epiphyses are ossified. **41.** The vestibular glands help to lubricate the vestibule. **42.** The human papillomavirus (HPV) is most associated with cervical cancer. **43.** Chlamydia is the most common bacterial sexually transmitted infection in the U.S.

Review Questions 1. c; **2.** a, c, e, f; **3.** a and b; **4.** d; **5.** d; **6.** b; **7.** d; **8.** d; **9.** (1)c, f; (2)e, h; (3)g; (4)a; (5)b, e, and g; (6)f; **10.** d; **11.** b

Chapter 28

Check Your Understanding 1. The cortical reaction involves the release of enzymes from cortical granules to the oocyte exterior, which accomplishes destruction of the zona pellucida sperm-binding receptors and also the detachment of any sperm still bound to these receptors. These events help ensure monospermy. **2.** A cell derived from the fusion of a sperm and a polar body would not likely survive and develop into an embryo because it would lack the cytoplasm containing the nutrients required for its journey to the uterus (see p. 1071). **3.** Region (a) is the acrosome, which contains hydrolytic enzymes that the sperm uses to help it penetrate and enter the egg. The acrosomal reaction (release of the contents of the acrosome) is triggered by sperm binding to sperm-binding receptors in the zona pellucida. Before the acrosomal reaction can occur, sperm must undergo capacitation. **4.** The blastocyst is only slightly larger than the zygote because, although cell division has been going on (cleavage divisions), there is essentially no time for growth between divisions, so the resulting cells get smaller and smaller. The result is a large number of cells with a high surface-to-volume ratio. **5.** The trophoblast cells contribute to the formation of the placenta. **6.** The syncytiotrophoblast actually accomplishes implantation. **7.** The chorion develops from the trophoblast and a layer of extraembryonic mesoderm. **8.** The decidua basalis cooperates with the chorionic villi to form the placenta. **9.** The placenta is usually fully functional by the end of the third month of pregnancy. **10.** The blastocyst secretes the hormone human chorionic gonadotropin, which is detectable in the urine. **11.** Before organogenesis can occur in earnest, the embryonic body must fold and undercut to form a tubular embryo. **12.** The mesoderm gives rise to essentially all body tissues except neural and epidermal tissue and mucosae. **13.** For the most part, the special fetal circulatory modifications are occluded at birth or shortly thereafter. **14.** › The foramen ovale and ductus arteriosus allow most of the blood to bypass the heart.



15. Without an amnion, the temperature of the developing fetus would fluctuate more. The fetus would also be less protected from physical trauma, and its body parts might adhere to each other during development. **16.** Difficult breathing during late pregnancy is due to the uterus pressing against and crowding the diaphragm (and hence the lungs). The waddling gait is due to the relaxing effect of relaxin on the pelvic ligaments and the pubic symphysis. **17.** The hormone hPL works with estrogens and progesterone to stimulate breast maturation in the pregnant woman, promotes fetal growth, and exerts a glucose-sparing effect on the mother. **18.** The enlarged uterus of a pregnant woman can press on the veins that return blood to the heart. Because the veins are downstream of the capillaries, the partial obstruction of venous flow would cause capillary hydrostatic

pressure to rise (just like stepping on the downstream part of a hose would cause pressure inside the hose to go up). The edema of preeclampsia, on the other hand, is due to a decrease in capillary colloid osmotic pressure. (See also p. 734.) **19.** Breech presentation is a buttock-first presentation of the baby during labor. **20.** Prostaglandins are most responsible for triggering true labor. **21.** The descent of the baby's head (the largest part of its body) follows the widest dimensions of the bony pelvis. **22.** An Apgar score is a quick assessment of the baby's overall physical status that is determined at 1 and 5 minutes after birth. **23.** Surfactant increases compliance (distensibility) by decreasing the alveolar surface tension. **24.** Oxytocin causes the let-down reflex. **25.** *In vitro* fertilization is the most common ART technique.

Review Questions 1. (1)a, (2)b, (3)b, (4)a; **2.** b; **3.** b; **4.** (1)e, (2)f, (3)a, (4)d, (5)h, (6)b, (7)g, (8)c; **5.** d; **6.** d; **7.** b; **8.** a; **9.** c; **10.** a; **11.** In breech (buttocks-first) presentation, delivery may be more difficult because the widest diameter of the baby, which is the skull, is not delivered first. When the pelvis or hips of a baby are delivered first, there is a possibility that the head may become stuck in the mother's pelvis. Also, the baby will not be able to breathe until it has completely exited the birth canal. **12.** The factors that bring about uterine contractions include high levels of estrogen (brought about by high levels of fetal cortisol). These high estrogen levels oppose the quieting actions of progesterone and cause insertion of myometrial oxytocin and prostaglandin receptors and formation of gap junctions between myometrial cells. Later, high estrogen levels trigger prostaglandin secretion by the placenta, This stimulates the rhythmic contractions of true labor and thinning of the cervix. Cervical distension activates the maternal hypothalamus, triggering the positive feedback release of oxytocin by the posterior pituitary. **13.** An episiotomy is an incision made to widen the vaginal orifice in order to reduce tissue tearing as the baby's head exits from the perineum.

Chapter 29

Check Your Understanding 1. Chromosomes other than sex chromosomes are called autosomes. **2.** An allele represented by a capital letter is presumed to be a dominant allele. **3.** Descriptions of his phenotype are blond, blue-eyed, and hairy chest. **4.** Stage (c) shows metaphase, which is the phase of the cell cycle from which chromosomes are used to prepare a karyotype. During interphase (b) the DNA-containing material is in the form of dispersed strands of chromatin. As mitosis begins, the chromatin coils and condenses, becoming visible as chromosomes in prophase (d). Chromosomes continue to condense throughout prophase and are most visible during metaphase when we can arrest cell division with a drug. **5.** The alleles on different pairs of homologous chromosomes are segregated independently of each other to different gametes. **6.** Crossing over causes separations of linked genes on the same chromosome, producing gametes with more varied genomes. **7.** In incomplete dominance, the heterozygote has a phenotype intermediate between that of the dominant and recessive alleles [for example, for the sickling gene, the dominant homozygote (*SS*) has no evidence of sickling; the heterozygote (*Ss*) has sickle-cell trait; and the homozygote for the recessive gene (*ss*) has sickle-cell anemia]. In codominance, both dominant alleles are expressed (as in ABO blood types). **8.** Height is an example of a trait conferred by polygene inheritance in which several genes on different chromosomes contribute to the trait. Such traits show a distribution of phenotypes that yields a bell-shaped curve. **9.** A lethal recessive allele would likely be more widespread in the population. This is because dominant alleles are expressed. So if the dominant allele is lethal, the person who has that allele would probably not live very long or would die during development, and as a result the allele would not be transferred to the next generation. In contrast, a lethal recessive allele would kill only 1/4 of the possible offspring of two carriers, and would be passed to the next generation by half of the potential offspring. **10.** As the Punnett square shows, half of the daughters of this union would be affected by hemophilia (genotype X^hX^h) and half would be carriers (X^HX^h). Also, half of the sons would be affected (X^hY) and half would have normal blood clotting (X^HY). **11.** Other genes, measles in a pregnant woman, and lack of key dietary nutrients all may alter gene expression. **12.** Genomic imprinting labels genes as maternal or paternal. **13.** Maternal mitochondrial DNA confers extranuclear inheritance. **14.** Amniocentesis analyzes chemicals and cells in amniotic fluid. **15.** Mrs. Lehman should be tested because Tay-Sachs disease is a recessive disorder. In order to be affected, the baby would need to receive one affected allele from each parent. Even though there is no incidence of the disease in her family, the recessive gene might be present and masked by the dominant gene. (Her husband should also be tested to see whether he received an affected allele from either of his parents.) **16.** Ultrasound imaging is used to determine some aspects of fetal development (fetal age for example) and is noninvasive.

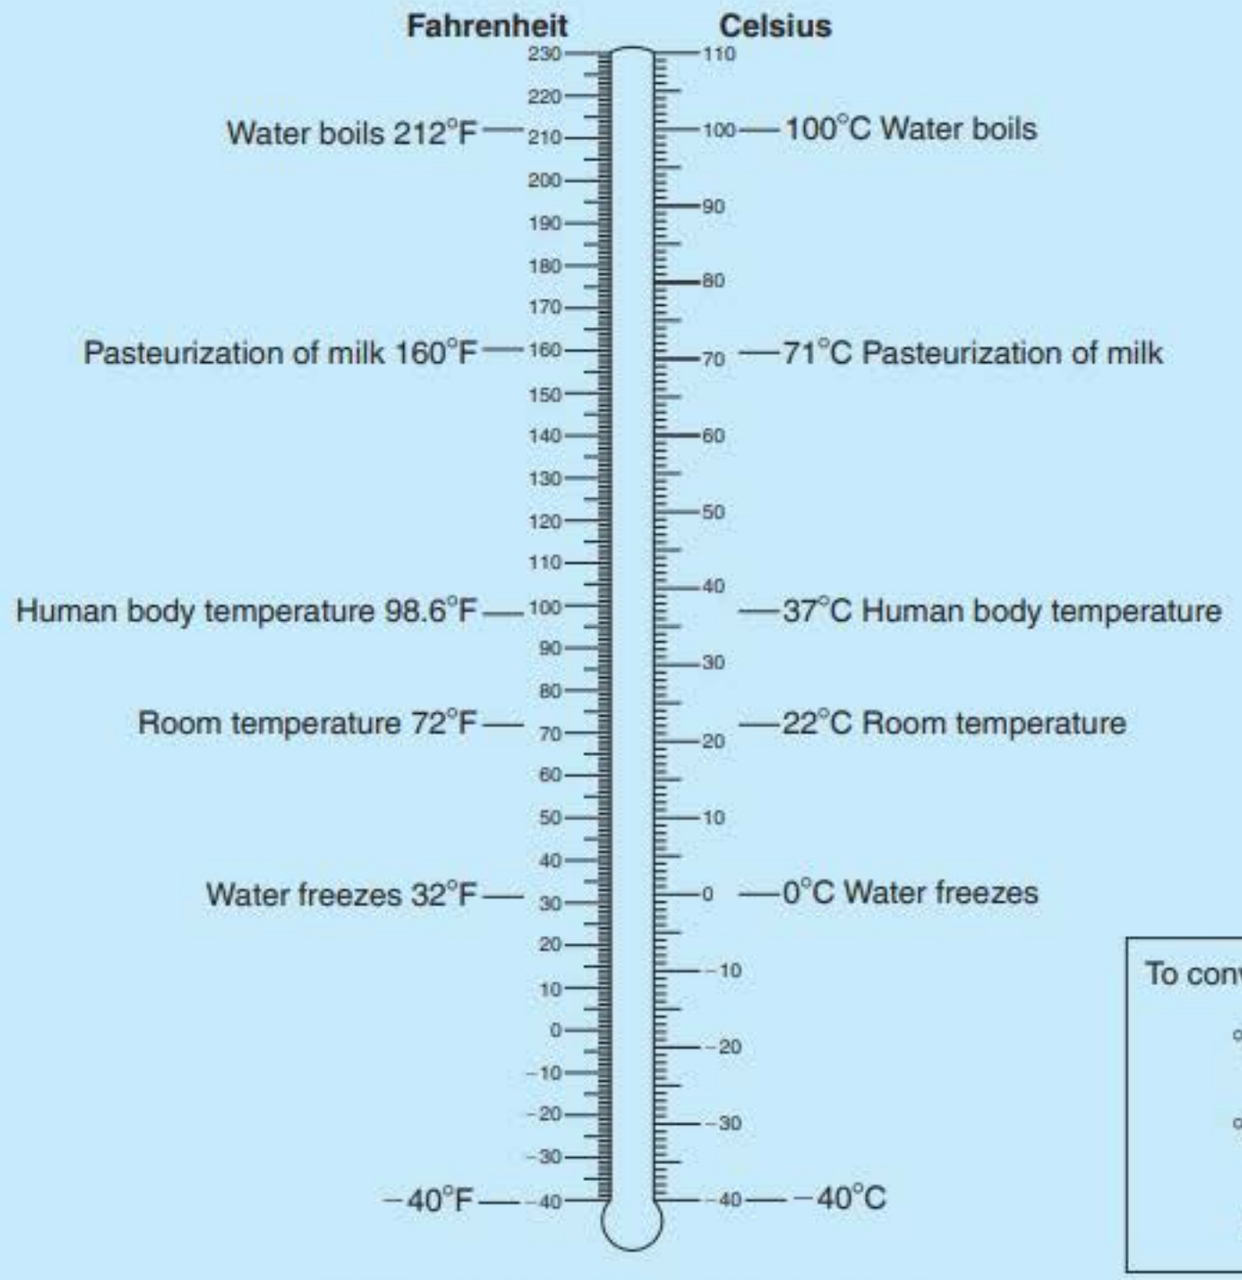
APPENDIX A The Metric System

MEASUREMENT	UNIT AND ABBREVIATION	METRIC EQUIVALENT	METRIC TO ENGLISH CONVERSION FACTOR	ENGLISH TO METRIC CONVERSION FACTOR
Length	1 kilometer (km)	= 1000 (10^3) meters	1 km = 0.62 mile	1 mile = 1.61 km
	1 meter (m)	= 100 (10^2) centimeters = 1000 millimeters	1 m = 1.09 yards 1 m = 3.28 feet 1 m = 39.37 inches	1 yard = 0.914 m 1 foot = 0.305 m
	1 centimeter (cm)	= 0.01 (10^{-2}) meter	1 cm = 0.394 inch	1 foot = 30.5 cm 1 inch = 2.54 cm
	1 millimeter (mm)	= 0.001 (10^{-3}) meter	1 mm = 0.039 inch	
	1 micrometer (μm)	= 0.000001 (10^{-6}) meter		
	1 nanometer (nm)	= 0.000000001 (10^{-9}) meter		
	1 angstrom (Å)	= 0.0000000001 (10^{-10}) meter		
Area	1 square meter (m^2)	= 10,000 square centimeters	1 m^2 = 1.1960 square yards 1 m^2 = 10.764 square feet	1 square yard = 0.8361 m^2 1 square foot = 0.0929 m^2
	1 square centimeter (cm^2)	= 100 square millimeters	1 cm^2 = 0.155 square inch	1 square inch = 6.4516 cm^2
Mass	1 metric ton (t)	= 1000 kilograms	1 t = 1.103 ton	1 ton = 0.907 t
	1 kilogram (kg)	= 1000 grams	1 kg = 2.205 pounds	1 pound = 0.4536 kg
	1 gram (g)	= 1000 milligrams	1 g = 0.0353 ounce 1 g = 15.432 grains	1 ounce = 28.35 g
	1 milligram (mg)	= 0.001 gram	1 mg = approx. 0.015 grain	
	1 microgram (μg)	= 0.000001 gram		
Volume (solids)	1 cubic meter (m^3)	= 1,000,000 cubic centimeters	1 m^3 = 1.3080 cubic yards 1 m^3 = 35.315 cubic feet	1 cubic yard = 0.7646 m^3 1 cubic foot = 0.0283 m^3
	1 cubic centimeter (cm^3 or cc)	= 0.000001 cubic meter = 1 milliliter	1 cm^3 = 0.0610 cubic inch	1 cubic inch = 16.387 cm^3
	1 cubic millimeter (mm^3)	= 0.000000001 cubic meter		
Volume (liquids and gases)	1 kiloliter (kl or kL)	= 1000 liters	1 kL = 264.17 gallons	1 gallon = 3.785 L
	1 liter (l or L)	= 1000 milliliters	1 L = 0.264 gallon 1 L = 1.057 quarts	1 quart = 0.946 L
	1 milliliter (ml or mL)	= 0.001 liter = 1 cubic centimeter	1 ml = 0.034 fluid ounce 1 ml = approx. $\frac{1}{5}$ teaspoon 1 ml = approx. 15–16 drops (gtt)	1 quart = 946 ml 1 pint = 473 ml 1 fluid ounce = 29.57 ml 1 teaspoon = approx. 5 ml
	1 microliter (μl or μL)	= 0.000001 liter		
Time	1 second (s)	= $\frac{1}{60}$ minute		
	1 millisecond (ms)	= 0.001 second		
Temperature	Degrees Celsius (°C)		°F = $\frac{9}{5}$(°C) + 32	°C = $\frac{5}{9}$(°F − 32)



Fahrenheit and Celsius scales compared

To convert temperature scales:

$$°C = \frac{5(°F - 32)}{9}$$

$$°F = \frac{9(°C)}{5} + 32$$

$$K = °C + 273$$

Functional Groups in Organic Molecules

Functional group	General formula	Name of compounds	Example	Where else found
Hydroxyl —OH (or HO—)	—O—H	Alcohols	 Ethanol	Sugars; water-soluble vitamins
Carbonyl 	 	Aldehydes Ketones	 Propanal  Acetone	Some sugars; formaldehyde (a preservative) Some sugars; "ketone bodies" in urine (from fat breakdown)
Carboxyl —COOH		Carboxylic acids	 Acetic acid	Amino acids; proteins; some vitamins; fatty acids
Amino —NH_2 (or H_2N—)		Amines	 Methylamine	Amino acids; proteins; urea in urine (from protein breakdown)

The Amino Acids

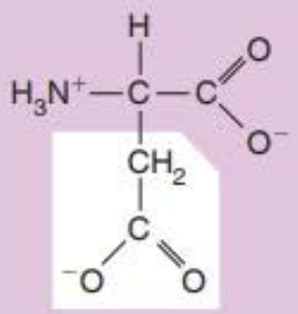
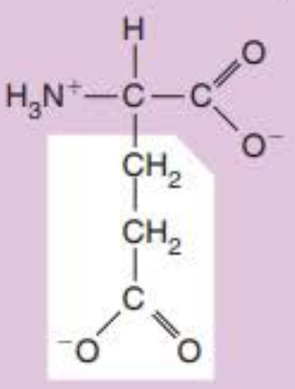
Acidic

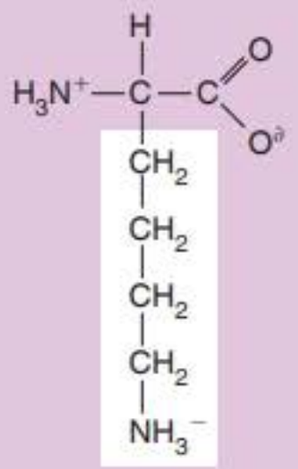


Aspartic acid (Asp)

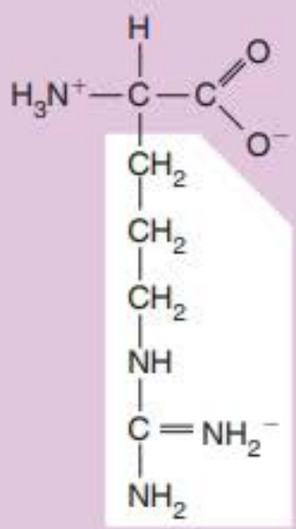


Glutamic acid (Glu)

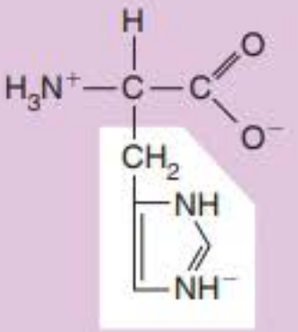
Basic



Lysine (Lys)



Arginine (Arg)



Histidine (His)

APPENDIX D

Two Important Metabolic Pathways

(1) Glucose enters the cell and is phosphorylated by the enzyme hexokinase, which catalyzes the transfer of a phosphate group, indicated as (P), from ATP to the number six carbon of the sugar, producing glucose-6-phosphate. The electrical charge of the phosphate group traps the sugar in the cell because the plasma membrane is impermeable to ions. Phosphorylation of glucose also makes the molecule more chemically reactive. Although glycolysis is supposed to *produce* ATP, ATP is actually consumed in step 1—an energy investment that will be repaid with dividends later in glycolysis.

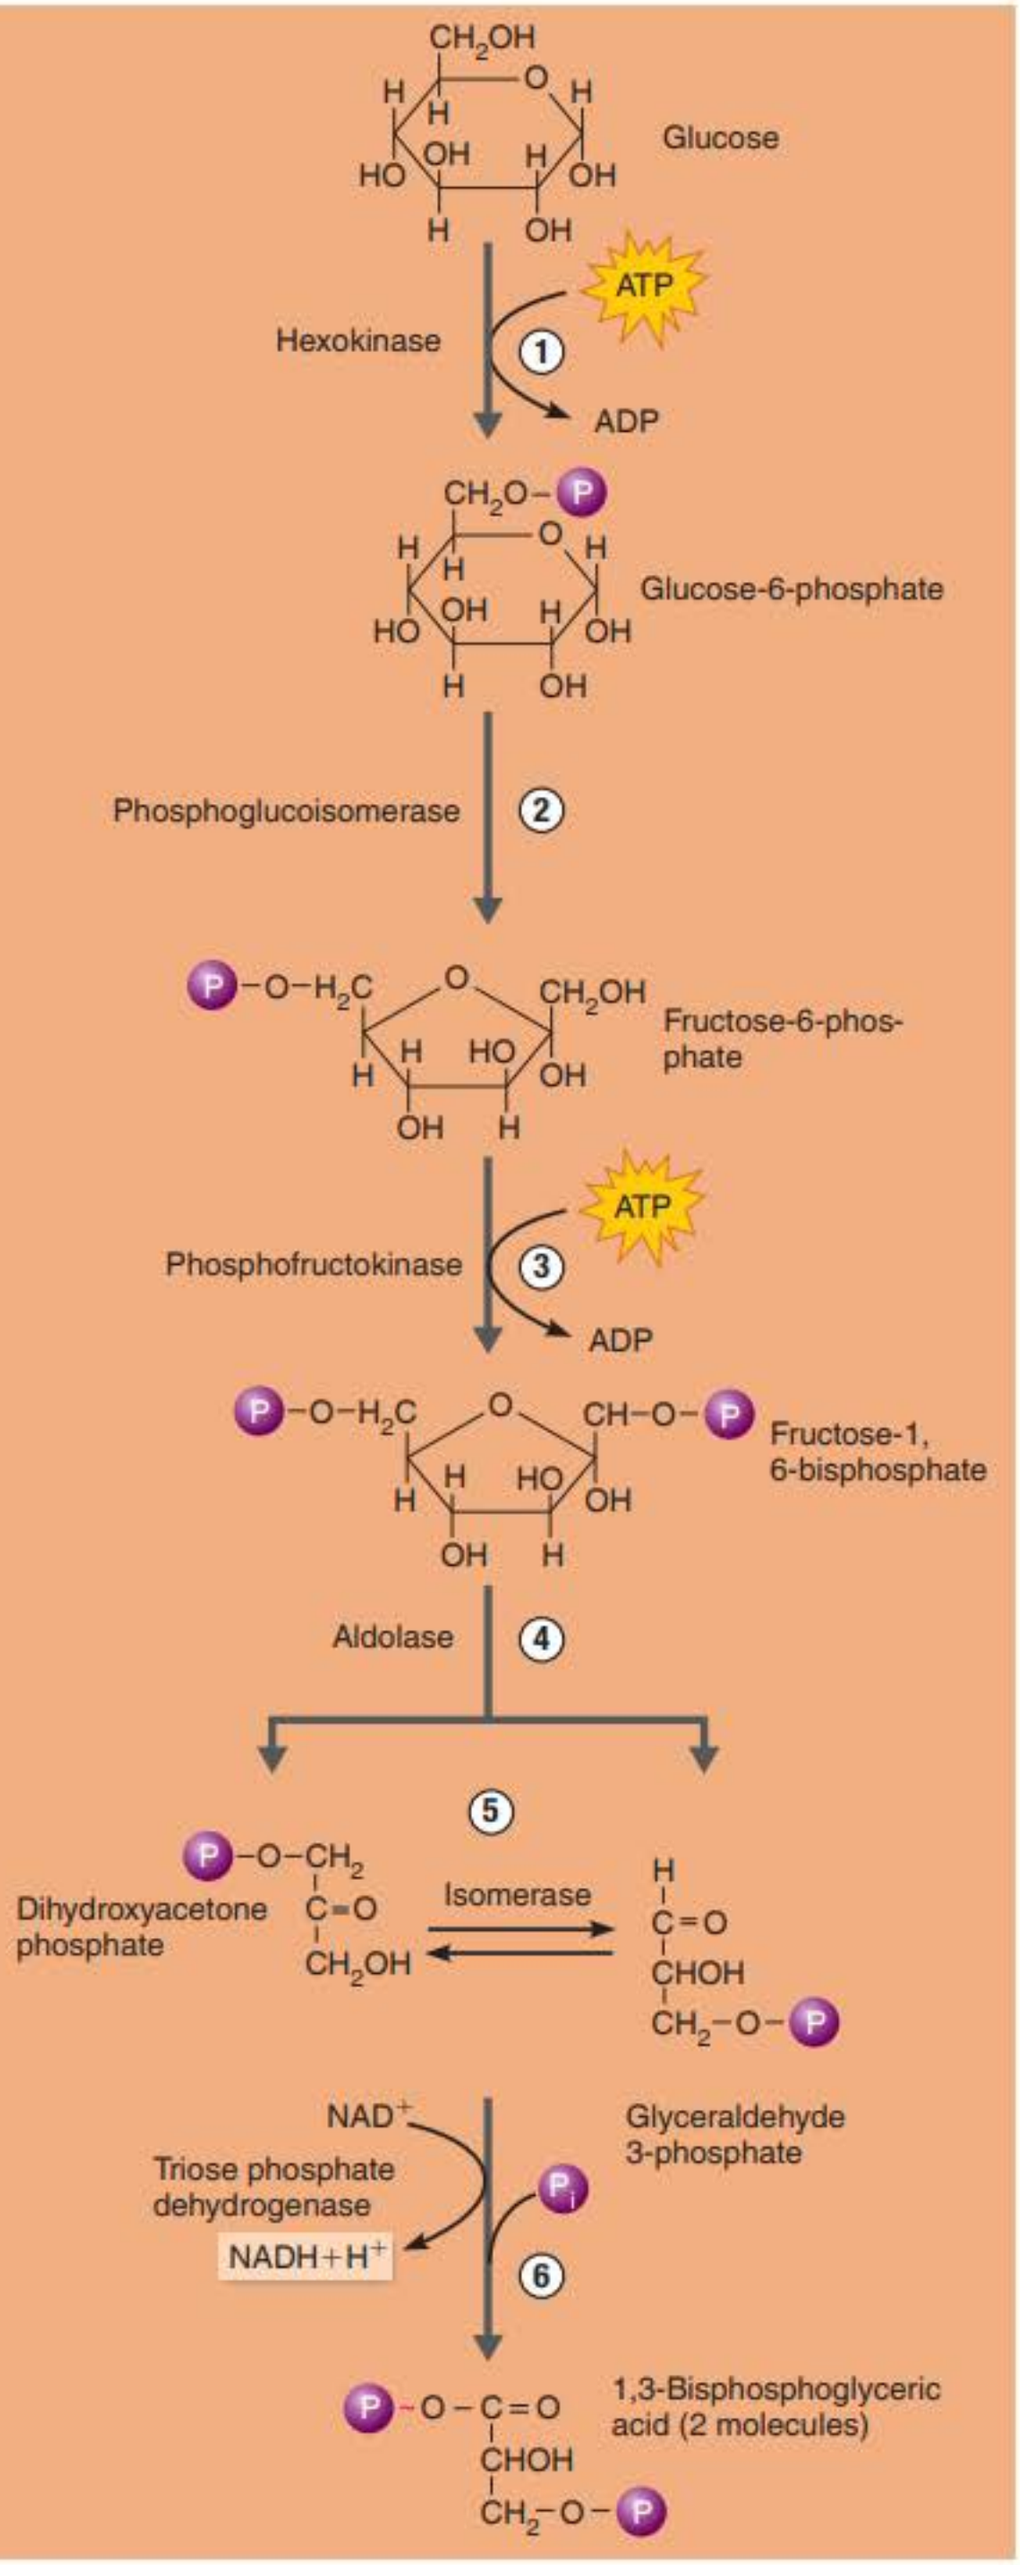
(2) Glucose-6-phosphate is rearranged and converted to its isomer, fructose-6-phosphate. Isomers, remember, have the same number and types of atoms but in different structural arrangements.

(3) In this step, still another molecule of ATP is used to add a second phosphate group to the sugar, producing fructose-1,6-bisphosphate. So far, the ATP ledger shows a debit of −2. With phosphate groups on its opposite ends, the sugar is now ready to be split in half.

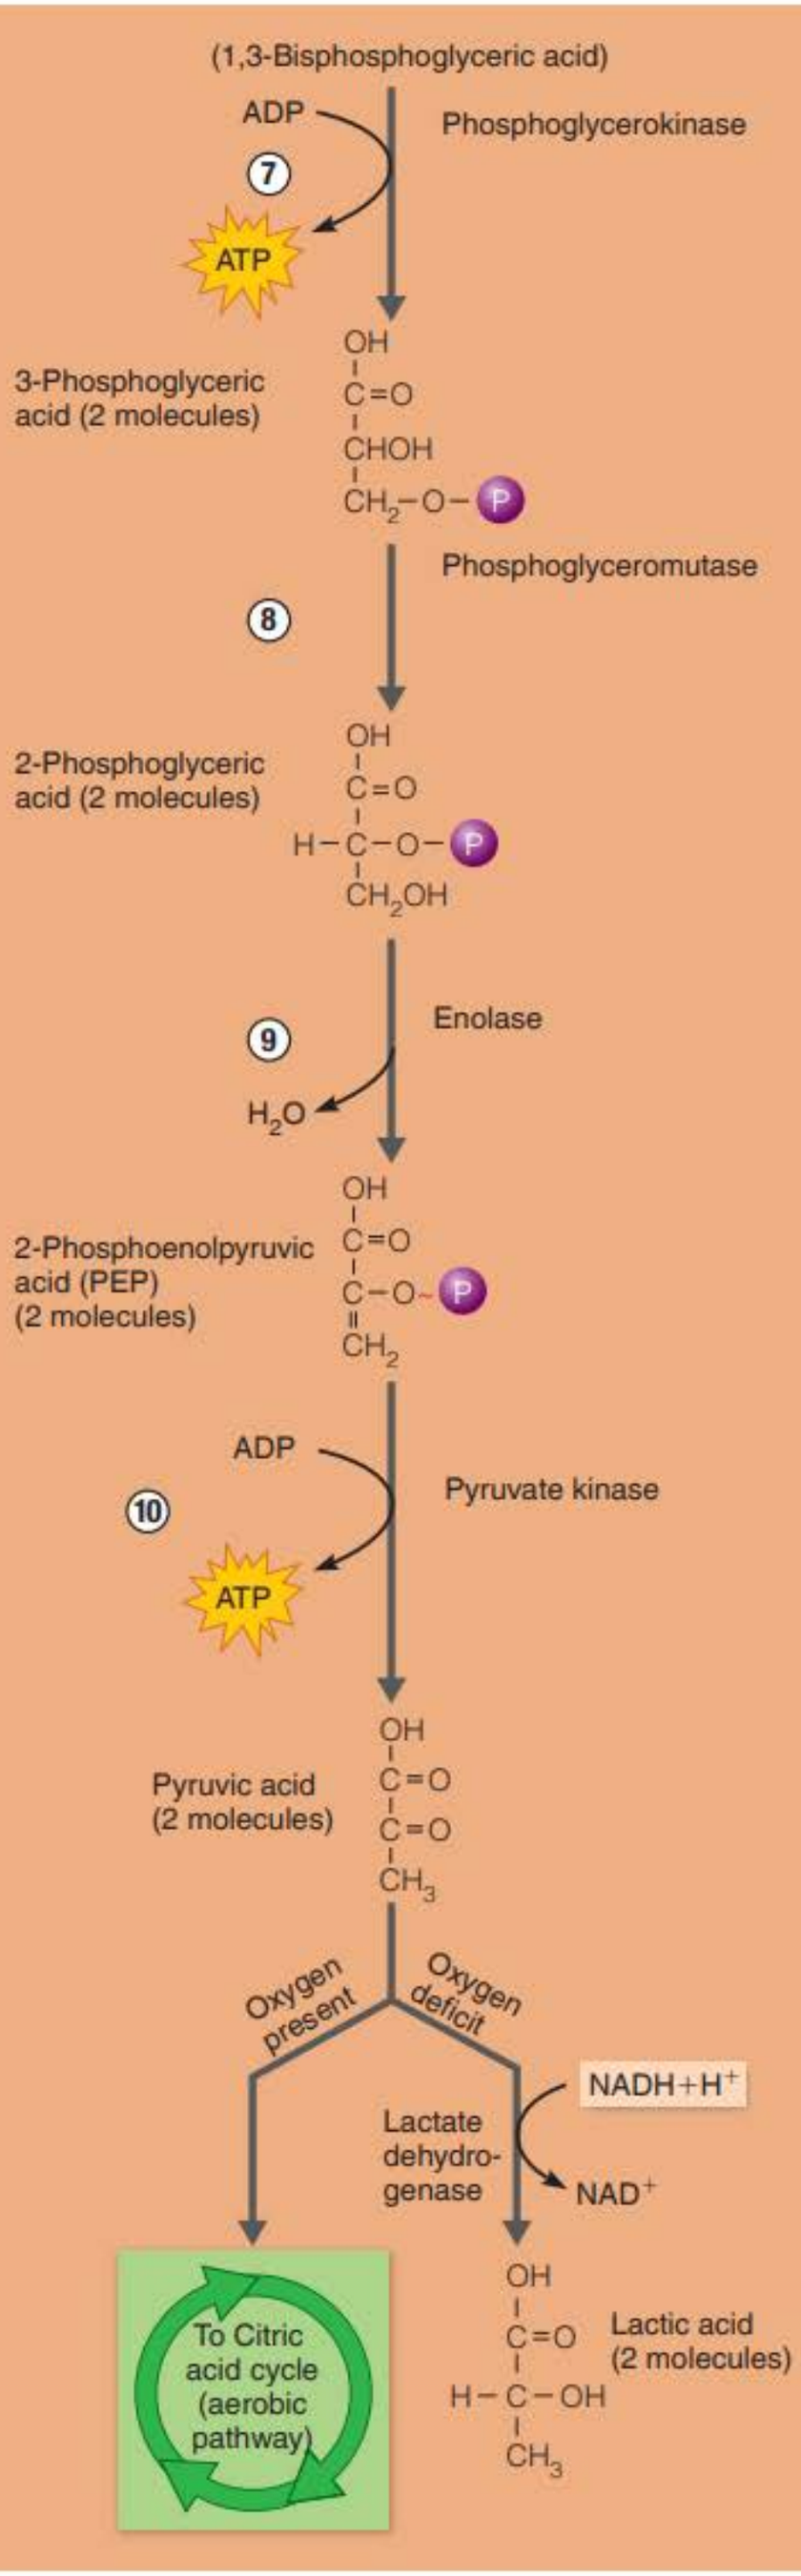
(4) This is the reaction from which glycolysis gets its name. An enzyme cleaves the sugar molecule into two different 3-carbon sugars: glyceraldehyde 3-phosphate and dihydroxyacetone phosphate. These two sugars are isomers of one another.

(5) An isomerase enzyme interconverts the 3-carbon sugars, and if left alone in a test tube, the reaction reaches equilibrium. This does not happen in the cell, however, because the next enzyme in glycolysis uses only glyceraldehyde 3-phosphate as its substrate and not dihydroxyacetone phosphate. This pulls the equilibrium between the two 3-carbon sugars in the direction of glyceraldehyde 3-phosphate, which is removed as fast as it forms. Thus, the net result of steps 4 and 5 is cleavage of a 6-carbon sugar into two molecules of glyceraldehyde 3-phosphate; each will progress through the remaining steps of glycolysis.

(6) An enzyme now catalyzes two sequential reactions while it holds glyceraldehyde 3-phosphate in its active site. First, the sugar is oxidized by the transfer of H from the number one carbon of the sugar to NAD^+, forming $NADH + H^+$. Here we see in metabolic context the oxidation-reduction reaction described in Chapter 24. This reaction releases substantial amounts of energy, and the enzyme capitalizes on this by coupling the reaction to the creation of a high-energy phosphate bond at the number one carbon of the oxidized substrate. The source of the phosphate is inorganic phosphate (P_i) always present in the cytosol. The enzyme releases $NADH + H^+$ and 1,3-bisphosphoglyceric acid as products. Notice in the figure that the new phosphate bond is symbolized with a squiggle (~), which indicates that the bond is at least as energetic as the high-energy phosphate bonds of ATP.



THE TEN STEPS OF GLYCOLYSIS Each of the ten steps of glycolysis is catalyzed by a specific enzyme found dissolved in the cytoplasm. All steps are reversible. An abbreviated version of the three major phases of glycolysis appears in the lower right-hand corner of the next page.



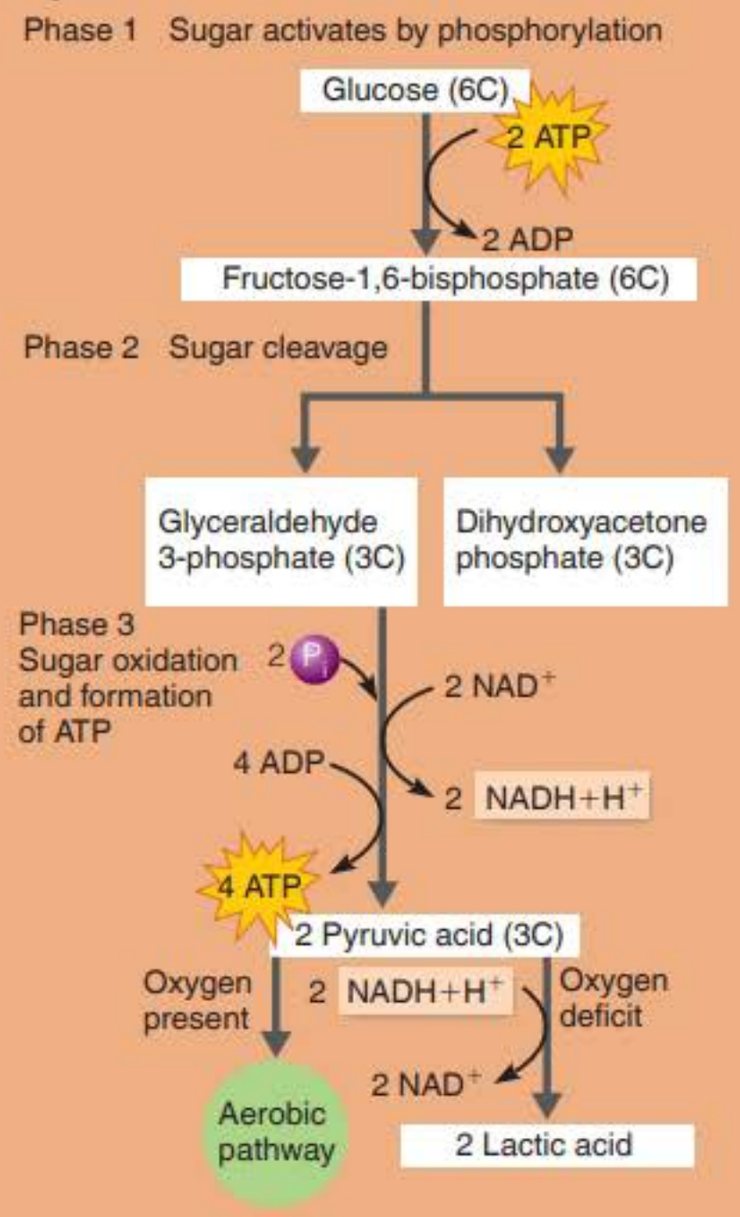
7 Finally, glycolysis produces ATP. The phosphate group, with its high-energy bond, is transferred from 1,3-bisphosphoglyceric acid to ADP. For each glucose molecule that began glycolysis, step 7 produces two molecules of ATP, because every product after the sugar-splitting step (step 4) is doubled. Of course, two ATPs were invested to get sugar ready for splitting. The ATP ledger now stands at zero. By the end of step 7, glucose has been converted to two molecules of 3-phosphoglyceric acid. This compound is not a sugar. The sugar was oxidized to an organic acid back in step 6, and now the energy made available by that oxidation has been used to make ATP.

8 Next, an enzyme relocates the remaining phosphate group of 3-phosphoglyceric acid to form 2-phosphoglyceric acid. This prepares the substrate for the next reaction.

9 An enzyme forms a double bond in the substrate by removing a water molecule from 2-phosphoglyceric acid to form phosphoenolpyruvic acid, or PEP. This results in the electrons of the substrate being rearranged in such a way that the remaining phosphate bond becomes very unstable; it has been upgraded to high-energy status.

10 The last reaction of glycolysis produces another molecule of ATP by transferring the phosphate group from PEP to ADP. Because this step occurs twice for each glucose molecule, the ATP ledger now shows a net gain of two ATPs. Steps 7 and 10 each produce two ATPs for a total credit of four, but a debt of two ATPs was incurred from steps 1 and 3. Glycolysis has repaid the ATP investment with 100% interest. In the meantime, glucose has been broken down and oxidized to two molecules of pyruvic acid, the compound produced from PEP in step 10.

Summary



① Two-carbon acetyl CoA is combined with oxaloacetic acid, a 4-carbon compound. The unstable bond between the acetyl group and CoA is broken as oxaloacetic acid binds and CoA is freed to prime another 2-carbon fragment derived from pyruvic acid. The product is the 6-carbon citric acid, for which the cycle is named.

② A molecule of water is removed, and another is added back. The net result is the conversion of citric acid to its isomer, isocitric acid.

③ The substrate loses a CO_2 molecule, and the remaining 5-carbon compound is oxidized, forming an α-ketoglutaric acid and reducing NAD^+.

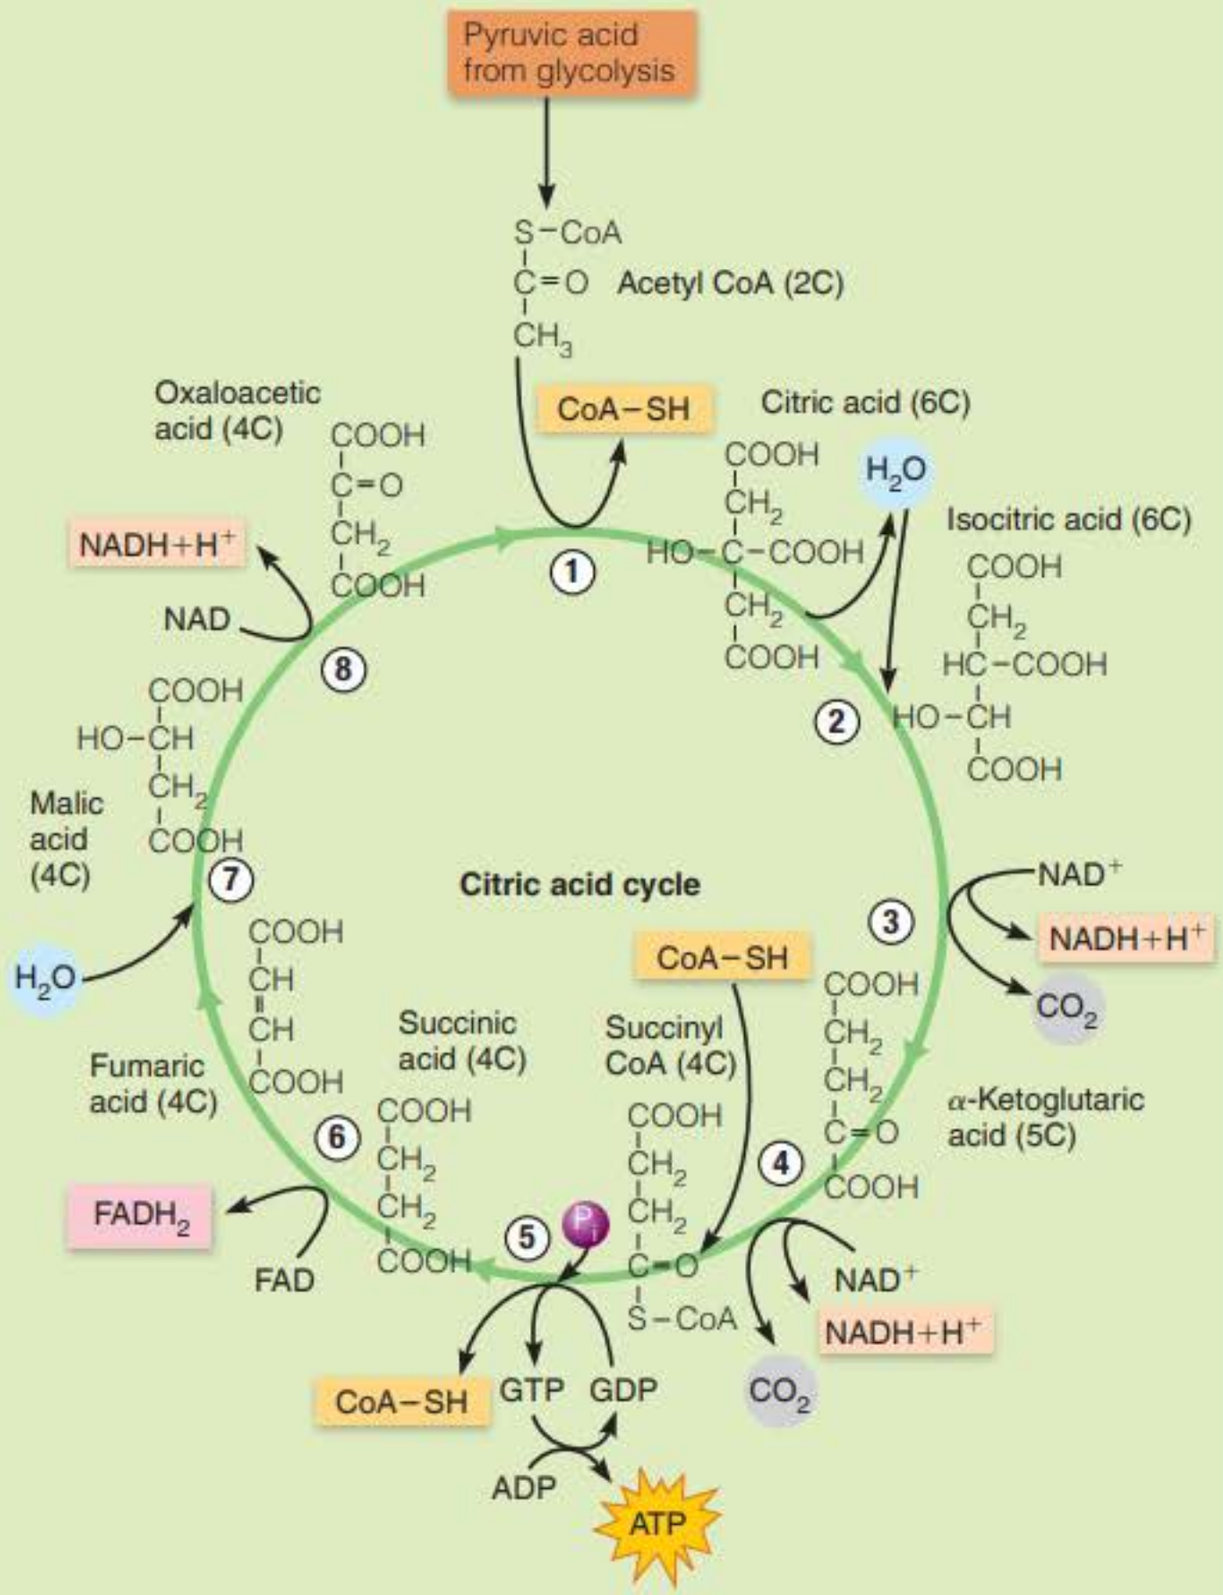
④ This step is catalyzed by a multienzyme complex very similar to the one that converts pyruvic acid to acetyl CoA. CO_2 is lost; the remaining 4-carbon compound is oxidized by the transfer of electrons to NAD^+ to form $NADH+H^+$ and is then attached to CoA by an unstable bond. The product is succinyl CoA.

⑤ Substrate-level phosphorylation occurs in this step. CoA is displaced by a phosphate group, which is then transferred to GDP to form guanosine triphosphate (GTP). GTP is similar to ATP, which is formed when GTP donates a phosphate group to ADP. The products of this step are succinic acid and ATP.

⑥ In another oxidative step, two hydrogens are removed from succinic acid (forming fumaric acid) and transferred to FAD to form $FADH_2$. The function of this coenzyme is similar to that of $NADH+H^+$, but $FADH_2$ stores less energy. The enzyme that catalyzes this oxidation-reduction reaction is the only enzyme of the cycle that is embedded in the mitochondrial membrane. All other enzymes of the citric acid cycle are dissolved in the mitochondrial matrix.

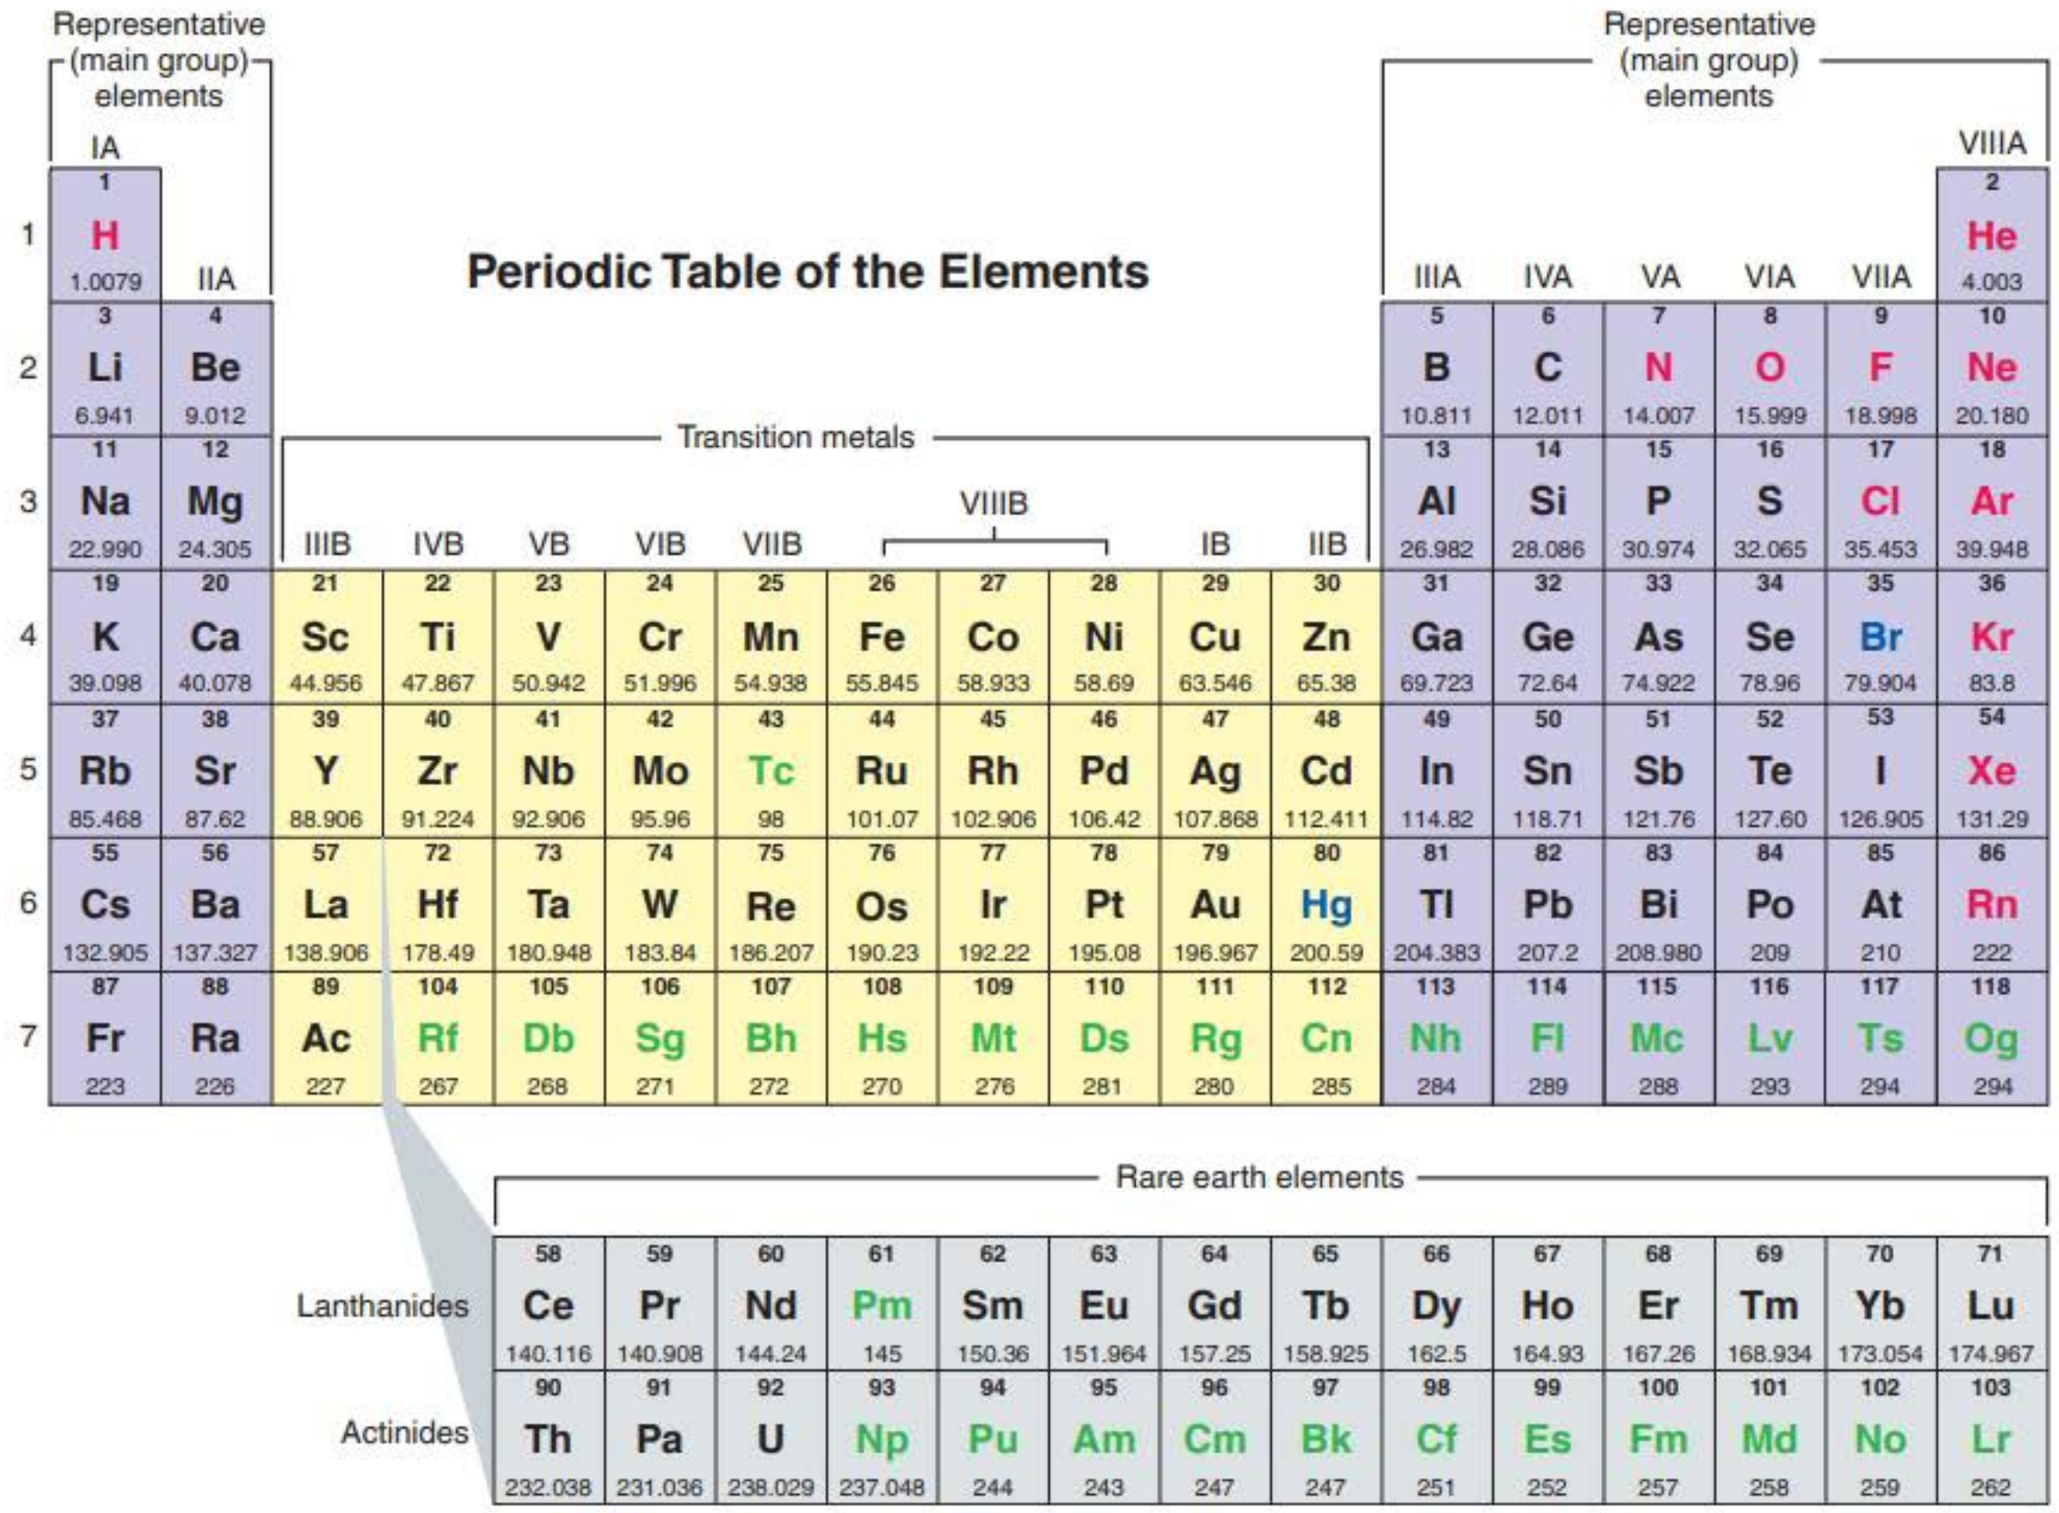
⑦ Bonds in the substrate are rearranged in this step by the addition of a water molecule. The product is malic acid.

⑧ The last oxidative step reduces another NAD^+ and regenerates oxaloacetic acid, which accepts a 2-carbon fragment from acetyl CoA for another turn of the cycle.



CITRIC ACID CYCLE (KREBS CYCLE) All but one of the steps (step 6) occur in the mitochondrial matrix. The preparation of pyruvic acid (by oxidation, decarboxylation, and reaction with coenzyme A) to enter the cycle as acetyl CoA is shown above the cycle. Acetyl CoA is picked up by oxaloacetic acid to form citric acid; and as it passes through the cycle, it is oxidized four more times [forming three molecules of reduced NAD ($NADH + H^+$) and one of reduced FAD ($FADH_2$)] and decarboxylated twice (releasing 2 CO_2). Energy is captured in the bonds of GTP, which then acts in a coupled reaction with ADP to generate one molecule of ATP by substrate-level phosphorylation.

APPENDIX E Periodic Table of the Elements*



The periodic table arranges elements according to atomic number and atomic weight into horizontal rows called periods and 18 vertical columns called groups or families. The elements in the groups are classified as being in either A or B classes.

Elements of each group of the A series have similar chemical and physical properties. This reflects the fact that members of a particular group have the same number of valence shell electrons, which is indicated by the roman numeral of the group. For example, group IA elements have one valence shell electron, group IIA elements have two, and group VA elements have five. In contrast, as you progress across a period from left to right, the properties of the elements change in discrete steps, varying gradually from the very metallic properties of groups IA and IIA elements to the nonmetallic properties seen in group VIIA (chlorine and others), and finally to the inert elements (noble gases) in group VIIIA. This change reflects the continual increase in the number of valence shell electrons seen in elements (from left to right) within a period.

Class B elements are referred to as transition elements. All transition elements are metals, and in most cases they have one or two valence shell electrons. (In these elements, some electrons occupy more distant electron shells before the deeper shells are filled.)

In this periodic table, the colors are used to convey information about the phase (solid, liquid, or gas) in which a pure element exists under standard conditions (25 degrees Celsius and 1 atmosphere of pressure). If the element's symbol is solid black, then the element exists as a solid. If its symbol is red, then it exists as a gas. If its symbol is dark blue, then it is a liquid. If the element's symbol is green, the element does not exist in nature and must be created by some type of nuclear reaction.

* Atomic weights of the elements per IUPAC Commission on Isotopic Abundances and Atomic Weights, 2007.

APPENDIX F

Reference Values for Selected Blood and Urine Studies

The reference values listed for the selected blood and urine studies are common ranges for adults, but specific "normals" are established by the laboratory performing the analysis. The values may be affected by a wide range of circumstances, including testing methods and equipment used, client age, body mass, sex, diet, activity level, medications, and extent of disease processes.

Reference values are identified in both standard or conventional units and in the system of international (SI) units. SI units (given in parentheses) are measurements of amount per volume and are used in most countries and scientific journals. SI units are often given as moles or millimoles per liter. Most clinical laboratories and textbooks in the United States use conventional or standard units, which measure mass per volume. These values are given as grams, milligrams, or milliequivalents per deciliter or liter. It is anticipated that the United States will eventually use SI units exclusively.

For enzymes, 1 international unit (IU) represents an arbitrary but defined amount of activity, whereas 1 katal (kat) is the amount of enzyme required to consume 1 mol of substrate per second.

Sample types in column 1 are serum (S), plasma (P), arterial whole blood (A), and whole blood (WB).

TEST (SAMPLE)	REFERENCE VALUES: CONVENTIONAL (SI)	PHYSIOLOGICAL INDICATION AND CLINICAL IMPLICATIONS
Blood Chemistry Studies		
Ammonia (P)	15–120 µg/dl (9–70 µmol/L)	Liver and renal function. Increased values in liver disease, renal failure, newborn hemolytic disease, heart failure, cor pulmonale. Decreased values in hypertension.
Amylase (S)	56–190 IU/L (0.4–2.1 µkat/L)	Pancreatic function. Increased values in pancreatitis, mumps, obstruction of pancreatic duct, ketoacidosis. Decreased values in kidney disease, pancreatic damage or cancer, toxemia of pregnancy.
Aspartate aminotransferase (AST, or SGOT) (S)	≤40 IU/L (≤0.7 µkat/L)	Cellular damage. Increased after myocardial infarction, acute liver disease, drug toxicity, muscle trauma. Decreased in pyridoxine (vitamin B_6) deficiency.
Bilirubin (S)	Total: 0.1–1.0 mg/dl (1.7–17.1 µmol/L) Direct: <0.4 mg/dl (<6.8 µmol/L) Indirect: 0.1–1.0 mg/dl (1.7–17.1 µmol/L) Newborn: <13.0 mg/dl (<222 µmol/L)	Liver function and red cell breakdown. Increased levels of direct in liver disease and biliary obstruction. Increased levels of indirect in hemolysis of red blood cells.
Blood urea nitrogen (S)	7–26 mg/dl (2.5–9.3 mmol/L)	Kidney function. Increased values in renal disease, dehydration, urinary obstruction, congestive heart failure, myocardial infarction, burns. Decreased values in liver failure, overhydration, impaired protein absorption, pregnancy.
Cholesterol	<200 mg/dl (<5.2 mmol/L)	Metabolism—fat utilization. Increased values in diabetes mellitus, pregnancy, use of oral contraceptives or anabolic steroids.
High-density lipoprotein (HDL) cholesterol (S)	20–30% of total >40 mg/dl (>1.0 mmol/L)	Increased levels in liver disease, aerobic exercise. Decreased levels in atherosclerotic heart disease, malnutrition.
Low-density lipoprotein (LDL) cholesterol (S)	60–70% of total <130 mg/dl (<3.4 mmol/L)	Increased values in hyperlipidemia, atherosclerotic heart disease. Decreased values in fat malabsorption and malnutrition.
Very low density lipoprotein cholesterol (VLDL) (S)	10–15% of total	Same as LDL.
Creatine kinase (CK) (S)	Female: ≤190 U/L (≤3.2 µkat/L) Male: ≤235 U/L (≤3.9 µkat/L)	Cellular damage. Increased values in myocardial infarction, muscular dystrophy, hypothyroidism, pulmonary infarction, cerebrovascular accident (CVA), shock, tissue damage, and trauma.
Creatinine (S)	0.5–1.2 mg/dl (44–106 µmol/L)	Renal function. Increased values in renal disease and acromegaly. Decreased in muscular dystrophy.

TEST (SAMPLE)	REFERENCE VALUES: CONVENTIONAL (SI)	PHYSIOLOGICAL INDICATION AND CLINICAL IMPLICATIONS
Blood Chemistry Studies *(continued)*		
Gases (A)		
Bicarbonate	22–26 mEq/L (22–26 mmol/L)	
Carbon dioxide content	Arterial: 19–24 mEq/L (19–24 mmol/L) Venous: 22–30 mEq/L (22–30 mmol/L)	Acid-base balance. Increased values in metabolic alkalosis and respiratory acidosis. Decreased values in metabolic acidosis and respiratory alkalosis.
Carbon dioxide partial pressure (P_{CO_2})	Arterial: 35–45 mm Hg Venous: 45 mm Hg	
Oxygen (O_2) saturation	95–98% (same)	Values increased slightly in hyperventilation. Decreased values (hypoxia) in pulmonary disease, hypoventilation, high altitude.
Oxygen partial pressure (P_{O_2})	80–105 mm Hg	
pH	7.35–7.45 (same)	Increased values in metabolic and respiratory alkalosis. Decreased values in metabolic and respiratory acidosis.
Glucose (S)	70–120 mg/dl (3.9–6.7 mmol/L)	Metabolic function. Increased values in diabetes mellitus, Cushing's syndrome, liver disease, acute stress, and acromegaly. Decreased levels in Addison's disease, insulinomas.
Immunoglobulins (S)		
IgG	560–1800 mg/dl (5.6–18 g/L)	Immune response. Increased levels in chronic infections, rheumatic fever, liver disease, rheumatoid arthritis. Decreased levels in amyloidosis, leukemia, and preeclampsia.
IgE	<43.2 µg/dl (<432 µg/L)	Allergic responses. Increased values in allergic responses. Decreased values in agammaglobulinemia.
IgA	85–563 mg/dl (0.85–5.6 g/L)	Immune integrity. Increased values in liver disease, rheumatic fever, chronic infection, inflammatory bowel disease. Decreased values in immunodeficiency disorders and immunosuppression.
IgM	55–375 mg/dl (0.5–3.8 g/L)	Immune integrity. Increased in autoimmune disease (e.g., rheumatoid arthritis), acute infections. Decreased in amyloidosis and leukemia.
IgD	0.5–14 mg/dl (5–140 mg/L)	Immune integrity. Increased values in myelomas.
Ketone bodies (S or P)	Negative Toxic level ≥20 mg/dl (0.2 g/L)	Fatty acid catabolism. Increased values (ketosis, ketoacidosis) in starvation, low-carbohydrate diet, uncontrolled diabetes mellitus, aspirin overdose.
Lactate dehydrogenase (LDH) (S)	105–333 U/L (1.7–5.6 µkat/L)	Tissue damage of organs or striated muscle. Increased in myocardial infarction, pulmonary infarction, liver disease, cerebrovascular accident, infectious mononucleosis, muscular dystrophy, fractures.
Lactic acid (lactate) (P)	9–16 mg/dl (1.0–1.8 mmol/L)	Anaerobic tissue metabolism. Increased values in congestive heart failure, shock, hemorrhage, strenuous exercise.
Osmolality (S)	280–300 mOsm/kg H_2O (280–300 mmol/kg H_2O)	Fluid and electrolyte balance. Increased levels in hypernatremia, dehydration, kidney disease, alcohol ingestion. Decreased levels in hyponatremia, overhydration, and syndrome of inappropriate ADH secretion (SIADH).
Phosphate (S) (phosphorus)	2.5–4.5 mg/dl (0.8–1.5 mmol/L)	Parathyroid function; bone disease. Increased levels in hypoparathyroidism, renal failure, bone metastasis, hypocalcemia. Decreased values in hyperparathyroidism, hypercalcemia, alcoholism, vitamin D deficiency, ketoacidosis, osteomalacia.
Potassium (S)	3.5–5.5 mEq/L (3.5–5.5 mmol/L)	Fluid and electrolyte balance. Increased levels in renal disease, Addison's disease, ketoacidosis, burns, and crush injuries. Decreased levels in vomiting, diarrhea, Cushing's syndrome, alkalosis, diuretics.

TEST (SAMPLE)	REFERENCE VALUES: CONVENTIONAL (SI)	PHYSIOLOGICAL INDICATION AND CLINICAL IMPLICATIONS
Blood Chemistry Studies *(continued)*		
Protein (S)		
Total	6.0–8.5 g/dl (60–85 g/L)	Osmotic pressure; immune system integrity. Increased values in multiple myeloma, dehydration, myxedema. Decreased values in protein malnutrition, burns, diarrhea, renal failure, liver failure.
Albumin	3.2–5.0 g/dl (32–50 g/L)	Osmotic pressure. Increased levels in dehydration. Decreased levels in liver disease, malnutrition, Crohn's disease, nephrotic syndrome, systemic lupus erythematosus.
Sodium (S)	135–145 mEq/L (135–145 mmol/L)	Fluid and electrolyte balance. Increased values in dehydration, diabetes insipidus, Cushing's syndrome. Decreased values in vomiting, diarrhea, burns, Addison's disease, myxedema, congestive heart failure, overhydration, syndrome of inappropriate ADH secretion (SIADH).
Triglycerides	10–150 mg/dl (0.1–1.5 g/L)	Increased values in diabetes mellitus, liver disease, nephrotic syndrome, pregnancy.
Uric acid (S)	Female: 2.0–7.3 mg/dl (119–434 µmol/L) Male: 2.1–8.5 mg/dl (125–506 µmol/L)	Renal function. Increased in lead poisoning, impaired renal function, gout, alcoholism, hematologic cancers. Decreased in Wilson's disease.
Hematology Studies		
Hemoglobin (S)	Female: 12–16 g/dl (120–160 g/L) Male: 13–18 g/dl (130–180 g/L)	Oxygenation status. Increased values in dehydration, polycythemia, congestive heart failure, chronic obstructive pulmonary disease, high altitudes. Decreased levels in anemia, hemorrhage, bone marrow cancer, renal disease, systemic lupus erythematosus, nutritional deficiency.
Hematocrit (WB)	Female: 37–47% (same) Male: 42–52% (same)	Oxygenation status. Increased levels in polycythemia, dehydration, congestive heart failure, shock, surgery. Decreased levels in anemia, hemorrhage, bone marrow disease, malnutrition, cirrhosis, rheumatoid arthritis.
Partial thromboplastin time (activated) (PTT or aPTT)	20–36 s (same)	Clotting mechanisms. Increased values in clotting factor deficiencies, cirrhosis, vitamin K deficiency, disseminated intravascular coagulation (DIC). Decreased values in early DIC, extensive cancer.
Platelet count (WB)	150,000–400,000/µl ($150–400 \times 10^9$/L)	Clotting mechanisms. Increased values in polycythemia, cancers, rheumatoid arthritis, trauma. Decreased values in liver disease, hemolytic uremic syndrome, disseminated intravascular coagulation (DIC), idiopathic thrombocytopenic purpura (ITP), systemic lupus erythematosus (SLE).
Prothrombin time (PT) (WB)	11–12.5 s (same) Reported as INR, a ratio to a standard time	Clotting mechanisms. Increased values in liver disease, vitamin K deficiency, salicylate intoxication. Decreased values in disseminated intravascular coagulation (DIC).
Red blood cell count (RBC) (WB)	Female: 4.2–5.4 million/µl ($4.2–5.4 \times 10^{12}$/L) Male: 4.7–6.1 million/µl ($4.7–6.1 \times 10^{12}$/L)	Oxygenation status. Increased values in high altitudes, polycythemia, hemoconcentration, cor pulmonale. Decreased values in hemorrhage, hemolysis, anemias, chronic illness, nutritional deficiencies, leukemia, overhydration.
Reticulocyte count (WB)	0.5–2.0% (same)	Bone marrow function. Increased values in hemolytic anemia, sickle-cell anemia, leukemia, pregnancy. Decreased values in pernicious anemia, folic acid deficiency, cirrhosis, chronic infection, bone marrow depression or failure.
White blood cell count (WBC) (WB)		
Total	4800–10,800/µl ($4.8–10.8 \times 10^9$/L)	Immune system integrity. Increased values in infection, trauma, stress, tissue necrosis, inflammation. Decreased values in bone marrow depression or failure, drug toxicity, overwhelming infection, malnutrition.

TEST (SAMPLE)	REFERENCE VALUES: CONVENTIONAL (SI)	PHYSIOLOGICAL INDICATION AND CLINICAL IMPLICATIONS
Hematology Studies *(continued)*		
White blood cell count, differential (WB)		
Neutrophils	50–70% (same)	Immune system integrity. Increased values in acute bacterial infections, stress, Cushing's syndrome, inflammatory disorders, ketoacidosis, gout. Decreased levels in aplastic anemia, bone marrow suppression, and overwhelming bacterial infections.
Lymphocytes	25–40% (same)	Immune system integrity. Increased values in viral infections (e.g., mumps, rubella, infectious mononucleosis, hepatitis), lymphocytic leukemia, certain bacterial infections. Decreased levels in leukemia, immunodeficiency, lupus erythematosus, bone marrow depressive drugs.
Eosinophils	1–4% (same)	Immune system integrity. Increased levels in allergic reactions, parasitic infections, leukemia. Decreased levels in excess adrenocorticosteroid production.
Monocytes	3–8% (same)	Immune system integrity. Increased levels in certain infections (e.g., tuberculosis, malaria), inflammatory disorders.
Basophils	0.5–1.0% (same)	Immune system integrity. Increased levels in myeloproliferative disorders, leukemia. Decreased levels in allergic reactions, hyperthyroidism, stress.
Urine Tests		
Amylase (24 h)	<6000 Somogyi units/24 h 0–500 U/24 h (0–8.3 μkat/24 h)	Pancreatic function. Increased values in pancreatic disease or obstruction, inflammation of the salivary glands, and cholecystitis.
Bilirubin (random)	Negative (same)	Liver function. Increased values in liver disease, extrahepatic obstruction (gallstones, tumor, inflammation).
Blood (hemoglobin) (random)	Negative (same)	Urinary system function. Increased values in cystitis, renal disease, hemolytic anemia, transfusion reaction, prostatitis, burns.
Osmolality (random or fasting)	Random: 50–1200 mOsm/kg H_2O (50–1200 mmol/kg H_2O) Fluid restriction: ≥850 mOsm/kg H_2O (≥850 mmol/kg H_2O)	Fluid and electrolyte balance, renal function, and endocrine function. Increased levels in hypernatremia, syndrome of inappropriate ADH secretion (SIADH), congestive heart failure, metabolic acidosis. Decreased levels in diabetes insipidus, water intoxication, pyelonephritis, renal tubular necrosis, aldosteronism.
Phosphate (24 h)	0.9–1.3g/24 hr (same)	Parathyroid function. Increased levels in hyperparathyroidism, osteomalacia, certain renal diseases, vitamin D deficiency. Decreased levels in hypoparathyroidism.
Potassium (24 h)	25–125 mEq/24 h (25–125 mmol/24 h)	Fluid and electrolyte balance. Increased values in renal tubular necrosis, metabolic acidosis, dehydration, aldosteronism, Cushing's syndrome. Decreased values in Addison's disease, malabsorption, acute renal failure.
Protein (random)	<8 mg/dl (<80 mg/L)	Renal function. Increased levels in nephrotic syndrome, renal trauma, hyperthyroidism, diabetic nephropathy, systemic lupus erythematosus.
Sodium (24 h)	40–220 mEq/24 h (40–220 mmol/24 h)	Fluid and electrolyte balance. Increased values in dehydration, ketoacidosis, syndrome of inappropriate ADH secretion (SIADH), adrenocortical insufficiency. Decreased levels in congestive heart failure, renal failure, diarrhea, aldosteronism.
Uric acid (24 h)	250–750 mg/24 h (1.5–4.5 mmol/24 h)	Renal function and metabolism. Increased in gout, leukemia, liver disease, ulcerative colitis. Decreased in renal disease, alcoholism, lead toxicity, folic acid deficiency.

TEST (SAMPLE)	REFERENCE VALUES: CONVENTIONAL (SI)	PHYSIOLOGICAL INDICATION AND CLINICAL IMPLICATIONS
Urine Tests *(continued)*		
Urinalysis (random)		
Color	Straw, yellow, amber	Fluid balance and renal function. Darker in dehydration. Lighter in overhydration, diabetes insipidus. Color varies with disease states, diet, and medications.
Odor	Aromatic	Metabolic function, infection. Abnormal odors in infection, ketonuria, rectal fistula, hepatic failure, phenylketonuria.
Specific gravity	1.001–1.035	An indirect measurement of urine concentration (osmolality). Same physiological indications and clinical implications as osmolality.
pH	4.5–8.0	A crude indicator of acid-base balance. Decreased by acidic diet (proteins). Increased by a vegetarian diet, prolonged vomiting, and bacterial infection of the urinary tract.
Urobilinogen (24 h)	0.2–1.0 mg/dl (2–10 mg/L)	Liver function. Increased in hemolytic anemias, hepatitis, cirrhosis, biliary disease. Decreased in common bile duct obstruction.
Volume (24 h)	800–2000 ml/24 h (0.8–2.0 L/24 h)	Fluid and electrolyte balance, renal function. Increased values in diabetes insipidus, diabetes mellitus, renal disease. Decreased values in dehydration, syndrome of inappropriate ADH secretion (SIADH), renal disease.

Glossary

Pronunciation Key

′ = Primary accent

″ = Secondary accent

Pronounce:

a, fa, āt	as in	fate	o, no, ōt	as in	note
ă, hă, at		hat	ŏ, frŏ, og		frog
ah		father	oo		soon
ar		tar	or		for
e, stre, ēt		street	ow		plow
ĕ, hĕ, en		hen	oy		boy
er		her	sh		she
ew		new	u, mu, ūt		mute
g		go	ŭ, sŭ, un		sun
i, bi, īt		bite	z		zebra
ĭ, hĭ, im		him	zh		measure
ng		ring			

Abduct (ab-dukt′) To move away from the midline of the body.

Absolute refractory period Period following stimulation during which no additional action potential can be evoked.

Absorption Process by which the products of digestion pass through the alimentary canal mucosa into the blood or lymph.

Accessory digestive organs Organs that contribute to the digestive process but are not part of the alimentary canal; include the tongue, teeth, salivary glands, pancreas, liver.

Accommodation The process of increasing the refractive power of the lens of the eye to focus on near objects.

Acetabulum (as″ĕ-tab′u-lum) Cuplike cavity on lateral surface of the hip bone that receives the femur.

Acetylcholine (ACh) (as″ĕ-til-ko′lēn) Chemical transmitter substance released by some nerve endings.

Acetylcholinesterase (AChE) (as″ĕ-til-ko″lin-es′ter-ās) Enzyme that degrades acetylcholine and terminates its action at the neuromuscular junction and synapses.

Achilles tendon *See* Calcaneal tendon.

Acid A substance that releases hydrogen ions when in solution (compare with Base); a proton donor.

Acid-base balance Situation in which the pH of the blood is maintained between 7.35 and 7.45.

Acidosis (as″ĭ-do′sis) State of abnormally high hydrogen ion concentration in the extracellular fluid.

Actin (ak′tin) A cytoskeletal element; a contractile protein of muscle.

Action potential (AP) A large transient depolarization event, including polarity reversal, that is propagated along the membrane of a muscle cell or an axon of a neuron.

Activation energy The amount of energy required to push a reactant to the level necessary for action.

Active immunity Immunity produced by an encounter with an antigen; provides immunological memory.

Active site Region on the surface of a functional (globular) protein where it binds and interacts chemically with other molecules of complementary shape and charge.

Active (transport) processes (1) Membrane transport processes for which ATP is directly or indirectly required, e.g., solute pumping and endocytosis. (2) "Active transport" also refers specifically to solute pumping.

Adaptation (1) Any change in structure or response to suit a new environment; (2) decline in the frequency of action potentials in a sensory nerve when a receptor is stimulated continuously and at constant stimulus strength.

Adduct (a-dukt′) To move toward the midline of the body.

Adenine (A) (ad′ĕ-nēn) One of the two major purines found in both RNA and DNA; also found in various free nucleotides of importance to the body, such as ATP.

Adenohypophysis (ad″ĕ-no-hi-pof′ĭ-sis) *See* Anterior pituitary.

Adenoids (ad′en-noids) Pharyngeal tonsil.

Adenosine triphosphate (ATP) (ah-den′o-sēn tri″fos′fāt) Organic molecule that stores and releases chemical energy for use in body cells.

Adenylate cyclase Enzyme that makes the second messenger cyclic AMP (cAMP) from ATP.

Adipocyte (ad′ĭ-po-sīt) An adipose, or fat, cell.

Adipose tissue (ad′ĭ-pōs) Areolar connective tissue modified to store fat; a connective tissue consisting chiefly of adipocytes.

Adrenal glands (ah-drē′nul) Hormone-producing glands located superior to the kidneys; each consists of medulla and cortex areas.

Adrenergic fibers (ad″ren-er′jik) Axons with axon terminals that, upon stimulation, release norepinephrine.

Adrenocorticotropic hormone (ACTH) (ah-dre″no-kor″tĭ-ko-trop′ik) Anterior pituitary hormone that influences the activity of the adrenal cortex.

Adventitia (ad″ven-tish′e-ah) Outermost layer or covering of some organs.

Aerobic (a′er-ōb″ik) Oxygen-requiring.

Aerobic endurance The length of time a muscle can continue to contract using aerobic pathways.

Aerobic respiration Respiration in which oxygen is consumed and glucose is broken down entirely; water, carbon dioxide, and large amounts of ATP are the final products.

Afferent (af′er-ent) Carrying to or toward a center.

Afferent (sensory) nerve Nerve that contains axons of sensory neurons and carries action potentials to the central nervous system.

Agglutination (ah-gloo″tĭ-na′shun) Clumping of (foreign) cells; induced by cross-linking of antigen-antibody complexes.

Agonist (ag′o-nist) Muscle that bears the major responsibility for effecting a particular movement; a prime mover.

Albumin (al-bu′min) The most abundant plasma protein.

Aldosterone (al-dos′ter-ōn) Hormone produced by the adrenal cortex that regulates Na^+ reabsorption and K^+ secretion by the kidneys.

Alimentary canal (al″ĭ-men′tar-e) The continuous hollow tube extending from the mouth to the anus; its walls are constructed by the oral cavity, pharynx, esophagus, stomach, and small and large intestines.

Alkalosis (al″kah-lo′sis) State of abnormally low hydrogen ion concentration in the extracellular fluid.

Allantois (ah″lan′to-is) Embryonic membrane; its blood vessels develop into blood vessels of the umbilical cord.

Alleles Genes coding for the same trait and found at the same locus on homologous chromosomes.

Allergy A type of hypersensitivity (overzealous immune response to an otherwise harmless antigen) that involves IgE antibodies and histamine release.

Alopecia (al″o-pe′she-ah) Baldness.

Alpha (α)-helix The most common type of secondary structure of the amino acid chain in proteins; resembles a coiled spring.

Alveolar (acinar) gland (al-ve′o-lar) A gland whose secretory cells form small, flasklike sacs.

Alveolar ventilation rate (AVR) An index of respiratory efficiency; measures volume of fresh air that flows in and out of alveoli.

Alveolus (al-ve′o-lus) (1) One of the microscopic air sacs of the lungs; (2) tiny milk-producing glandular sac in the breast; (3) tooth socket.

Alzheimer's disease (AD) (altz′hi-merz) Degenerative brain disease resulting in progressive loss of memory and motor control, and increasing dementia.

Amino acid (ah-me′no) Organic compound containing nitrogen, carbon, hydrogen, and oxygen; building block of protein.

Ammonia (NH_3) Common waste product of protein breakdown in the body; a colorless volatile gas, very soluble in water and capable of acting as a weak base; a proton acceptor.

Amnion (am′ne-on) Fetal membrane that forms a fluid-filled sac around the embryo.

Amoeboid motion (ah-me′boyd) The flowing movement of the cytoplasm of a phagocyte as it moves across a surface.

Amphiarthrosis (am″fe-ar-thro′sis) A slightly movable joint.

Ampulla (am-pul′lah) A localized dilation of a canal or duct.

Amylase Digestive system enzyme that breaks down starchy foods.

Anabolism (ah-nab′o-lizm) Energy-requiring building phase of metabolism in which simpler substances are combined to form more complex substances.

Anaerobic (an-a′er-ōb-ik) Not requiring oxygen.

Anaerobic threshold The point at which muscle metabolism converts to anaerobic glycolysis.

Anaphase Third stage of mitosis, meiosis I, and meiosis II in which chromosomes move toward each pole of a cell.

Anastomosis (ah-nas″to-mo′sis) A union or joining of nerves, blood vessels, or lymphatic vessels.

Anatomy Study of the structure of living organisms.

Androgen (an′dro-jen) A hormone such as testosterone that controls male secondary sex characteristics.

Anemia (ah-ne′me-ah) Reduced oxygen-carrying ability of blood resulting from too few erythrocytes or abnormal hemoglobin.

Aneurysm (an′u-rizm) Blood-filled sac in an artery wall caused by dilation or weakening of the wall.

Angina pectoris (an′jĭ-nah pek′tor-is) Severe suffocating chest pain caused by brief lack of oxygen supply to heart muscle.

Angiotensin II (an″je-o-ten′sin) Triggers release of aldosterone; also a potent vasoconstrictor, and stimulates thirst and antidiuretic hormone release. Part of renin-angiotensin-aldosterone mechanism.

Anion (an′i-on) An ion with a negative charge.

Anoxia (ah-nok′se-ah) Deficiency of oxygen.

Antagonist (an-tag′o-nist) (1) Muscle that reverses, or opposes, the action of another muscle. (2) Hormone that opposes the action of another hormone.

Anterior pituitary The glandular part of the pituitary gland. Also called adenohypophysis.

Antibody A protein molecule that is released by a plasma cell (a daughter cell of an activated B lymphocyte) and that binds specifically to an antigen; an immunoglobulin.

Anticodon (an″ti-ko′don) The three-base sequence complementary to the messenger RNA (mRNA) codon.

Antidiuretic hormone (**ADH**, also called vasopressin) (an″ti-di″yer-eh′tik) Hormone produced by the hypothalamus and released by the posterior pituitary; stimulates the kidneys to reabsorb more water, reducing urine volume.

Antigen (an′tĭ-jen) A substance or part of a substance (living or nonliving) that is recognized as foreign by the immune system, activates the immune system, and reacts with immune cells or their products.

Antigen-presenting cell (APC) A specialized cell (dendritic cell, macrophage, or B cell) that captures, processes, and presents antigens on its surface to T lymphocytes.

Anucleate cell (a-nu′kle-āt) A cell without a nucleus.

Anus (a′nus) Distal end of digestive tract; outlet of rectum.

Aorta (a-or′tah) Major systemic artery; arises from the left ventricle of the heart.

Aortic body Receptor in the aortic arch sensitive to changing oxygen, carbon dioxide, and pH levels of the blood.

Apnea Breathing cessation.

Apocrine sweat gland (ap′o-krin) The less numerous type of sweat gland; produces a secretion containing water, salts, proteins, and fatty acids.

Apoenzyme (ap′ō-en-zīm) The protein portion of an enzyme.

Aponeurosis (ap″o-nu-ro′sis) Fibrous or membranous sheet connecting a muscle and the part it moves.

Apoptosis A process of controlled cellular suicide; eliminates cells that are unneeded, stressed, or aged.

Appendicitis (ă-pen′dĭ-sī′tis) Inflammation of the appendix (wormlike sac attached to the cecum of the large intestine).

Appendicular Relating to the limbs; one of the two major divisions of the skeleton.

Appositional growth Growth accomplished by the addition of new layers onto those previously formed.

Aquaporins (ă″kwă-por′ins) Transmembrane proteins that form water channels.

Aqueous humor (a′kwe-us) Watery fluid in the anterior segment of the eye.

Arachnoid (ah-rak′noid) Weblike; specifically, the weblike arachnoid mater, the middle layer of the three meninges.

Areola (ah-re′o-lah) (1) Circular, pigmented area surrounding the nipple; (2) any small space in a tissue.

Areolar connective tissue A type of loose connective tissue.

Arrector pili (ah-rek′tor pi′li) Tiny, smooth muscles attached to hair follicles; contraction causes the hair to stand upright.

Arrhythmia (a-rith′me-ah) Irregular heart rhythm, often caused by defects in the intrinsic conduction system.

Arteries Blood vessels that conduct blood away from the heart and into the circulation.

Arteriole (ar-tēr′e-ōl) A minute artery.

Arteriosclerosis (ar-tēr′e-o-skler-o′sis) Any of a number of proliferative and degenerative changes in the arteries leading to their decreased elasticity.

Arthritis Inflammation of the joints.

Arthroscopic surgery (ar-thro-skop′ik) Procedure enabling a surgeon to repair the interior of a joint through a small incision.

Articular capsule Double-layered capsule composed of an outer fibrous layer lined by synovial membrane; encloses the joint cavity of a synovial joint.

Articular cartilage Hyaline cartilage covering bone ends at movable joints.

Articulation (joint) The junction of two or more bones.

Association areas Functional areas of the cerebral cortex that act mainly to integrate diverse information for purposeful action.

Astigmatism (ah-stig′mah-tiz-em) A condition in which unequal curvatures in different parts of the cornea or lens of the eye lead to blurred vision.

Astrocyte (as′tro-sīt) A type of CNS supporting cell; assists in exchanges between blood capillaries and neurons.

Atelectasis (at″ĕ-lek′tah-sis) Lung collapse.

Atherosclerosis (a″ther-o″skler-o′sis) Changes in the walls of large arteries consisting of lipid deposits on the artery walls; one form of arteriosclerosis.

Atmospheric pressure Force that air exerts on the surface of the body (760 mm Hg at sea level).

Atom Smallest particle of an elemental substance that exhibits the properties of that element; composed of protons, neutrons, and electrons.

Atomic number The number of protons in an atom.

Atomic symbol The one- or two-letter symbol used to indicate an element; usually the first letter(s) of the element's name.

Atomic weight The average of the mass numbers of all the isotopes of an element.

ATP *See* Adenosine triphosphate.

Atria (a′tre-ah) The two superior receiving chambers of the heart.

Atrial natriuretic peptide (ANP) (a′tre-al na″tre-u-ret′ik) A hormone released by certain cells of the heart atria that reduces blood pressure and blood volume by inhibiting nearly all events that promote Na^+ and water retention and vasoconstriction.

Atrioventricular (AV) bundle (a″tre-o-ven-trĭ′kyoo-ler) Bundle of specialized fibers that conduct impulses from the AV node to the right and left ventricles; also called bundle of His.

Atrioventricular (AV) node Specialized mass of conducting cells located at the atrioventricular junction in the heart.

Atrioventricular (AV) valve Valve that prevents backflow into the atrium when the connected ventricle is contracting.

Atrophy (at′ro-fe) Reduction in size or wasting away of an organ or cell resulting from disease or lack of use.

Auditory ossicles (ah′sĭ-kulz) The three tiny bones serving as transmitters of vibrations and located within the middle ear: the malleus, incus, and stapes.

Auditory tube *See* Pharyngotympanic tube.

Autoimmunity Production of antibodies or effector T cells that attack a person's own tissue.

Autolysis (aw″tol′ĭ-sis) Process of autodigestion (self-digestion) of cells, especially dead or degenerate cells.

Autonomic ganglion Collection of sympathetic or parasympathetic postganglionic neuronal cell bodies.

Autonomic nervous system (ANS) Efferent division of the peripheral nervous system that innervates cardiac and smooth muscles and glands; also called the involuntary or visceral motor system.

Autonomic (visceral) reflexes Reflexes that activate smooth or cardiac muscle and/or glands.

Autoregulation The automatic local adjustment of blood flow to a particular body area in response to its current requirements.

Autosomes Chromosomes number 1 to 22; do not include the sex chromosomes.

Avogadro's number (av″o-gad′rōz) The number of molecules in one mole of any substance, 6.02×10^{23}.

Axial Relating to the head, neck, and trunk; one of the two major divisions of the skeleton.

Axon Neuron process that carries action potentials away from the nerve cell body; efferent process; the conducting portion of a nerve cell.

Axon terminals The bulbous distal endings of the terminal branches of an axon where neurotransmitters are released.

B cells Also called B lymphocytes; oversee humoral immunity; their descendants differentiate into antibody-producing plasma cells.

Baroreceptor (bayr″o-re-sep′tor) A sensory nerve ending in the wall of the carotid sinus or aortic arch sensitive to vessel stretching.

Basal body (ba′sal) An organelle structurally identical to a centriole and forming the base of a cilium or flagellum.

Basal ganglia *See* Basal nuclei.

Basal lamina (lam′ĭ-nah) Noncellular, adhesive supporting sheet consisting largely of glycoproteins secreted by epithelial cells.

Basal metabolic rate (BMR) Rate at which energy is expended (heat produced) by the body per unit time under controlled (basal) conditions: 12 hours after a meal, at rest.

Basal nuclei (basal ganglia) Specific gray matter areas located deep within the white matter of the cerebral hemispheres.

Basal surface The surface near the base or interior of a structure; nearest the lower side or bottom of a structure.

Base A substance capable of binding with hydrogen ions; a proton acceptor.

Basement membrane Extracellular material consisting of a basal lamina secreted by epithelial cells and a reticular lamina secreted by underlying connective tissue cells.

Basophil (ba′zo-fil) White blood cell whose granules stain purplish-black with basic dye.

Benign (be-nīn′) Not malignant.

Bicarbonate buffer system Chemical system that helps maintain pH homeostasis of the blood. Also called carbonic acid–bicarbonate buffer system.

Bile Greenish-yellow or brownish fluid produced in and secreted by the liver, stored in the gallbladder, and released into the small intestine.

Bilirubin (bil″ĭ-roo′bin) Yellow pigment of bile.

Bipolar neuron Neuron with axon and dendrite that extend from opposite sides of the cell body.

Blastocyst (blas′to-sist) Stage of early embryonic development; the product of cleavage.

Blood brain barrier Mechanism that inhibits passage of materials from the blood into brain tissues; reflects relative impermeability of brain capillaries.

Blood pressure (BP) Force exerted by blood against a unit area of the blood vessel walls; differences in blood pressure between different areas of the circulation provide the driving force for blood circulation.

Bolus (bo′lus) A rounded mass of food prepared by the mouth for swallowing; any soft round mass.

Bone marrow Adipose- or blood-forming tissue found within bone cavities; called yellow and red bone marrow, respectively.

Bone (osseous tissue) (os′e-us) A connective tissue that forms the bony skeleton.

Bone remodeling Process involving bone formation and destruction in response to hormonal and mechanical factors.

Bone resorption The removal of osseous tissue; part of the continuous bone remodeling process.

Bowman's capsule (bo-manz) *See* Glomerular capsule.

Boyle's law States that when the temperature is constant, the pressure of a gas varies inversely with its volume.

Bradycardia (brad″e-kar′de-ah) A heart rate below 60 beats per minute.

Brain death State of irreversible coma, even though life-support measures may have restored other body organs.

Brain stem Collectively the midbrain, pons, and medulla of the brain.

Brain ventricle Fluid-filled cavity of the brain.

Bronchioles Smaller (<1 mm in diameter) branching air passageways inside the lungs.

Bronchus (brong′kus) One of the two large branches of the trachea that lead to the lungs, or any of its smaller branches leading to bronchioles.

Buffer Chemical substance or system that minimizes changes in pH by releasing or binding hydrogen ions.

Burn Tissue damage inflicted by intense heat, electricity, radiation, or certain chemicals, all of which denature cell proteins and kill cells in the affected areas.

Bursa (ber′sa) A fibrous sac lined with synovial membrane and containing synovial fluid; occurs between bones and muscle tendons (or other structures), where it acts to decrease friction during movement.

Bursitis Inflammation of a bursa.

Calcaneal tendon (kal-ka′ne-al) Tendon that attaches the calf muscles to the heelbone (calcaneus); also called the Achilles tendon.

Calcitonin (kal″sĭ-to′nin) Hormone released by the thyroid. Lowers blood calcium levels only when present at high (therapeutic) levels.

Calculus (kal′ku-lus) A stone formed within various body parts.

Callus (kal′lus) (1) Localized thickening of skin epidermis resulting from physical trauma; (2) repair tissue (fibrous or bony) formed at a fracture site.

Calorie (cal) Amount of energy needed to raise the temperature of 1 gram of water 1° Celsius. Energy exchanges associated with biochemical reactions are usually reported in kilocalories (1 kcal = 1000 cal), also called large calories (Cal).

Calyx (ka′liks) A cuplike extension of the pelvis of the kidney.

Canaliculus (kan″ah-lik′u-lus) Extremely small tubular passage or channel.

Cancer A malignant, invasive cellular neoplasm that has the capability of spreading throughout the body or body parts.

Capillaries (kap′il-layr″ēs) The smallest of the blood vessels and the sites of exchange between the blood and tissue cells.

Carbohydrate (kar″bo-hi′drāt) Organic compound composed of carbon, hydrogen, and oxygen; includes starches, sugars, cellulose.

Carbonic anhydrase (kar-bon′ik an-hi′drās) Enzyme that reversibly facilitates the joining of carbon dioxide with water to form carbonic acid.

Carcinogen (kar″sĭ′no-jin) Cancer-causing agent.

Cardiac cycle Sequence of events encompassing one complete contraction and relaxation of the atria and ventricles of the heart.

Cardiac muscle Specialized muscle of the heart.

Cardiac output (CO) Amount of blood pumped out of a ventricle in one minute.

Cardiac reserve The difference between resting and maximal cardiac output.

Cardiogenic shock Pump failure; the heart is so inefficient that it cannot sustain adequate circulation.

Cardiovascular system Organ system that distributes the blood to deliver nutrients and remove wastes.

Carotene (kar′o-tēn) Yellow to orange pigment that accumulates in the stratum corneum epidermal layer and in fatty tissue of the subcutaneous tissue.

Carotid body (kah-rot′id) A receptor in the common carotid artery sensitive to changing oxygen, carbon dioxide, and pH levels of the blood.

Carotid sinus (si′nus) A dilation of a common carotid artery; involved in regulation of systemic blood pressure.

Carrier A transmembrane protein that changes shape to envelop and transport a polar substance across the cell membrane.

Cartilage (kar′tĭ-lij) One of four types of connective tissue—avascular and not innervated.

Cartilage bone (endochondral bone) Bone formed by using hyaline cartilage structures as models for ossification.

Cartilaginous joints (kar″tĭ-laj′ĭ-nus) Bones united by cartilage; no joint cavity is present.

Catabolism (ka-tab′o-lizm) Process in which living cells break down substances into simpler substances.

Catalyst (kat′ah-list) Substance that increases the rate of a chemical reaction without itself becoming chemically changed or part of the product.

Cataract Clouding of the eye's lens; often congenital or age-related.

Catecholamines (kat″ĕ-kol′ah-mēnz) Epinephrine, norepinephrine, and dopamine; a class of amines that act as chemical messengers.

Cation (kat′i-on) An ion with a positive charge.

Caudal (kaw′dul) Literally, toward the tail; in humans, the inferior portion of the anatomy.

Cecum (se′kum) The blind-ended pouch at the beginning of the large intestine.

Cell Structural unit of all living things.

Cell cycle Series of changes a cell goes through from the time it is formed until it has reproduced itself.

Cell differentiation The development of specific and distinctive features in cells, from a single cell (the fertilized egg) to all the specialized cells of adulthood.

Cell membrane *See* Plasma membrane.

Cellular immunity Immunity conferred by activated T cells, which directly kill infected or cancerous body cells or cells of foreign grafts and release chemicals that regulate the immune response. Also called cell-mediated immunity.

Cellular respiration Metabolic processes in which ATP is produced.

Cellulose (sel′u-lōs) A fibrous carbohydrate (polysaccharide) that is the main structural component of plant tissues.

Central (Haversian) canal (hah-ver′zhan) The canal in the center of each osteon that contains minute blood vessels and nerve fibers that serve the needs of the osteocytes.

Central nervous system (CNS) Brain and spinal cord.

Centriole (sen′tre-ōl) Minute body found in pairs near the nucleus of the cell; active in cell division.

Centrosome (cell center) A region near the nucleus that contains paired organelles called centrioles.

Cerebellum (ser″ĕ-bel′um) Brain region most involved in producing smooth, coordinated skeletal muscle activity.

Cerebral aqueduct (ser′ĕ-bral, sĕ-re′bral) The slender cavity of the midbrain that connects the third and fourth ventricles.

Cerebral arterial circle (*circle of Willis*) An arterial anastomosis at the base of the brain.

Cerebral cortex The outer gray matter region of the cerebral hemispheres.

Cerebral dominance Designates the hemisphere that is dominant for language.

Cerebral palsy Neuromuscular disability in which voluntary muscles are poorly controlled or paralyzed as a result of brain damage.

Cerebral white matter Consists largely of myelinated fibers bundled into large tracts; provides for communication between cerebral areas and lower CNS centers.

Cerebrospinal fluid (CSF) (ser″ĕ-bro-spi′nal) Plasmalike fluid that fills the cavities of the CNS and surrounds the CNS externally; protects the brain and spinal cord.

Cerebrovascular accident (CVA) (ser″ĕ-bro-vas′ku-lar) Condition in which brain tissue is deprived of a blood supply, as in blockage of a cerebral blood vessel; a stroke.

Cerebrum (ser′ĕ-brum) The cerebral hemispheres (including the cerebral cortex, white matter, and basal nuclei).

Cervical vertebrae The seven vertebrae of the vertebral column that are located in the neck.

Cervix Lower outlet of the uterus extending into the vagina.

Channel A transmembrane protein that forms an aqueous pore, allowing substances to move from one side of the membrane to the other.

Chemical bond An energy relationship holding atoms together; involves the interaction of electrons.

Chemical energy Energy stored in the bonds of chemical substances.

Chemical equilibrium A state of apparent repose created by two reactions proceeding in opposite directions at equal speed.

Chemical reaction Process in which molecules are formed, changed, or broken down.

Chemically gated channel An ion channel that opens when a molecule (ligand) binds to it. Also called a ligand-gated channel.

Chemoreceptor (ke″mo-re-sep′ter) Receptor sensitive to various chemicals in solution.

Chemotaxis (ke″mo-tak′sis) Movement of a cell, organism, or part of an organism toward or away from a chemical substance.

Cholecystokinin (CCK) (ko″le-sis″to-ki′nin) An intestinal hormone that stimulates gallbladder contraction and pancreatic juice release.

Cholesterol (ko-les′ter-ol″) Steroid found in animal fats as well as in most body tissues; made by the liver.

Cholinergic fibers (ko″lin-er′jik) Axons with axon terminals that, upon stimulation, release acetylcholine.

Chondroblast (kon′dro-blast) Actively mitotic cell of cartilage.

Chondrocyte (kon′dro-sīt) Mature cell of cartilage.

Chorion (kor′e-on) Outermost fetal membrane; helps form the placenta.

Choroid (ko′roid) The vascular middle layer of the eye.

Choroid plexus (ko′roid plex′sus) A capillary knot that protrudes into a brain ventricle; produces cerebrospinal fluid.

Chromatin (kro′mah-tin) Strands of DNA (genes) and associated proteins; forms chromosomes when condensed (tightly coiled).

Chromosomes (kro′mo-somz) Barlike bodies of tightly coiled chromatin; visible during cell division.

Chronic obstructive pulmonary disease (COPD) Collective term for progressive, obstructive respiratory disorders; includes emphysema, chronic bronchitis.

Chyme (kīm) Semifluid, creamy mass consisting of partially digested food and gastric juice.

Cilia (sil′e-ah) Tiny, hairlike projections of a cell; may move in a wavelike manner to propel substances across the exposed cell surface.

Circumduction (ser″kum-duk′shun) Movement of a body part so that it outlines a cone in space.

Cirrhosis (sĭ-ro′sis) Chronic disease of the liver, characterized by an overgrowth of connective tissue, or fibrosis.

Cistern (sis′tern) Any cavity or enclosed space serving as a reservoir.

Cisterna chyli (sis-ter′nah ki′li) An enlarged sac at the base of the thoracic duct; the origin of the thoracic duct.

Citric acid cycle Aerobic metabolic pathway occurring within mitochondria, in which food metabolites are oxidized and CO_2 is liberated, and coenzymes are reduced. Also called the Krebs cycle.

Cleavage An early embryonic phase consisting of rapid mitotic cell divisions without intervening growth periods; product is a blastocyst.

Clonal selection (klo′nul) Process during which a B cell or T cell becomes activated by binding with an antigen.

Clone Descendants of a single cell.

Coagulation Process in which blood is transformed from a liquid to a gel; blood clotting.

Cochlea (kok′le-ah) Snail-shaped chamber of the bony labyrinth that houses the receptor for hearing [the spiral organ (organ of Corti)].

Codon (ko′don) The three-base sequence on a messenger RNA molecule that provides the genetic information used in protein synthesis; codes for a given amino acid.

Coenzyme (ko-en′zīm) Nonprotein substance associated with and activating an enzyme; typically a vitamin.

Cofactor Metal ion or organic molecule that is required for enzyme activity.

Collagen fiber The most abundant of the three types of protein fibers found in the extracellular matrix of connective tissue.

Colloid (kol′oid) (1) A mixture in which the solute particles (usually proteins) do not settle out readily. (2) Substance in the thyroid gland containing thyroglobulin protein.

Colloid osmotic pressure (kol′oid ahz-mah′tik) Pressure created in a fluid by large nondiffusible molecules, such as plasma proteins that are prevented from moving across a capillary wall. Such substances tend to draw water to them.

Colon Region of the large intestine; includes ascending, transverse, descending, and sigmoid portions.

Combination (synthesis) reaction Chemical reaction in which larger, more complex molecules are formed from simpler molecules or atoms.

Complement A group of bloodborne proteins, which, when activated, enhance the inflammatory and immune responses and may lead to cell lysis.

Complementarity of structure and function The relationship between a structure and its function; i.e., structure determines function.

Complementary base Refers to how a given nitrogenous base of DNA or RNA bonds to another nitrogenous base. For example, adenine (A) is the complementary base of thymine (T). The result is base pairing.

Complete blood count (CBC) Clinical test that includes counts of all formed elements, a hematocrit, and measurements of erythrocyte size and hemoglobin content.

Compound Substance composed of two or more different elements, the atoms of which are chemically united.

Concentration gradient The difference in the concentration of a particular substance between two different areas.

Conducting zone Includes all respiratory passageways that provide conduits for air to reach the sites of gas exchange (the respiratory zone).

Conductivity A measure of the ability of a substance to transmit an electrical current.

Cones One of the two types of photoreceptor cells in the retina of the eye; provide for color vision.

Congenital (kun-jeh′nĭ-tul) Existing at birth.

Congestive heart failure (CHF) Condition in which the pumping efficiency of the heart is depressed so that circulation is inadequate to meet tissue needs.

Conjunctiva (kon″junk-ti′vah) Thin, protective mucous membrane lining the eyelids and covering the anterior surface of the eye itself.

Connective tissue A primary tissue; form and function vary extensively. Functions include support, storage, and protection.

Consciousness The ability to perceive, communicate, remember, understand, appreciate, and initiate voluntary movements.

Contraception The prevention of conception; birth control.

Contractility Muscle cell's ability to move by shortening.

Contraction To shorten or develop tension, an ability highly developed in muscle cells.

Contralateral Relating to the opposite side.

Cornea (kor′ne-ah) Transparent anterior portion of the eyeball; part of the fibrous layer.

Corona radiata (kor-o′nah ra-de-ah′tah) (1) Arrangement of elongated follicle cells around a mature ovum; (2) crownlike arrangement of nerve fibers radiating from the internal capsule of the brain to every part of the cerebral cortex.

Coronary circulation The functional blood supply of the heart; shortest circulation in the body.

Cortex (kor′teks) Outer surface layer of an organ.

Corticosteroids (kor″tĭ-ko-stĕ′roidz) Steroid hormones released by the adrenal cortex.

Cortisol (hydrocortisone) (kor′tĭ-sol) Glucocorticoid produced by the adrenal cortex.

Covalent bond (ko-va′lent) Chemical bond created by electron sharing between atoms.

Cranial nerves The 12 nerve pairs that are associated with the brain.

Craniosacral division Another name for the parasympathetic division of the autonomic nervous system.

Cranium (cranial bones) (kra′ne-um) Bony protective encasement of the brain and organs of hearing and equilibrium.

Creatine kinase (kre′ah-tin) Enzyme that catalyzes the transfer of phosphate from creatine phosphate to ADP, forming creatine and ATP; helps power muscle contraction.

Creatine phosphate (CP) (fos-fāt) Compound that serves as an alternative energy source for muscle tissue.

Creatinine (kre-at′ĭ-nin) A nitrogenous waste molecule that is not reabsorbed by the kidney; this characteristic makes it useful for measurement of the GFR and glomerular function.

Crista ampullaris Sensory receptor organ for rotational acceleration and deceleration housed within the ampulla of each semicircular canal of the inner ear.

Cross section A cut running horizontally from right to left, dividing the body or an organ into superior and inferior parts.

Cutaneous (ku-ta′ne-us) Pertaining to the skin.

Cutaneous sensory receptors Receptors located throughout the skin that respond to stimuli arising outside the body; part of the nervous system.

Cyclic AMP (cAMP) Intracellular second messenger that mediates the effects of the first (extracellular) messenger (hormone or neurotransmitter); formed from ATP by a plasma membrane enzyme (adenylate cyclase).

Cystic fibrosis (CF) Genetic disorder in which secretion of overly viscous mucus clogs the respiratory passages, predisposes to fatal respiratory infections.

Cytochromes (si′to-krōmz) Brightly colored iron-containing proteins that form part of the inner mitochondrial membrane and function as electron carriers in oxidative phosphorylation.

Cytokines Small proteins that act as chemical messengers between various parts of the immune system.

Cytokinesis (si″to-kĭ-ne′sis) The division of cytoplasm that occurs after the cell nucleus has divided.

Cytoplasm (si′to-plazm) The cellular material surrounding the nucleus and enclosed by the plasma membrane.

Cytosine (C) (si′to-sēn) Nitrogen-containing base that is part of a nucleotide structure.

Cytoskeleton Literally, cell skeleton. An elaborate series of structural proteins running through the cytosol, supporting cellular structures and providing the machinery to generate various cell movements.

Cytosol Viscous, semitransparent fluid substance of cytoplasm in which other elements are suspended.

Cytotoxic T cell (T_C cell) Effector T cell that directly kills foreign cells, cancer cells, or virus-infected body cells by inducing apoptosis (cell suicide).

Deamination (de″am-ĭ-na′shun) Removal of an amine group from an organic compound.

Decomposition reaction Chemical reaction in which a molecule is broken down into smaller molecules or its constituent atoms.

Defecation (def″ĭ-ka′shun) Elimination of the contents of the bowels (feces).

Deglutition (deg″loo-tish′un) Swallowing.

Dehydration (de″hi-dra′shun) Condition of excessive water loss.

Dehydration synthesis Process by which a large molecule is synthesized by removing water and covalently bonding smaller molecules together.

Dendrite (den′drīt) Branching neuron process that serves as a receptive, or input, region; transmits an electrical signal toward the cell body.

Dendritic cells Protective cells that engulf antigens, migrate to lymph nodes, and present the antigen to T cells, causing them to activate and mount an immune response; those in the skin are sometimes called Langerhans cells.

Depolarization (de-po″ler-ah-za′shun) Loss of a state of polarity; loss or reduction of negative membrane potential.

Dermatome (der′mah-tōm) Portion of somite mesoderm that forms the dermis of the skin; also the area of skin innervated by the cutaneous branches of a single spinal nerve.

Dermis Layer of skin deep to the epidermis; composed mostly of dense irregular connective tissue.

Desmosome (dez′muh-sōm) Cell junction composed of thickened plasma membranes joined by filaments.

Diabetes insipidus (di″ah-be′tēz in-sĭ′pĭ-dus) Disease characterized by passage of a large quantity of dilute urine plus intense thirst and dehydration caused by inadequate release of antidiuretic hormone (ADH).

Diabetes mellitus (DM) (meh′lĭ-tus) Disease caused by deficient insulin release or by insulin resistance, leading to inability of the body cells to use carbohydrates.

Dialysis (di-al′ah-sis) Diffusion of solute(s) through a semipermeable membrane.

Diapedesis (di″ah-pĕ-de′sis) Passage of white blood cells through intact vessel walls into tissue.

Diaphragm (di′ah-fram) (1) Any partition or wall separating one area from another; (2) a muscle that separates the thoracic cavity from the lower abdominopelvic cavity.

Diaphysis (di-af′ĭ-sis) Elongated shaft of a long bone.

Diarthrosis (di″ar-thro′sis) Freely movable joint.

Diastole (di-as′to-le) Period of the cardiac cycle when either the ventricles or the atria are relaxing.

Diastolic pressure (di-as-tah′lik) Arterial blood pressure reached during or as a result of diastole; lowest level of any given cardiac cycle.

Diencephalon (di″en-seh′fuh-lon) That part of the forebrain between the cerebral hemispheres and the midbrain including the thalamus, the epithalamus, and the hypothalamus.

Differential white blood cell count Diagnostic test to determine relative proportion of individual leukocyte types.

Diffusion (dĭ-fu′zhun) The spreading of particles in a gas or solution with a movement toward uniform distribution of particles; driven by kinetic energy.

Digestion A series of catabolic steps in which complex food molecules are broken down to their building blocks by enzymes.

Digestive system System that processes food into absorbable units and eliminates indigestible wastes.

Dipeptide A combination of two amino acids united by means of a peptide bond.

Diploë (dip′lo-e) The internal layer of spongy bone in flat bones.

Diploid chromosomal number The chromosomal number characteristic of an organism, symbolized as $2n$; twice the chromosomal number (n) of the gamete; in humans, $2n = 46$.

Diplopia (dĭ-plo′pe-ah) Double vision.

Dipole (polar molecule) Nonsymmetrical molecules that contain electrically unbalanced atoms.

Disaccharide (di-sak′ah-rīd, di-sak′ah-rid) Literally, double sugar; e.g., sucrose, lactose.

Dislocation (luxation) Occurs when bones are forced out of their normal alignment at a joint.

Displacement (exchange) reaction Chemical reaction in which bonds are both made and broken; atoms become combined with different atoms.

Distal (dis′tul) Away from the attached end of a limb or the origin of a structure.

Diuretics (di″u-ret′iks) Chemicals that enhance urinary output.

Diverticulum (di″ver-tik′u-lum) A pouch or sac in the walls of a hollow organ or structure.

DNA (deoxyribonucleic acid) (de-ok″sĭ-ri″bo-nu-klā′ik) A nucleic acid found in all living cells; it carries the organism's hereditary information.

DNA replication Process that occurs before cell division; ensures that all daughter cells have identical genes.

Dominant trait Occurs when one allele masks or suppresses the expression of its partner.

Dominant-recessive inheritance Reflects the interaction of dominant and recessive alleles.

Dorsal (dor′sul) Pertaining to the back; posterior.

Dorsal root ganglion Peripheral collection of cell bodies of first-order afferent neurons whose central axons enter the spinal cord.

Double helix The secondary structure assumed by two strands of DNA, held together throughout their length by hydrogen bonds between bases on opposite strands.

Duct (dukt) A canal or passageway; a tubular structure that provides an exit for the secretions of a gland, or for conducting any fluid.

Ductus (vas) deferens Extends from the epididymis to the urethra; propels sperm into the urethra by peristalsis during ejaculation.

Duodenum (du″o-de′num) First part of the small intestine.

Dura mater (du′rah ma′ter) Outermost and toughest of the three membranes (meninges) covering the brain and spinal cord.

Dynamic equilibrium Sense that reports on angular (rotational) acceleration or deceleration of the head in space.

Dyspnea (disp-ne′ah) Difficult or labored breathing; air hunger.

Eccrine sweat glands (ek′rin) Sweat glands abundant on the palms, soles of feet, and the forehead. Also called merocrine sweat glands.

Ectoderm (ek′to-derm) Embryonic germ layer; forms the epidermis of the skin and its derivatives, and nervous tissues.

Edema (ĕ-de′mah) Abnormal increase in the amount of interstitial fluid; causes swelling.

Effector (ef-ek′ter) Muscle or gland (or other organ) capable of being activated by nerve endings.

Efferent (ef′er-ent) Carrying away or away from, especially a nerve fiber that carries action potentials away from the central nervous system.

Elastic cartilage Cartilage with abundant elastic fibers; more flexible than hyaline cartilage.

Elastic fiber Fiber formed from the protein elastin, which gives a rubbery and resilient quality to the matrix of connective tissue.

Electrical energy Energy formed by the movement of charged particles, e.g., across or along cell membranes.

Electrocardiogram (ECG or EKG) (e-lek″tro-car′de-o-gram″) Graphic record of the electrical activity of the heart.

Electrochemical gradient The combined difference in concentration and charge; influences the distribution and direction of diffusion of ions.

Electroencephalogram (EEG) (e-lek″tro-en-sef′ah-lo-gram″) Graphic record of the electrical activity of nerve cells in the brain.

Electrolyte (e-lek′tro-līt) Chemical substances, such as salts, acids, and bases, that ionize and dissociate in water and are capable of conducting an electrical current.

Electrolyte balance Refers to the balance between input and output of salts (sodium, potassium, calcium, magnesium) in the body.

Electromagnetic radiation Emitted photons (wave packets) of energy, e.g., light, X ray, infrared.

Electron Negatively charged subatomic particle; orbits the atom's nucleus.

Electron shells (energy levels) Regions of space that consecutively surround the nucleus of an atom; the atom's electrons are most likely to be found in these regions.

Element One of a limited number of unique varieties of matter that composes substances of all kinds; e.g., carbon, hydrogen, oxygen.

Embolism (em′bo-lizm) Obstruction of a blood vessel by an embolus (blood clot, fatty mass, bubble of air, or other debris) floating in the blood.

Embryo (em′bre-o) Developmental stage extending from fertilization to the end of the eighth week.

Embryoblast Accumulation of cells in the blastocyst from which the embryo develops. Also called the inner cell mass.

Emesis Reflexive emptying of the stomach through the esophagus and pharynx; also known as vomiting.

Endergonic reaction Chemical reaction that absorbs energy, e.g., an anabolic reaction.

Endocardium (en″do-kar′de-um) Endothelial membrane that lines the interior of the heart.

Endochondral ossification (en″do-kon′dral) Embryonic formation of bone by the replacement of calcified cartilage; most skeletal bones are formed by this process.

Endocrine glands (en′do-krin) Ductless glands that empty their hormonal products directly into the blood.

Endocrine system Body system that includes internal organs that secrete hormones.

Endocytosis (en″do-si-to′sis) Means by which fairly large extracellular molecules or particles enter cells, e.g., phagocytosis, pinocytosis, receptor-mediated endocytosis.

Endoderm (en′do-derm) Embryonic germ layer; forms the lining of the digestive tube and its associated structures.

Endogenous (en-doj′ĕ-nus) Originating or produced within the organism or one of its parts.

Endometrium (en″do-me′tre-um) Mucous membrane lining of the uterus.

Endomysium (en″do-mis′e-um) Thin connective tissue surrounding each muscle cell.

Endoplasmic reticulum (ER) (en″do-plaz′mik rĕ-tik′u-lum) Membranous network of tubular or saclike channels in the cytoplasm of a cell.

Endosteum (en-dos′te-um) Connective tissue membrane covering internal bone surfaces.

Endothelium (en″do-the′le-um) Single layer of simple squamous cells that line the walls of the heart, blood vessels, and lymphatic vessels.

Energy The capacity to do work; may be stored (potential energy) or in action (kinetic energy).

Energy intake Energy liberated during food oxidation.

Energy output Sum of energy lost as heat, as work, and as fat or glycogen storage.

Enzyme (en′zīm) A protein that acts as a biological catalyst to speed up a chemical reaction.

Eosinophil (e″o-sin′o-fil) Granular white blood cell whose granules readily take up an acid stain called eosin.

Ependymal cell (ĕ-pen′dĭ-mul) A type of CNS supporting cell; lines the central cavities of the brain and spinal cord.

Epidermis (ep″ĭ-der′mis) Superficial layer of the skin; composed of keratinized stratified squamous epithelium.

Epididymis (ep″ĭ-dĭ′dĭ-mis) That portion of the male duct system in which sperm mature. Empties into the ductus (or vas) deferens.

Epidural space Area between the bony vertebrae and the dura mater of the spinal cord.

Epiglottis (ep″ĭ-glot′is) Elastic cartilage at the back of the throat; covers the opening of the larynx during swallowing.

Epileptic seizures Abnormal electrical discharges of groups of brain neurons, during which no other messages can get through.

Epimysium (ep″ĭ-mis′e-um) Sheath of fibrous connective tissue surrounding a muscle.

Epinephrine (ep″ĭ-nef′rin) Chief hormone produced by the adrenal medulla. Also called adrenaline.

Epiphyseal plate (e″pĭ-fis′e-ul) Plate of hyaline cartilage at the junction of the diaphysis and epiphysis that provides for growth in length of a long bone.

Epiphysis (e-pif′ĭ-sis) The end of a long bone, attached to the shaft.

Epithalamus Most dorsal portion of the diencephalon; forms the roof of the third ventricle with the pineal gland extending from its posterior border.

Epithelium (epithelial tissue) (ep″ĭ-the′le-ul) Pertaining to a primary tissue that covers the body surface, lines its internal cavities, and forms glands.

Erythrocytes (ĕ-rith′ro-sīts) Red blood cells.

Erythropoiesis (ĕ-rith″ro-poy-e′sis) Process of erythrocyte formation.

Erythropoietin (EPO) (ĕ-rith″ro-poy′ĕ-tin) Hormone that stimulates production of red blood cells.

Esophagus (ĕ-sof′ah-gus) Muscular tube extending from the laryngopharynx through the diaphragm to join the stomach; collapses when not involved in food propulsion.

Estrogens (es′tro-jenz) Hormones that stimulate female secondary sex characteristics; female sex hormones.

Eupnea (ūp-ne′ah) Normal respiratory rate and rhythm.

Excess postexercise oxygen consumption (EPOC) The volume of oxygen required after exercise to replenish stores of O_2, ATP, creatine phosphate, and glycogen and oxidize the lactic acid formed during exercise. Also called oxygen debt.

Exchange (displacement) reaction Chemical reaction in which bonds are both made and broken; atoms are combined with different atoms.

Excitability (responsiveness) Ability to respond to stimuli.

Excitation-contraction (E-C) coupling Sequence of events by which transmission of an action potential along the sarcolemma leads to the sliding of myofilaments.

Excitatory postsynaptic potential (EPSP) Depolarizing graded potential in a postsynaptic neuron.

Excretion (ek-skre′shun) Elimination of waste products from the body.

Exergonic reaction Chemical reaction that releases energy, e.g., a catabolic or oxidative reaction.

Exocrine glands (ek′so-krin) Glands that have ducts through which their secretions are carried to a particular site.

Exocytosis (ek″so-si-to′sis) Mechanism by which substances are moved from the cell interior to the extracellular space as a secretory vesicle fuses with the plasma membrane.

Exons Amino acid–specifying informational sequences (separated by introns) in the genes of higher organisms.

Extension Movement that increases the angle of a joint, e.g., straightening a flexed knee.

Exteroceptor (ek″ster-o-sep′tor) Sensory receptor that responds to stimuli from the external world.

Extracellular fluid (ECF) Internal fluid located outside cells; includes interstitial fluid, blood plasma, and cerebrospinal fluid.

Extracellular matrix Nonliving material in connective tissue consisting of ground substance and fibers; separates the living cells.

Extrasystole (ek″strah-sis′to-le) Premature heart contraction.

Extrinsic (ek-strin′sik) Of external origin.

Extrinsic eye muscles The six skeletal muscles that attach to and move each eye.

Facilitated diffusion Passive transport process used by certain large or charged molecules (e.g., glucose, Na^+) that are unable to pass through the plasma membrane unaided. Involves movement through channels or movement facilitated by a membrane carrier.

Fallopian tube (fah-lō′pe-un) *See* Uterine tube.

Fascia (fash′e-ah) Layers of fibrous tissue covering and separating muscle.

Fascicle (fas′ĭ-kl) Bundle of nerve or muscle fibers bound together by connective tissue.

Fatty acids Linear chains of carbon and hydrogen atoms (hydrocarbon chains) with an organic acid group at one end. A constituent of fat.

Feces (fe′sēz) Material discharged from the bowel; composed of food residue, secretions, bacteria.

Fenestrated (fen′es-tra-tid) Pierced with one or more small openings.

Fertilization Fusion of the sperm and egg nuclei.

Fetus Developmental stage extending from the ninth week of development to birth.

Fiber A slender threadlike structure or filament. May refer to a cell, part of a cell, or a protein. *See also* Muscle fiber, Nerve fiber, Collagen fiber.

Fibrillation Condition of rapid and irregular or out-of-phase heart contractions.

Fibrin (fi′brin) Fibrous insoluble protein formed during blood clotting.

Fibrinogen (fi-brin′o-jin) A soluble blood protein that is converted to insoluble fibrin during blood clotting.

Fibrinolysis Process that removes unneeded blood clots when healing has occurred.

Fibroblast (fi′bro-blast) Young, actively mitotic cell that forms the fibers of connective tissue.

Fibrocartilage The cartilage most resistant to compression and stretch. Forms vertebral discs and knee joint cartilages.

Fibrocyte (fi′bro-sīt) Mature fibroblast; maintains the matrix of fibrous types of connective tissue.

Fibrosis Proliferation of fibrous connective tissue called scar tissue.

Fibrous joints Bones joined by dense fibrous connective tissue; no joint cavity is present.

Filtrate A plasma-derived fluid that is processed by the renal tubules to form urine.

Filtration Passage of a solvent and dissolved substances through a membrane or filter.

First-degree burn A burn in which only the epidermis is damaged.

Fissure (fĭ′sher) (1) A groove or cleft; (2) the deepest depressions or inward folds on the brain.

Fixator (fix′a-ter) Muscle that immobilizes one or more bones, allowing other muscles to act from a stable base.

Flagellum (flah-jel′lum) Long, whiplike cellular extension containing microtubules; propels sperm and some single-celled eukaryotes.

Flexion (flek′shun) Movement that decreases the angle of the joint, e.g., bending the knee from a straight to an angled position.

Flexor (withdrawal) reflex Reflex initiated by a painful stimulus (actual or perceived); causes automatic withdrawal of the threatened body part from the stimulus.

Fluid mosaic model A depiction of the structure of the membranes of a cell as phospholipid bilayers in which proteins are dispersed.

Follicle (fah′lĭ-kul) (1) Ovarian structure consisting of a developing egg surrounded by one or more layers of follicle cells; (2) colloid-containing structure of the thyroid gland; (3) B cell–rich region in lymphoid tissue.

Follicle-stimulating hormone (FSH) Hormone produced by the anterior pituitary that stimulates ovarian follicle production in females and sperm production in males.

Fontanelles (fon″tah-nelz′) Fibrous membranes at the angles of cranial bones that accommodate brain growth in the fetus and infant.

Foramen (fo-ra′men) Hole or opening in a bone or between body cavities.

Forebrain (prosencephalon) Anterior portion of the brain consisting of the telencephalon and the diencephalon.

Formed elements Cellular portion of blood.

Fossa (fos′ah) A depression, often an articular surface.

Fovea (fo′ve-ah) A pit.

Fracture A break in a bone.

Free radicals Highly reactive chemicals with unpaired electrons that can scramble the structure of proteins, lipids, and nucleic acids.

Frontal (coronal) plane Longitudinal (vertical) plane that divides the body or an organ into anterior and posterior parts.

Fulcrum The fixed point on which a lever moves when a force is applied.

Fundus (fun′dus) Base of an organ; part farthest from the opening of the organ. For example, the posterior wall of the eye.

G protein Protein that relays signals between extracellular first messengers (such as hormones or neurotransmitters) and intracellular second messengers (such as cyclic AMP) via an effector enzyme.

Gallbladder Sac beneath the right lobe of the liver used for bile storage.

Gallstones (biliary calculi) Crystallized cholesterol that obstructs the flow of bile from the gallbladder.

Gamete (gam′ēt) Sex or germ cell.

Gametogenesis (gam″e-to-jen′eh-sis) Formation of gametes.

Ganglion (gang′gle-on) Collection of nerve cell bodies outside the CNS.

Gap junction A passageway between two adjacent cells; formed by transmembrane proteins called connexons.

Gastrin Hormone secreted in the stomach; regulates gastric juice secretion by stimulating HCl production.

Gastroenteritis Inflammation of the gastrointestinal tract.

Gastrulation (gas″troo-la′shun) Developmental process that produces the three primary germ layers (ectoderm, mesoderm, and endoderm).

Gene One of the biological units of heredity located in DNA; transmits hereditary information.

Genetic code Refers to the rules by which the base sequence of a DNA gene is translated into protein structures (amino acid sequences).

Genitalia (jen″ĭ-ta′le-ă) The internal and external reproductive organs.

Genome The complete set of chromosomes derived from one parent (the haploid genome); or the two sets of chromosomes, i.e., one set from the egg, the other from the sperm (the diploid genome).

Genotype (jēn′o-tīp) One's genetic makeup or genes.

Germ layers Three cellular layers (ectoderm, mesoderm, and endoderm) that represent the initial specialization of cells in the embryonic body and from which all body tissues arise.

Gestation period (jes-ta′shun) The period of pregnancy; about 280 days for humans.

Gland Organ specialized to secrete substances for further use in the body or excrete substances for elimination.

Glaucoma (glaw-ko′mah) Condition in which intraocular pressure increases to levels that cause compression of the retina and optic nerve; results in blindness unless detected early.

Glial cells (gle′al) *See* Neuroglia.

Glomerular capsule (glo-mer′yoo-ler) Double-walled cup at end of a renal tubule; encloses a glomerulus. Also called Bowman's capsule.

Glomerular filtration rate (GFR) Rate of filtrate formation by the kidneys.

Glomerulus (glo-mer′u-lus) (1) Cluster of capillaries forming part of the nephron; forms filtrate; (2) odor-specific processing unit in olfactory bulb.

Glottis (glah′tis) Opening between the vocal cords in the larynx.

Glucagon (gloo′kah-gon) Hormone formed by alpha cells of pancreatic islets; raises the glucose level of blood.

Glucocorticoids (gloo″ko-kor′tĭ-koidz) Adrenal cortex hormones that increase blood glucose levels and aid the body in resisting long-term stressors.

Gluconeogenesis (gloo″ko-ne″o-jen′ĕ-sis) Formation of glucose from noncarbohydrate molecules.

Glucose (gloo′kōs) Principal blood sugar; a hexose.

Glycerol (glis′er-ol) A modified simple sugar (a sugar alcohol); a building block of fats.

Glycocalyx (gli″ko-ka′liks) A layer of externally facing glycoproteins and glycolipids (a "cell coat") on or near a cell's plasma membrane; its components determine blood type and are involved in cellular interactions.

Glycogen (gli′ko-jin) Main carbohydrate stored in animal cells; a polysaccharide.

Glycogenesis (gli″ko-jen′ĕ-sis) Formation of glycogen from glucose.

Glycogenolysis (gli″ko-jĕ-nol′ĭ-sis) Breakdown of glycogen to glucose.

Glycolipid (gli″ko-lip′id) A lipid with one or more covalently attached sugars.

Glycolysis (gli-kol′ĭ-sis) Breakdown of glucose to pyruvic acid—an anaerobic process.

Goblet cells Individual cells (unicellular glands) that produce mucus.

Golgi apparatus (gol′je) Membranous system close to the cell nucleus that packages protein secretions for export, packages enzymes into lysosomes for cellular use, and modifies proteins destined to become part of cellular membranes.

Gonad (go′nad) Primary reproductive organ; i.e., the testis of the male or the ovary of the female.

Gonadocorticoids (gon″ah-do-kor′tĭ-koidz) Sex hormones, primarily androgens, secreted by the adrenal cortex.

Gonadotropins (gon″ah-do-trōp′inz) Gonad-stimulating hormones produced by the anterior pituitary.

Graded muscle contractions Variations in the degree of muscle contraction by changing either the frequency or strength of the stimulus.

Graded potential A local change in membrane potential that varies directly with the strength of the stimulus, declines with distance.

Graves' disease Autoimmune disorder in which the thyroid gland is directly stimulated by antibodies; causes markedly increased secretion of thyroid hormone.

Gray matter Gray area of the central nervous system; contains neuronal cell bodies and their dendrites.

Growth hormone (GH) Hormone that stimulates growth in general; produced in the anterior pituitary; also called somatotropin.

Guanine (G) (gwah′nēn) One of two major purines occurring in all nucleic acids.

Gustation (gus-ta′shun) Sense of taste.

Gyrus (ji′rus) An outward fold of the surface of the cerebral cortex.

Hair follicle Structure with outer and inner root sheaths extending from the epidermal surface into the dermis and from which new hair develops.

Hapten (hap′ten) An incomplete antigen; has reactivity but not immunogenicity.

Haversian system (hah-ver′zhen) *See* Osteon.

Heart attack (coronary) *See* Myocardial infarction.

Heart block Impaired transmission of impulses from atrium to ventricle resulting in abnormally slow heart rhythms.

Heart murmur Abnormal heart sound (usually resulting from valve problems).

Heimlich maneuver Procedure in which the air in a person's own lungs is used to expel an obstructing piece of food.

Helper T cell (T_H cell) Type of T lymphocyte that orchestrates the entire adaptive immune response (both cellular and humoral immunity); also activates macrophages.

Hematocrit (he-mat′o-krit) The percentage of total blood volume occupied by erythrocytes.

Hematoma (he″mah-to′mah) Mass of clotted blood that forms at an injured site.

Hematopoiesis (hem″ah-to-poy-e′sis) Blood cell formation; hemopoiesis.

Hematopoietic stem cell (hem″ah-to-poy-et′ik) Bone marrow cell that gives rise to all the formed elements of blood; hemocytoblast.

Heme (hēm) Iron-containing pigment that is essential to oxygen transport by hemoglobin.

Hemoglobin (he′mo-glo″bin) Oxygen-transporting protein of erythrocytes.

Hemolysis (he-mah′lĕ-sis) Rupture of erythrocytes.

Hemophilia (he″mo-fil′e-ah) A term loosely applied to several different hereditary bleeding disorders that exhibit similar signs and symptoms.

Hemopoiesis (he″mo-poy-e′sis) *See* Hematopoiesis.

Hemorrhage (hem′or-ij) Loss of blood from the vessels by flow through ruptured walls; bleeding.

Hemostasis (he″mo-sta′sis) Stoppage of bleeding.

Heparin Natural anticoagulant secreted into blood plasma.

Hepatic portal system (hĕ-pat′ik) Circulation in which the hepatic portal vein carries dissolved nutrients to the liver tissues for processing.

Hepatitis (hep″ah-ti′tis) Inflammation of the liver.

Hernia (her′ne-ah) Abnormal protrusion of an organ or a body part through the containing wall of its cavity.

Heterozygous (het″er-o-zi′gus) Having different allelic genes at a given locus or (by extension) many loci.

Hilton's law Any nerve serving a muscle that produces movement at a joint also innervates the joint and the skin over the joint.

Hilum (hi′lum) The indented region of an organ from which blood and/or lymphatic vessels and nerves enter and exit.

Hippocampus Limbic system structure that plays a role in converting new information into long-term memories.

Histamine (his′tuh-mēn) A chemical messenger (neurotransmitter or paracrine); causes vasodilation and increased capillary permeability; in stomach causes acid secretion.

Histology (his-tol′o-je) Branch of anatomy dealing with the microscopic structure of tissues.

HIV (human immunodeficiency virus) Virus that destroys helper T cells, thus depressing adaptive immunity; symptomatic AIDS gradually appears when lymph nodes can no longer contain the virus.

Holocrine glands (hol′o-krin) Glands that accumulate their secretions within their cells; secretions are discharged only upon rupture and death of the cell.

Homeostasis (ho″me-o-sta′sis) A state of body equilibrium or stable internal environment of the body.

Homologous (ho-mol′ŏ-gus) (1) Parts or organs corresponding in embryonic origin and structure but not necessarily in function. (2) In chromosomes, a pair of chromosomes (one from each parent) that carry genes for the same traits but may differ in the details of their genetic instructions.

Homozygous (ho-mo-zi′gus) Having identical genes at one or more loci.

Hormones Steroidal or amino acid–based molecules released to the blood that act as chemical messengers to regulate specific body functions.

Humoral immunity (hu′mer-ul) Immunity conferred by antibodies present in blood plasma and other body fluids.

Huntington's disease Hereditary disorder leading to degeneration of the basal nuclei and the cerebral cortex.

Hyaline cartilage (hi′ah-līn) The most abundant cartilage type in the body; provides firm support with some pliability.

Hydrochloric acid (HCl) (hi″dro-klor′ik) Acid that aids protein digestion in the stomach; produced by parietal cells.

Hydrogen bond Weak bond in which a hydrogen atom forms a bridge between two electron-hungry atoms. An important intramolecular bond.

Hydrogen ion (H^+) A hydrogen atom minus its electron and therefore carrying a positive charge (i.e., a proton).

Hydrolysis (hi″drah′lă-sis) Process in which water is used to split a substance into smaller parts.

Hydrophilic (hi″dro-fil′ik) Refers to molecules, or portions of molecules, that interact with water and charged particles.

Hydrophobic (hi″dro-fo′bik) Refers to molecules, or portions of molecules, that interact only with nonpolar molecules.

Hydrostatic pressure (hi″dro-stă′tic) Pressure of fluid in a system.

Hydroxyl ion (OH^-) (hi-drok′sil) An ion liberated when a hydroxide (a common inorganic base) is dissolved in water.

Hyperalgesia Greater than normal sensitivity to pain.

Hypercapnia (hi″per-kap′ne-ah) High carbon dioxide levels in the blood.

Hyperemia An increase in blood flow into a tissue or organ; congested with blood.

Hyperglycemic (hi″per-gli-se′mik) Term used to describe hormones such as glucagon that elevate blood glucose level.

Hyperopia (hi″per-o′pe-ah) A condition in which visual images are routinely focused behind rather than on the retina; commonly known as farsightedness.

Hyperplasia (hi″per-pla′ze-ah) Accelerated cell division, e.g., in anemia, the bone marrow produces red blood cells at a faster rate.

Hyperpnea (hi″perp-ne′ah) An increase in ventilation in response to metabolic need (e.g., during exercise).

Hyperpolarization An increase in membrane potential in which the membrane becomes more negative than resting membrane potential.

Hypersensitivity Overzealous immune response to an otherwise harmless antigen.

Hypertension (hi″per-ten′shun) High blood pressure.

Hypertonic (hi″per-ton′ik) Excessive, above normal, tone or tension.

Hypertonic solution A solution that has a higher concentration of nonpenetrating solutes than the reference cell; having greater osmotic pressure than the reference solution (blood plasma or interstitial fluid).

Hypertrophy (hi-per′trah-fe) Growth of an organ or tissue due to an increase in the size of its cells; differs from hyperplasia (an increase in size due to increased cell numbers).

Hyperventilation An increase in the depth and rate of breathing that is in excess of the body's need for removal of carbon dioxide.

Hypocapnia Low carbon dioxide levels in the blood.

Hypoglycemia Abnormally low concentration of glucose in extracellular fluids.

Hypoglycemic (hi″po-gli-se′mik) Term used to describe hormones such as insulin that decrease blood glucose level.

Hyponatremia Abnormally low concentrations of sodium ions in extracellular fluid.

Hypoproteinemia (hi″po-pro″te-ĭ-ne′me-ah) A condition of unusually low levels of plasma proteins causing a reduction in colloid osmotic pressure; results in tissue edema.

Hypotension Low blood pressure.

Hypothalamic-hypophyseal tract (hi″po-thah-lam′ik hi″po-fiz′e-al) Bundle of axons that runs through the infundibulum and connects the posterior pituitary to the hypothalamus.

Hypothalamus (hi″po-thal′ah-mus) Region of the diencephalon forming the floor of the third ventricle of the brain.

Hypotonic (hi″po-ton′ik) Below normal tone or tension.

Hypotonic solution A solution that is more dilute (containing fewer nonpenetrating solutes) than the reference cell. Cells placed in hypotonic solutions plump up rapidly as water diffuses into them.

Hypoventilation A decrease in the depth and rate of breathing; characterized by an increase in blood carbon dioxide.

Hypovolemic shock (hi″po-vo-le′mik) Most common form of shock; results from extreme blood loss.

Hypoxia (hi-pok′se-ah) Condition in which inadequate oxygen is available to tissues.

Ileocecal valve (il″e-o-se′kal) Site where the small intestine joins the large intestine.

Ileum (il′e-um) Terminal part of the small intestine; between the jejunum and the cecum of the large intestine.

Immune system A functional system whose components attack foreign substances or prevent their entry into the body.

Immunity (im″ūn′ĭ-te) Ability of the body to resist many agents (both living and nonliving) that can cause disease; resistance to disease.

Immunocompetence Ability of the body's immune cells to recognize (by binding) specific antigens; reflects the presence of plasma membrane–bound receptors.

Immunodeficiency Any congenital or acquired condition causing a deficiency in the production or function of immune cells or certain molecules (complement, antibodies, etc.) required for normal immunity.

In vitro (in ve′tro) In a test tube, glass, or artificial environment.

In vivo (in ve′vo) In the living body.

Incompetent valve Valve that does not close properly.

Incontinence Inability to control micturition or defecation voluntarily.

Infarct (in′farkt) Region of dead, deteriorating tissue resulting from a lack of blood supply.

Infectious mononucleosis Highly contagious viral disease; marked by excessive agranulocytes.

Inferior (caudal) Pertaining to a position toward the lower or tail end of the long axis of the body.

Inferior vena cava Vein that returns blood from body areas below the diaphragm.

Inflammation (in″flah-ma′shun) An innate (nonspecific) defensive response of the body to tissue injury; includes dilation of arterioles and an increase in capillary permeability; cardinal signs are redness, heat, swelling, and pain.

Infundibulum (in″fun-dib′u-lum) (1) A stalk of tissue that connects the pituitary gland to the hypothalamus; (2) the distal end of the uterine (fallopian) tube.

Inguinal (ing′wĭ-nal) Pertaining to the groin region.

Inhibitory postsynaptic potential (IPSP) A graded potential in a postsynaptic neuron that inhibits action potential generation; usually hyperpolarizing.

Innervation (in″er-va′shun) Supply of nerves to a body part.

Inorganic compound Chemical substances that do not contain carbon, including water, salts, and many acids and bases.

Insertion Movable attachment of a muscle.

Insula Lobe of the cerebral cortex that is buried in the lateral sulcus beneath portions of the parietal, frontal, and temporal lobes.

Insulin A hormone that enhances the carrier-mediated diffusion of glucose into tissue cells, thus lowering blood glucose levels.

Insulin resistance State in which a greater than normal amount of insulin is required to maintain normal glucose blood levels.

Integration The process by which the nervous system processes and interprets sensory input and makes decisions about what should be done at each moment.

Integumentary system (in-teg″u-men′tar-e) Skin and its derivatives; provides the external protective covering of the body.

Intercalated discs (in-ter′kah-la″ted) Specialized connections between myocardial cells containing gap junctions and desmosomes.

Interferons (IFNs) (in-ter-fēr′ons) Proteins released from virus-infected (and other) cells that protect uninfected cells from viral takeover. Also inhibit some cancers.

Internal capsule Band of projection fibers that runs between the basal nuclei and the thalamus.

Internal respiration Exchange of gases between blood and tissue fluid and between tissue fluid and cells.

Interneuron (association neuron) Nerve cell located between motor and sensory neurons that shuttles signals through CNS pathways where integration occurs.

Interoceptor (in″ter-o-sep′tor) Sensory receptor in the viscera that is sensitive to changes and stimuli within the body's internal environment; also called visceroceptor.

Interphase One of two major periods in the cell life cycle; includes the period from cell formation to cell division.

Interstitial endocrine cells Cells located in the loose connective tissue surrounding the seminiferous tubules of the testes; they produce androgens (most importantly testosterone), which are secreted into the surrounding interstitial fluid.

Interstitial fluid (IF) (in″ter-stish′al) Fluid between the cells.

Interstitial lamellae Incomplete lamellae that lie between intact osteons, filling the gaps between forming osteons, or representing the remnants of an osteon that has been cut through by bone remodeling.

Intervertebral discs (in″ter-ver′teh-brul) Discs of fibrocartilage between vertebrae.

Intracapsular ligament Ligament located within and separate from the articular capsule of a synovial joint.

Intracellular fluid (ICF) (in″trah-sel′u-ler) Fluid within a cell.

Intrinsic factor Substance produced by the stomach that is required for vitamin B_{12} absorption.

Intron Noncoding segment or portion of DNA that ranges from 60 to 100,000 nucleotides long.

Involuntary muscle Muscle that cannot ordinarily be controlled voluntarily (e.g., smooth and cardiac muscle).

Involuntary nervous system The autonomic nervous system.

Ion (ī′on) Atom or molecule with a positive or negative electric charge.

Ion channel Transmembrane protein with a central pore that allows ions to pass through.

Ionic bond (ī-ah′nik) Chemical bond formed by electron transfer between atoms.

Ipsilateral (ip″sĭ-lă′ter-ul) Situated on the same side.

Ischemia (is-ke′me-ah) Local decrease in blood supply.

Isograft Tissue graft donated by an identical twin.

Isomer (i′so-mer) One of two or more substances that has the same molecular formula but with its atoms arranged differently.

Isometric contraction (i″so-mĕ′trik) Contraction in which the muscle does not shorten (the load is too heavy) but its internal tension increases.

Isotonic contraction (i″so-tah′nik) Contraction in which muscle tension remains constant at a given load, and the muscle shortens.

Isotonic solution A solution with a concentration of nonpenetrating solutes equal to that found in the reference cell.

Isotopes (i′so-tōps) Different atomic forms of the same element, which vary only in the number of neutrons they contain; the heavier species tend to be radioactive.

Jejunum (jĕ-joo′num) The part of the small intestine between the duodenum and the ileum.

Joint (articulation) The junction of two or more bones.

Joint kinesthetic receptor (kin″es-thet′ik) Receptor that provides information on joint position and motion.

Juxtaglomerular complex (JGC) (juks″tah-glo-mer′u-lar) Cells of the distal part of the ascending limb of the nephron loop and afferent arteriole located close to the glomerulus; involved in blood pressure regulation (via release of the hormone renin) and autoregulation of GFR.

Karyotype (kar′e-o-tīp) The diploid chromosomal complement, typically shown as homologous chromosome pairs arranged from longest to shortest (X and Y are arranged by size rather than paired).

Keratin (ker′ah-tin) Fibrous protein found in the epidermis, hair, and nails that makes those structures hard and water resistant; precursor is keratohyaline.

Ketones (ketone bodies) (ke′tōnz) Fatty acid metabolites; strong organic acids.

Ketosis (kē-tō′sis) Excess levels of ketone bodies in blood. Called ketoacidosis if blood pH is low.

Kilocalories (kcal) *See* Calorie.

Kinetic energy (ki-net′ik) The energy of motion or movement, e.g., the constant movement of atoms, or the push given to a swinging door that sets it into motion.

Labia (la′be-ah) (1) Lips; (2) skin folds of the female external genitalia; singular: labium.

Labor Collective term for the series of events that expel the fetus from the uterus.

Labyrinth (lab′ĭ-rinth″) Bony cavities and membranes of the inner ear.

Lacrimal (lak′rĭ-mal) Pertaining to tears.

Lactation (lak-ta′shun) Production and secretion of milk.

Lacteal (lak′te-al) Special lymphatic capillaries of the small intestine that take up lipids.

Lactic acid (lak′tik) Product of anaerobic metabolism, especially in muscle.

Lacuna (lah-ku′nah) A small space, cavity, or depression; lacunae in bone or cartilage are occupied by cells.

Lamella (lah-mel′ah) A layer, such as of bone matrix in an osteon of compact bone.

Lamina (lam′ĭ-nah) (1) A thin layer or flat plate; (2) the portion of a vertebra between the transverse process and the spinous process.

Lamina propria Loose connective tissue supporting an epithelium; part of a mucous membrane (mucosa).

Large intestine Portion of the digestive tract extending from the ileocecal valve to the anus; includes the cecum, appendix, colon, rectum, and anal canal.

Larynx (lar′ingks) Cartilaginous organ located between the trachea and the pharynx; voice box.

Latent period Period of time between stimulation and the onset of a response (such as muscle contraction).

Lateral Away from the midline of the body.

Leakage channel An ion channel that is always open (a nongated channel).

Leptin Hormone released by fat cells that signals satiety.

Leukemia Refers to a group of cancerous conditions of white blood cells.

Leukocytes (loo′ko-sīts) White blood cells; formed elements involved in body protection that take part in inflammatory and immune responses.

Leukocytosis An increase in the number of leukocytes (white blood cells); usually the result of a pathogen attack on the body.

Leukopenia (loo″ko-pe′ne-ah) Abnormally low white blood cell count.

Leukopoiesis The production of white blood cells.

Lever system Consists of a lever (bone), effort (muscle action), resistance (weight of object to be moved), and fulcrum (joint).

Ligament (lig′ah-ment) Band of dense regular connective tissue that connects bones.

Ligands Signaling chemicals that bind specifically to membrane receptors.

Limbic system (lim′bik) Functional brain system involved in emotional response and memory formation.

Lipid (lĭ′pid) Hydrophobic organic compound formed of carbon, hydrogen, and oxygen; examples are fats and cholesterol.

Lipolysis (lĭ-pol′ĭ-sis) The breakdown of stored fats into glycerol and fatty acids.

Liver Lobed accessory organ that overlies the stomach; produces bile to help digest fat, and serves other metabolic and regulatory functions.

Lumbar (lum′bar) Portion of the back between the thorax and the pelvis.

Lumbar vertebrae The five vertebrae of the lumbar region of the vertebral column, commonly called the small of the back.

Lumen (loo′min) Cavity inside a tube, blood vessel, or hollow organ.

Luteinizing hormone (LH) (lu′te-in-īz″ing) Anterior pituitary hormone that aids maturation of cells in the ovary and triggers ovulation in females. In males, causes the interstitial endocrine cells of the testis to produce testosterone.

Lymph (limf) Protein-containing fluid transported by lymphatic vessels.

Lymph node Small lymphoid organ that filters lymph; contains macrophages and lymphocytes.

Lymphatic system (lim-fat′ik) System consisting of lymphatic vessels, lymph nodes, and lymph; drains excess tissue fluid from the extracellular space. The nodes provide sites for immune surveillance.

Lymphatics General term used to designate the lymphatic vessels that collect and transport lymph.

Lymphocyte Agranular white blood cell that arises from bone marrow and becomes functionally mature in the lymphoid organs of the body.

Lysosomes (li′so-sōmz) Organelles that originate from the Golgi apparatus and contain strong digestive enzymes.

Lysozyme (li′so-zīm) Enzyme in sweat, saliva, and tears that is capable of destroying certain kinds of bacteria.

M (mitotic) phase One of two major periods in the cell life cycle; involves the division of the nucleus (mitosis) and the division of the cytoplasm (cytokinesis).

Macromolecules Large, complex molecules containing from 100 to over 10,000 subunits.

Macrophage (mak′ro-fāj″) Immune cell type common in connective tissue, lymphoid tissue, and many body organs; phagocytizes tissue cells, bacteria, and other foreign debris; presents antigens to T cells in the immune response.

Macula (mak′u-lah) (1) Receptor for linear acceleration, deceleration, and gravity, located within the vestibule of the inner ear; (2) a colored area or spot (as on the retina).

Malignant (muh-lig′nent) Life threatening; pertains to neoplasms that spread and lead to death, such as cancer.

Malignant melanoma (mel″ah-no′mah) Cancer of the melanocytes; can begin wherever there is pigment.

MALT (mucosa-associated lymphoid tissue) Diffusely distributed collections of lymphoid tissue in mucous membranes.

Mammary glands (mam′mer-e) Milk-producing glands of the breast.

Molarity (mo-lar′ĭ-te) A way to express the concentration of a solution; moles per liter of solution.

Mole (mōl) A mole of any element or compound is equal to its atomic weight or its molecular weight (sum of atomic weights) measured in grams.

Molecule Particle consisting of two or more atoms joined together by chemical bonds.

Monoclonal antibodies (mon″o-klo′nal) Pure preparations of identical antibodies that exhibit specificity for a single antigen.

Monocyte (mon′o-sīt) Large single-nucleus white blood cell; agranular leukocyte.

Monosaccharide (mon″o-sak′ah-rīd) Literally, one sugar; building block of carbohydrates; e.g., glucose.

Motor areas Functional areas in the cerebral cortex that control voluntary motor functions.

Motor (efferent) nerves Nerves that carry action potentials leaving the brain and spinal cord, and destined for effectors.

Motor unit A motor neuron and all the muscle cells it stimulates.

Mucous membranes (mucosae) Membranes that form the linings of body cavities open to the exterior (digestive, respiratory, urinary, and reproductive tracts).

Mucus (myoo′kus) A sticky, thick fluid secreted by mucous glands and mucous membranes; keeps the free surface of membranes moist.

Multinucleate cell (mul″tĭ-nu′kle-āt) Cell with more than one nucleus, e.g., skeletal muscle cells, osteoclasts.

Multiple sclerosis (MS) Demyelinating disorder of the CNS; causes hardened patches (sclerosis) in the brain and spinal cord.

Multipolar neurons Neurons with three or more processes; most common neuron type in the CNS.

Muscarinic receptors (mus″kah-rin′ik) Acetylcholine-binding receptors of the autonomic nervous system's target organs; named for activation by the mushroom poison muscarine.

Muscle fiber A muscle cell.

Muscle spindle Encapsulated receptor found in skeletal muscle that is sensitive to stretch.

Muscle tension The force exerted by a contracting muscle on some object.

Muscle tone Low levels of contractile activity in relaxed muscle; keeps the muscle healthy and ready to act.

Muscle twitch The response of a muscle to a single brief threshold stimulus.

Muscular dystrophy A group of inherited muscle-destroying diseases.

Muscular system The organ system consisting of the skeletal muscles of the body and their connective tissue attachments.

Myelencephalon A secondary brain vesicle; lower part of the developing hindbrain, especially the medulla oblongata.

Myelin sheath (mi′ĕ-lin) Fatty insulating sheath that surrounds all but the smallest nerve fibers.

Myoblasts Embryonic mesoderm cells from which all muscle fibers develop.

Myocardial infarction (MI) (mi″o-kar′de-al in-fark′shun) Condition characterized by dead tissue areas in the myocardium; caused by interruption of blood supply to the area. Commonly called heart attack.

Myocardium (mi″o-kar′de-um) Layer of the heart wall composed of cardiac muscle.

Myofibril (mi″o-fi′bril) Rodlike bundle of contractile filaments (myofilaments) found in muscle fibers (cells).

Myofilament (mi″o-fil′ah-ment) Filament that constitutes myofibrils. Of two types: actin and myosin.

Myoglobin (mi″o-glo′bin) Oxygen-binding pigment in muscle.

Myogram A graphic recording of mechanical contractile activity produced by an apparatus that measures muscle contraction.

Myometrium (mi″o-me′tre-um) Thick uterine musculature.

Myopia (mi-o′pe-ah) A condition in which visual images are focused in front of rather than on the retina; nearsightedness.

Myosin (mi′o-sin) One of the principal contractile proteins found in muscle.

Myxedema (mik″sĕ-de′mah) Severe hypothyroidism.

Nares (na′rez) Nostrils.

Natural killer (NK) cell Defensive cell (a type of lymphocyte) that can kill cancer cells and virus-infected body cells before the adaptive immune system is activated.

Necrosis (nĕ-kro′sis) Death or disintegration of a cell or tissues caused by disease or injury.

Negative feedback mechanisms The most common homeostatic control mechanism. The net effect is that the output of the system shuts off the original stimulus or reduces its intensity.

Neonatal period The four-week period immediately after birth.

Neoplasm (ne′o-plazm) An abnormal mass of proliferating cells. Benign neoplasms remain localized; malignant neoplasms are cancers, which can spread to other organs.

Nephron (nef′ron) Structural and functional unit of the kidney; consists of the renal corpuscle and renal tubule.

Nerve A bundle of axons in the peripheral nervous system.

Nerve fiber Axon of a neuron.

Nerve growth factor (NGF) Protein that promotes survival and development of neurons; secreted by their target cells and many other cell types.

Nerve impulse A self-propagating wave of depolarization; also called an action potential.

Nerve plexuses Interlacing nerve networks that occur in the cervical, brachial, lumbar, and sacral regions and primarily serve the limbs.

Nervous system Fast-acting control system that triggers muscle contraction or gland secretion.

Neural crest cells Embryonic cells of ectodermal origin that migrate away from the forming neural tube to become a wide variety of different cells such as certain adrenal medulla cells, melanocytes, and neurons in various ganglia.

Neural tube Fetal structure that gives rise to the brain, spinal cord, and associated neural structures; formed from ectoderm.

Neuroglia (nu-rog′le-ah) Nonexcitable cells of neural tissue that support, protect, and insulate the neurons; glial cells.

Neurohypophysis (nu″ro-hi-pof′ĭ-sis) Posterior pituitary plus infundibulum; portion of the pituitary gland derived from the brain.

Neuromuscular junction (motor end plate) Region where a motor neuron comes into close contact with a skeletal muscle cell.

Neuron (nerve cell) (nu′ron) Cell of the nervous system specialized to generate and transmit electrical signals (action potentials and graded potentials).

Neuron cell body The biosynthetic center of a neuron; also called the perikaryon, or soma.

Neuronal pools Functional groups of neurons that process and integrate information.

Neuropeptides (nu″ro-pep′tīds) A class of neurotransmitters including beta endorphins and enkephalins (which act as euphorics and reduce perception of pain) and gut-brain peptides.

Neurotransmitter Chemical messenger released by neurons that, upon binding to receptors of neurons or effector cells, stimulate or inhibit those neurons or effector cells.

Neutralization reaction Displacement reaction in which mixing an acid and a base forms water and a salt.

Neutron (nu′tron) Uncharged subatomic particle; found in the atomic nucleus.

Neutrophil (nu′tro-fil) Most abundant type of white blood cell.

Nicotinic receptors (nik″o-tin′ik) Acetylcholine-binding receptors of all autonomic postganglionic neurons and skeletal muscle neuromuscular junctions; named for activation by nicotine.

Nitric oxide (NO) A gaseous chemical messenger; diverse functions include participation in memory formation in the brain, and causing local vasodilation.

Nociceptor (no″se-sep′tor) Receptor sensitive to potentially damaging stimuli that result in pain.

Nondisjunction Failure of sister chromatids to separate during mitosis or failure of homologous pairs to separate during meiosis; results in abnormal numbers of chromosomes in the resulting daughter cells.

Nonmyelinated fibers (non-mi′ĕ-lĭ-nāt″ed) Axons lacking a myelin sheath and therefore conducting action potentials quite slowly.

Nonpolar molecules Electrically symmetrical molecules.

Nonvolatile (fixed) acid Acid generated by cellular metabolism that must be eliminated by the kidneys.

Norepinephrine (NE) (nor″ep-ĭ-nef′rin) A catecholamine neurotransmitter and adrenal medullary hormone, associated with sympathetic nervous system activation.

Nuclear envelope The double membrane barrier of a cell nucleus.

Nucleic acid (nu-kle′ik) Class of organic molecules that includes DNA and RNA.

Nucleoli (nu-kle′o-li) Dense spherical bodies in the cell nucleus involved with ribosomal RNA (rRNA) synthesis and ribosomal subunit assembly.

Nucleosome (nu′kle-o-sōm) Fundamental unit of chromatin; consists of a strand of DNA wound around a cluster of eight histone proteins.

Nucleotide (nu′kle-o-tīd) Building block of nucleic acids; consists of a sugar, a nitrogen-containing base, and a phosphate group.

Nucleus (nu′kle-is) (1) Control center of a cell; contains genetic material; (2) clusters of neuron cell bodies in the CNS; (3) center of an atom; contains protons and neutrons.

Nutrients Chemical substances taken in via the diet that are used for energy and cell building.

Oblique section A cut made diagonally between the horizontal and vertical plane of the body or an organ.

Occlusion (ah-kloo′zhun) Closure or obstruction.

Octet rule (rule of eights) (ok-tet′) The tendency of atoms to interact in such a way that they have eight electrons in their valence shell.

Olfaction (ol-fak′shun) Sense of smell.

Oligodendrocyte (ol″ĭ-go-den′dro-sīt) A type of CNS supporting cell that composes myelin sheaths.

Oocyte (o′o-sīt) Immature female gamete.

Oogenesis (o″o-jen′ĕ-sis) Process of ovum (female gamete) formation.

Ophthalmic (of-thal′mik) Pertaining to the eye.

Optic (op′tik) Pertaining to the eye or vision.

Optic chiasma (op′tik ki-az′muh) The partial crossover of fibers of the optic nerves to form the optic tracts.

Organ A part of the body formed of two or more tissues and adapted to carry out a specific function; e.g., the stomach.

Organ system A group of organs that work together to perform a vital body function; e.g., the nervous system.

Organelles (or″gah-nelz′) Small subcellular structures (ribosomes, mitochondria, and others) that perform specific functions for the cell as a whole.

Organic compound Any compound composed of atoms (some of which are carbon) held together by covalent (shared electron) bonds. Examples are proteins, fats, and carbohydrates.

Organism The living animal (or plant), which represents the sum total of all its organ systems working together to maintain life; also applies to a microorganism.

Origin Attachment of a muscle that remains relatively fixed during muscular contraction.

Osmolality The number of solute particles dissolved in 1 kilogram (1000 g) of water; reflects the solution's ability to cause osmosis.

Osmolarity (oz″mo-lar′ĭ-te) The number of solute particles present in 1 liter of a solution.

Osmoreceptor (oz″mo-re-sep′tor) Structure sensitive to osmotic pressure or concentration of a solution.

Osmosis (oz-mo′sis) Diffusion of a solvent through a selectively permeable membrane from a dilute solution into a more concentrated one.

Osmotic pressure A measure of the tendency of a solvent to move into a more concentrated solution.

Ossicles *See* Auditory ossicles.

Ossification (os″ĭ-fi-ka′shun) *See* Osteogenesis.

Osteoblasts (os′te-o-blasts) Bone-forming cells.

Osteoclasts (os′te-o-klasts) Large cells that resorb or break down bone matrix.

Osteocyte (os′te-o-sīt) Mature bone cell.

Osteogenesis (os″te-o-jen′e-sis) The process of bone formation; also called ossification.

Osteoid (os′te-oid) Unmineralized bone matrix.

Osteomalacia (os″te-o-mah-la′she-ah) Disorder in which bones are inadequately mineralized; soft bones.

Osteon (os′te-on) System of interconnecting canals in the microscopic structure of adult compact bone; unit of bone; also called Haversian system.

Osteoporosis (os″te-o-po-ro′sis) Decreased density and strength of bone resulting from a gradual decrease in rate of bone formation.

Ovarian cycle (o-vayr′e-an) Monthly cycle of follicle development, ovulation, and corpus luteum formation in an ovary.

Ovary (o′var-e) Female reproductive organ in which ova (eggs) are produced; female gonad.

Ovulation (ov″u-la′shun) Ejection of an oocyte (immature egg) from the ovary.

Ovum (o′vum) Female gamete; egg.

Oxidases Enzymes that catalyze the transfer of oxygen in oxidation-reduction reactions.

Oxidation (oks′ĭ-da″shun) Process of substances combining with oxygen or the removal of hydrogen.

Oxidation-reduction (redox) reaction A reaction that couples the oxidation (loss of electrons) of one substance with the reduction (gain of electrons) of another substance.

Oxidative phosphorylation (ok′sĭ-da″tiv fos″for-ĭ-la′shun) Process of ATP synthesis during which an inorganic phosphate group is attached to ADP; occurs via the electron transport chain within the mitochondria.

Oxyhemoglobin (ok″sĭ-he″mo-glo′bin) Oxygen-bound form of hemoglobin.

Oxytocin (ok″sĭ-to′sin) Hormone synthesized in the hypothalamus and secreted by the posterior pituitary; stimulates contraction of the uterus during childbirth and the ejection of milk during nursing.

Pacemaker cells Specialized cells in cardiac or unitary (visceral) smooth muscle that have unstable resting membrane potentials and so periodically fire spontaneous action potentials, triggering contraction of surrounding myocytes.

Paget's disease (paj′ets) Disorder characterized by excessive bone breakdown and abnormal bone formation.

Palate (pal′at) Roof of the mouth.

Pancreas (pan′kre-us) Gland located behind the stomach, between the spleen and the duodenum; produces both endocrine and exocrine secretions.

Pancreatic juice (pan″kre-at′ik) Bicarbonate-rich secretion of the pancreas containing enzymes for digestion of all food categories.

Papilla (pah-pil′ah) Small, nipple-like projection; e.g., dermal papillae are projections of dermal tissue into the epidermis.

Paracrine (par′ah-krin) A chemical messenger that acts locally within the same tissue and is rapidly destroyed. Examples are prostaglandins and nitric oxide.

Parasagittal planes All sagittal planes offset from the midline.

Parasympathetic division The division of the autonomic nervous system that oversees digestion, elimination, and glandular function; the resting and digesting subdivision.

Parasympathetic tone Normal (background) level of parasympathetic output; sustains normal gastrointestinal and urinary tract activity, lowers heart rate.

Parathyroid glands (par″ah-thi′roid) Small endocrine glands located on the posterior aspect of the thyroid gland.

Parathyroid hormone (PTH) Hormone released by the parathyroid glands that regulates blood calcium level.

Parietal (pah-ri′ĕ-tal) Pertaining to the walls of a cavity.

Parietal serosa The part of the double-layered membrane that lines the walls of the ventral body cavity.

Parkinson's disease Neurodegenerative disorder of the basal nuclei due to insufficient secretion of the neurotransmitter dopamine; symptoms include tremor and rigid movement.

Partial pressure The pressure exerted by a single component of a mixture of gases.

Parturition (par″tu-rish′un) Culmination of pregnancy; giving birth.

Passive immunity Short-lived immunity resulting from the introduction of "borrowed antibodies" obtained from an immune animal or human donor; immunological memory is not established.

Passive (transport) processes Membrane transport processes that move substances down their concentration gradients (e.g., diffusion). They are driven by kinetic energy and so do not require cellular energy (such as ATP).

Pathogen (path′o-jen) Disease-causing organism.

Pectoral (pek′tor-al) Pertaining to the chest.

Pectoral (shoulder) girdle Bones that attach the upper limbs to the axial skeleton; includes the clavicle and scapula.

Pedigree Diagram that traces a particular genetic trait through several generations and helps predict the genotype of future offspring.

Pelvic girdle (hip girdle) Consists of the paired coxal bones and sacrum that attach the lower limbs to the axial skeleton.

Pelvis (pel′vis) (1) Basin-shaped bony structure composed of the hip bones, sacrum, and coccyx; (2) funnel-shaped tube within the kidney continuous with the ureter.

Penis (pe′nis) Male organ of copulation and urination.

Pepsin Enzyme capable of digesting proteins in an acid pH.

Peptide bond (pep′tīd) Bond joining the amine group of one amino acid to the acid carboxyl group of a second amino acid with the loss of a water molecule.

Perforating canals Canals that run at right angles to the long axis of the bone, connecting the vascular and nerve supplies of the periosteum to those of the central canals and medullary cavity; also called Volkmann's canals.

Pericardium (per″ĭ-kar′de-um) Double-layered sac enclosing the heart and forming its superficial layer; has fibrous and serous layers.

Perichondrium (per″ĭ-kon′dre-um) Fibrous, connective-tissue membrane covering the external surface of cartilaginous structures.

Perimysium (per″ĭ-mis′e-um) Connective tissue that bundles muscle fibers into fascicles.

Perineum (per″ĭ-ne′um) That region of the body spanning the region between the ischial tuberosities and extending from the pubic arch to the coccyx.

Periosteum (per″e-os′te-um) Double-layered connective tissue that covers and nourishes the bone.

Peripheral congestion Condition caused by failure of the right side of the heart; results in edema in the extremities.

Peripheral nervous system (PNS) Portion of the nervous system consisting of nerves, ganglia, sensory receptors, and motor endings that lie outside of the brain and spinal cord.

Peristalsis (per″ĭ-stal′sis) Progressive, wavelike contractions that move foodstuffs through the alimentary tube organs (or that move other substances through other hollow body organs).

Peritoneum (per″ĭ-to-ne′um) Serous membrane lining the interior of the abdominal cavity and covering the surfaces of abdominal organs.

Peritonitis (per″ĭ-to-ni′tis) Inflammation of the peritoneum.

Permeability A measure of the ability of molecules and ions to pass through a membrane.

Peroxisomes (pĕ-roks′ĭ-sōmz) Membranous sacs in cytoplasm containing powerful oxidase enzymes that use molecular oxygen to detoxify harmful or toxic substances, such as free radicals.

Peyer's patches (pi′erz) Lymphoid organs located in the small intestine; also called aggregated lymphoid nodules.

pH unit (pe-āch) The measure of the relative acidity or alkalinity of a solution.

Phagocytosis (fag″o-si-to′sis) Engulfing of solids by (phagocytic) cells.

Phagosome (fag′o-sōm) Vesicle formed as a result of phagocytosis.

Pharmacological dose A drug dose that is dramatically higher than normal levels of that substance (e.g., hormone) in the body.

Pharyngeal cleft An indentation of the surface ectoderm in the embryo; the external acoustic meatus develops from it. Also called branchial groove.

Pharyngotympanic tube Tube that connects the middle ear and the pharynx. Also called auditory tube, eustachian tube.

Pharynx (fayr′inks) Muscular tube extending from the region posterior to the nasal cavities to the esophagus.

Phenotype (fe′no-tīp) Observable expression of the genotype.

Phospholipid (fos″fo-lip′id) Modified lipid, contains phosphorus.

Phosphorylation A chemical reaction in which a phosphate molecule is added to a molecule; for example, phosphorylation of ADP yields ATP.

Photoreceptor (fo″to-re-sep′tor) Specialized receptor cell that responds to light energy; rods and cones.

Physiological acidosis (as″ĭ-do′sis) Arterial pH lower than 7.35 resulting from any cause.

Physiological dose A drug dose that replicates normal levels of that substance (e.g., hormone) in the body. (Compare with Pharmacological dose.)

Physiology (fiz″e-ol′o-je) Study of the function of living organisms.

Pineal gland (body) (pin′e-al) A hormone-secreting part of the diencephalon of the brain thought to be involved in setting the biological clock and influencing reproductive function.

Pinocytosis (pe″no-si-to′sis) Engulfing of extracellular fluid by cells.

Pituitary gland (pĭ-tu′ĭ-tayr″e) Neuroendocrine gland located beneath the brain that serves a variety of functions including regulation of gonads, thyroid, adrenal cortex, lactation, and water balance.

Placenta (plah-sen′tah) Temporary organ formed from both fetal and maternal tissues that provides nutrients and oxygen to the developing fetus, carries away fetal metabolic wastes, and produces the hormones of pregnancy.

Plasma (plaz′mah) The nonliving fluid component of blood within which formed elements and various solutes are suspended and circulated.

Plasma cells Members of a B cell clone; effector B cells specialized to produce and release antibodies.

Plasma membrane Membrane, composed of phospholipids, cholesterol, and proteins, that encloses cell contents; outer limiting cell membrane.

Platelet (plāt′let) Cell fragment found in blood; involved in clotting.

Pleurae (ploo′re) Two layers of serous membrane that line the thoracic cavity and cover the external surface of the lung.

Pleural cavity (ploo′ral) A potential space between the two layers of pleura; contains a thin film of serous fluid.

Plexus (plek′sus) A network of converging and diverging nerve fibers, blood vessels, or lymphatics.

Polar molecules Electrically asymmetric molecules.

Polarized State of a plasma membrane of an unstimulated neuron or muscle cell in which the inside of the cell is relatively negative in comparison to the outside; the resting state.

Polycythemia (pol″e-si-the′me-ah) An abnormally high number of erythrocytes.

Polymer A substance of high molecular weight with long, chainlike molecules consisting of many similar (repeated) units.

Polypeptide (pol″e-pep′tīd) A chain of amino acids.

Polyps Benign mucosal tumors.

Polysaccharide (pol″e-sak′ah-rīd) Literally, many sugars, a polymer of linked monosaccharides; e.g., starch, glycogen.

Pons (1) Any bridgelike structure or part; (2) the part of the brain stem connecting the medulla with the midbrain, providing linkage between upper and lower levels of the central nervous system.

Pore The surface opening of the duct of a sweat gland.

Positive feedback mechanisms Feedback that tends to cause the level of a variable to change in the same direction as an initial change.

Posterior pituitary Neural part of pituitary gland; part of the neurohypophysis.

Postganglionic neuron (post″gan″gle-ah′nik) Autonomic motor neuron that has its cell body in an autonomic ganglion and projects its axon to an effector.

Potential energy Stored or inactive energy.

Preganglionic neuron Autonomic motor neuron that has its cell body in the central nervous system and projects its axon to an autonomic ganglion.

Presbyopia (pres″be-o′pe-ah) A condition that results in the loss of near focusing ability; typical onset is around age 40.

Pressure gradient Difference in pressure (hydrostatic or osmotic) that drives movement of fluid.

Primary active transport A type of active transport in which the energy needed to drive the transport process is provided directly by hydrolysis of ATP.

Primary lymphoid organs The red bone marrow and thymus; lymphoid organs in which lymphocytes develop and mature.

Prime mover Muscle that bears the major responsibility for effecting a particular movement; an agonist.

Process (1) Prominence or projection; (2) series of actions for a specific purpose.

Progesterone (pro-jes′ter-ōn) Hormone partly responsible for preparing the uterus for the fertilized ovum.

Prolactin (PRL) (pro-lak′tin) Anterior pituitary hormone that stimulates the breasts to produce milk.

Pronation (pro-na′shun) Inward rotation of the forearm causing the radius to cross diagonally over the ulna—palms face posteriorly.

Prophase The first stage of mitosis, meiosis I, and meiosis II. The chromosomes become visible, the nuclear envelope breaks down, and a spindle forms.

Proprioceptor (pro″pre-o-sep′tor) Receptor located in a joint, muscle, or tendon; concerned with locomotion, posture, and muscle tone.

Prostaglandin (pros″tah-glan′din) A lipid-based chemical messenger synthesized by most tissue cells; acts locally as a paracrine.

Prostate Accessory reproductive gland; produces one-third of semen volume, including fluids that activate sperm.

Protein (pro′tēn) Organic compound composed of carbon, oxygen, hydrogen, and nitrogen; types include enzymes, structural components; 10–30% of cell mass.

Protein kinase Enzyme that phosphorylates a protein (transfers an inorganic phosphate from ATP to the protein), resulting in activation or inactivation of the protein.

Prothrombin time Diagnostic test to determine status of the body's hemostasis system.

Proton (pro′ton) Subatomic particle that bears a positive charge; located in the atomic nucleus.

Proton acceptor A substance that takes up hydrogen ions in detectable amounts. Commonly referred to as a base.

Proton donor A substance that releases hydrogen ions in detectable amounts; an acid.

Proximal (prok′si-mul) Toward the attached end of a limb or the origin of a structure.

Pseudounipolar neuron (soo″do-u″nĭ-po′lar) Another term for unipolar neuron.

Puberty Period of life when reproductive maturity is achieved.

Pulmonary (pul′muh-nayr-e) Pertaining to the lungs.

Pulmonary arteries Vessels that deliver blood to the lungs to be oxygenated.

Pulmonary circuit System of blood vessels that serves gas exchange in the lungs; i.e., pulmonary arteries, capillaries, and veins.

Pulmonary edema (ĕ-de′muh) Leakage of fluid into the air sacs and tissue of the lungs.

Pulmonary veins Vessels that deliver freshly oxygenated blood from the respiratory zones of the lungs to the heart.

Pulmonary ventilation Breathing; consists of inspiration and expiration.

Pulse Rhythmic expansion and recoil of arteries resulting from heart contraction; can be felt from outside the body.

Pupil Opening in the center of the iris through which light enters the eye.

Pus Fluid product of inflammation composed of white blood cells, the debris of dead cells, and a thin fluid.

Pyloric sphincter (pi-lor′ik sfink′ter) Valve of the distal end of the stomach that controls food entry into the duodenum.

Pyramidal (corticospinal) tracts Major motor pathways concerned with voluntary movement; descend from pyramidal cells in the frontal lobes of each cerebral hemisphere.

Pyruvic acid An intermediate compound in the metabolism of carbohydrates.

Radioactivity The process of spontaneous decay seen in some of the heavier isotopes, during which particles or energy is emitted from the atomic nucleus; results in the atom becoming more stable.

Radioisotope (ra″de-o-i′so-tōp) Isotope that exhibits radioactive behavior.

Ramus (ra′mus) Branch of a nerve, artery, vein, or bone.

Rapid eye movement (REM) sleep Stage of sleep in which rapid eye movements, an alert EEG pattern, and dreaming occur.

Reactant A substance that is an input to a chemical reaction.

Receptor (re-sep′tor) (1) A cell or nerve ending of a sensory neuron specialized to respond to particular types of stimuli; (2) protein that binds specifically with other molecules, e.g., neurotransmitters, hormones, paracrines, antigens.

Receptor-mediated endocytosis The type of endocytosis in which engulfed particles attach to receptors before endocytosis occurs.

Receptor potential A graded potential that occurs at a sensory receptor membrane.

Recessive traits A trait due to a particular allele that does not manifest itself in the presence of other alleles that generate traits dominant to it; must be present in double dose to be expressed.

Reduction Chemical reaction in which electrons and energy are gained by a molecule (often accompanied by gain of hydrogen ions) or oxygen is lost.

Referred pain Pain felt at a site other than the area of origin.

Reflex Automatic reaction to stimuli.

Refraction The bending of a light ray when it meets a different surface at an oblique rather than right angle.

Regeneration Replacement of destroyed tissue with the same kind of tissue.

Regulatory T cells (T_{Reg} cells) Population of T cells (usually expressing CD4) that suppress the immune response.

Relative refractory period Follows the absolute refractory period; interval when a threshold for action potential stimulation is markedly elevated.

Renal (re′nal) Pertaining to the kidney.

Renal autoregulation Process the kidney uses to maintain a nearly constant glomerular filtration rate despite fluctuations in systemic blood pressure.

Renal clearance The volume of plasma from which a particular substance is completely removed in a given time, usually 1 minute; provides information about renal function.

Renin (re′nin) Enzyme released by the kidneys that raises blood pressure by initiating the renin-angiotensin-aldosterone mechanism.

Renin-angiotensin-aldosterone mechanism Hormone mechanism that acts to increase blood sodium content and blood pressure.

Rennin Stomach-secreted enzyme that acts on milk protein; not produced in adults.

Repolarization Return of the membrane potential to the initial resting (polarized) state.

Reproductive system Organ system that functions to produce offspring.

Respiration The processes involved in supplying the body with oxygen and disposing of carbon dioxide.

Respiratory system Organ system that carries out gas exchange; includes the nose, pharynx, larynx, trachea, bronchi, lungs.

Resting membrane potential The voltage that exists across the plasma membrane during the resting state of an excitable cell; typically ranges from −50 to −90 millivolts depending on cell type.

Reticular activating system (RAS) (re-tik′u-lar) Diffuse brain stem neural network that receives a wide variety of sensory input and maintains wakefulness of the cerebral cortex.

Reticular connective tissue Connective tissue with a fine network of reticular fibers that form the internal supporting framework of lymphoid organs.

Reticular formation Functional system that spans the brain stem; involved in regulating sensory input to the cerebral cortex, cortical arousal, and control of motor behavior.

Reticular lamina A layer of extracellular material containing a fine network of collagen fibers; together with the basal lamina it is a major component of the basement membrane.

Reticulocyte (rĕ-tik′u-lo-sīt) Immature erythrocyte.

Retina (ret′ĭ-nah) Inner layer of the eyeball; contains photoreceptors (rods, cones).

Rhombencephalon (hindbrain) (romb″en-sef′ah-lon) Caudal portion of the developing brain; constricts to form the metencephalon and myelencephalon; includes the pons, cerebellum, and medulla oblongata.

Ribosomal RNA (rRNA) A constituent of ribosomes that assists in protein synthesis.

Ribosomes (ri′bo-sōmz) Cytoplasmic organelles at which proteins are synthesized.

RNA (ribonucleic acid) (ri′bo-nu-kle′ik) Nucleic acid that contains ribose and the bases A, G, C, and U. Carries out DNA's instructions for protein synthesis.

Rods One of the two types of photoreceptor cells in the retina.

Rotation Movement at a synovial joint in which a bone turns around its own long axis.

Rugae (ru′ge) Elevations or ridges, as in stomach mucosa.

Rule of nines Method of computing the extent of burns by dividing the body into a number of areas, each accounting for 9% (or a multiple thereof) of the total body area.

S (synthetic) phase The part of the interphase period of the cell cycle in which DNA replicates itself, ensuring that the two future cells will receive identical copies of genetic material.

Sagittal plane (saj′ĭ-tal) A longitudinal (vertical) plane that divides the body or any of its parts into right and left portions.

Saliva Secretion of the salivary glands; cleanses and moistens the mouth and begins chemical digestion of starchy foods.

Saltatory conduction Transmission of an action potential along a myelinated fiber in which the action potentials appears to leap from gap to gap.

Sarcolemma The plasma membrane of a muscle fiber.

Sarcomere (sar′ko-mēr) The smallest contractile unit of muscle; extends from one Z disc to the next.

Sarcoplasm The cytoplasm of a muscle fiber.

Sarcoplasmic reticulum (SR) (sar″ko-plaz′mik rĕ-tik′u-lum) Specialized endoplasmic reticulum of muscle cells.

Schwann cell A type of supporting cell in the PNS; forms myelin sheaths and is vital to peripheral nerve fiber regeneration. Also called a neurolemmocyte.

Sclera (skler′ah) White opaque portion of the fibrous layer of the eyeball.

Scrotum (skro′tum) External sac enclosing the testes.

Sebaceous glands (oil glands) (se-ba′shus) Epidermal glands that produce an oily secretion called sebum.

Sebum (se′bum) Oily secretion of sebaceous glands.

Second-degree burn A burn in which the epidermis and the upper region of the dermis are damaged.

Second messenger Intracellular molecule generated by the binding of a chemical (e.g., hormone or neurotransmitter) to a receptor protein; mediates intracellular responses to the chemical messenger.

Secondary active transport A type of active transport in which the energy needed to drive the transport process is provided by the electrochemical gradient of another molecule (which moves "downhill" through the transport protein at the same time as another molecule is moved "uphill" against its gradient). Also called cotransport or symport (when the two transported molecules move in the same direction) or antiport (when the two transported molecules move in opposite directions).

Secondary lymphoid organs Lymph nodes, spleen, and mucosa-associated lymphoid tissue (MALT); lymphoid organs in which lymphocytes encounter antigens and are activated.

Secondary sex characteristics Anatomical features, not directly involved in the reproductive process, that develop under the influence of sex hormones, e.g., male or female pattern of muscle development, bone growth, body hair distribution.

Secretion (se-kre′shun) (1) The passage of material formed by a cell to its exterior; (2) cell product that is transported to the exterior of a cell.

Secretory vesicles (granules) Vesicles that migrate to the plasma membrane of a cell and discharge their contents from the cell by exocytosis.

Section A cut through the body (or an organ) that is made along a particular plane; a thin slice of tissue prepared for microscopic study.

Segregation During meiosis, the distribution of the members of the allele pair to different gametes.

Selectively permeable membrane A membrane that allows certain substances to pass while restricting the movement of others; also called differentially permeable membrane.

Semen (se′men) Fluid mixture containing sperm and secretions of the male accessory reproductive glands.

Semilunar (SL) valves (sĕ″me-loo′ner) Valves that prevent blood return to the ventricles after contraction; aortic and pulmonary valves.

Seminiferous tubules (sem″ĭ-nif′er-us) Highly convoluted tubes within the testes; form sperm.

Sense organs Localized collections of many types of cells working together to accomplish a specific receptive process.

Sensory (afferent) nerves Nerves that contain processes of sensory neurons and carry action potentials to the central nervous system.

Sensory areas Functional areas of the cerebral cortex that provide for conscious awareness of sensation.

Sensory receptor A cell or part of a cell (e.g., receptive endings of sensory neurons) specialized to respond to a stimulus.

Serosa (serous membrane) (se-ro′sah) The moist membrane found in closed ventral body cavities.

Serous fluid (sēr′us) Clear, watery fluid secreted by cells of a serous membrane.

Serum (sēr′um) Amber-colored fluid that exudes from clotted blood as the clot shrinks; plasma without clotting factors.

Sesamoid bones (ses′ah-moid) Short bones embedded in tendons, variable in size and number, many of which influence the action of muscles; largest is the patella (kneecap).

Severe combined immunodeficiency syndromes (SCIDs) Congenital conditions resulting in little or no protection against disease-causing organisms of any type.

Sex chromosomes The chromosomes, X and Y, that determine genetic sex (XX = female; XY = male); the 23rd pair of chromosomes.

Sex-linked inheritance Inherited traits determined by genes on the sex chromosomes, e.g., X-linked genes are passed from mother to son, Y-linked genes are passed from father to son.

Sexually transmitted infection (STI) Any infectious disease spread through sexual contact.

Signal sequence A short peptide segment present in a protein being synthesized that causes the associated ribosome to attach to the membrane of rough ER.

Simple diffusion The unassisted transport across a plasma membrane of a lipid-soluble or very small particle.

Sinoatrial (SA) node (si″no-a′tre-al) Specialized myocardial cells in the wall of the right atrium; pacemaker of the heart.

Sinus (si′nus) (1) Mucous-membrane-lined, air-filled cavity in certain cranial bones; (2) dilated channel for the passage of blood or lymph.

Skeletal muscle Muscle composed of cylindrical multinucleate cells with obvious striations; the muscle(s) attached to the body's skeleton; voluntary muscle.

Skeletal system System of protection and support composed primarily of bone and cartilage.

Skull Bony protective encasement of the brain and the organs of hearing and equilibrium; includes cranial and facial bones.

Small intestine Convoluted tube extending from the pyloric sphincter to the ileocecal valve where it joins the large intestine; the site where digestion is completed and virtually all absorption occurs.

Smooth muscle Spindle-shaped cells with one centrally located nucleus and no externally visible striations (bands). Found mainly in the walls of hollow organs.

Sodium-potassium (Na^+-K^+) pump A primary active transport system that simultaneously drives Na^+ out of the cell against a steep gradient and pumps K^+ back in. Also called Na^+-K^+ ATPase.

Sol-gel transformation Reversible change of a colloid from a fluid (sol) to a more solid (gel) state.

Solute (sol′yoot) The substance that is dissolved in a solution.

Solute pump Enzyme-like protein carrier that mediates active transport of solutes such as amino acids and ions uphill against their concentration gradients.

Somatic nervous system (so-mă′tik) Division of the peripheral nervous system that provides the motor innervation of skeletal muscles; also called the voluntary nervous system.

Somatic reflexes Reflexes that activate skeletal muscle.

Somatosensory system That part of the sensory system dealing with reception in the body wall and limbs; receives inputs from exteroceptors, proprioceptors, and interoceptors.

Somite (so′mīt) A mesodermal segment of the body of an embryo that contributes to the formation of skeletal muscles, vertebrae, and dermis of skin.

Spatial discrimination The ability of neurons to identify the site or pattern of stimulation.

Special senses The senses of taste, smell, vision, hearing, and equilibrium.

Specific gravity Term used to compare the weight of a substance to the weight of an equal volume of distilled water.

Sperm Male gamete. Also called spermatozoon.

Spermatogenesis (sper″mah-to-jen′ĕ-sis) The process of sperm (male gamete) formation; involves meiosis.

Sphincter (sfink′ter) A circular muscle surrounding an opening; acts as a valve.

Spinal cord The bundle of nervous tissue that runs from the brain to the first to third lumbar vertebrae and provides a conduction pathway to and from the brain.

Spinal nerves The 31 nerve pairs that arise from the spinal cord.

Splanchnic circulation (splangk′nik) The blood vessels serving the digestive system.

Spleen Largest lymphoid organ; provides a site for immune surveillance, lymphocyte activation, and erythrocyte destruction.

Spongy bone Internal layer of skeletal bone. Also called trabecular bone.

Sprain Ligaments reinforcing a joint are stretched or torn.

Static equilibrium Sense of head position in space with respect to gravity.

Stem cells Unspecialized cells that can divide to produce various kinds of more specialized cell types.

Stenosis (stĕ-no′sis) Abnormal constriction or narrowing.

Steroids (stĕ′roidz) A class of lipids derived from (and including) cholesterol; act as hormones and as constituents of phospholipid bilayer membranes.

Stimulus (stim′u-lus) An excitant; a change in the environment that evokes a response.

Stomach Temporary reservoir in the gastrointestinal tract where chemical breakdown of proteins begins and food is converted into chyme.

Stressor Any stimulus that directly or indirectly causes the hypothalamus to initiate stress-compensating responses, such as the fight-or-flight response.

Stroke *See* Cerebrovascular accident.

Stroke volume (SV) Amount of blood pumped out of a ventricle during one contraction.

Stroma (stro′mah) The basic internal structural framework of an organ.

Structural (fibrous) proteins Consist of extended, strandlike polypeptide chains forming a strong, ropelike structure that is linear, insoluble in water, and very stable; e.g., collagen.

Subcutaneous (sub″kyu-ta′ne-us) Beneath the skin.

Subcutaneous tissue Tissue just deep to the skin; consists of adipose plus some areolar connective tissue. Also called hypodermis or superficial fascia.

Subendocardial conducting network Modified ventricular muscle fibers of the conduction system of the heart. Also called Purkinje fibers.

Submucosa Connective tissue underlying a mucosa (mucous membrane that lines body cavities open to the exterior).

Substrate A reactant on which an enzyme acts to cause a chemical action to proceed.

Sudoriferous gland (su″do-rif′er-us) *See* Sweat gland.

Sulcus (sul′kus) A furrow on the brain, less deep than a fissure.

Summation Accumulation of effects, especially those of muscular, sensory, or mental stimuli.

Superficial Located toward or on the body surface.

Superior Toward the head or upper body regions.

Superior vena cava Vein that returns blood from body regions superior to the diaphragm.

Supination (soo″pĭ-na′shun) The outward rotation of the forearm causing palms to face anteriorly.

Surfactant (ser-fak′tant) Secretion produced by certain cells of the alveoli that reduces the surface tension of water molecules, thus preventing the collapse of the alveoli after each expiration.

Suspension Heterogeneous mixtures with large, often visible solutes that tend to settle out.

Suture (soo′cher) An immovable fibrous joint; with one exception, all bones of the skull are united by sutures.

Sweat gland Epidermal gland that produces sweat. Also called sudoriferous gland.

Sympathetic division The division of the autonomic nervous system that prepares the body for activity or to cope with some stressor (danger, excitement, etc.); the fight, fright, and flight subdivision.

Sympathetic (vasomotor) tone State of partial vasoconstriction of the blood vessels maintained by sympathetic fibers.

Symphysis (sim′fih-sis) A joint in which the bones are connected by fibrocartilage.

Synapse (sin′aps) Functional junction or point of close contact between two neurons or between a neuron and an effector cell.

Synapsis (sĭ-nap′sis) Pairing of homologous chromosomes during the first meiotic division.

Synaptic cleft (sĭ-nap′tik) Fluid-filled space at a synapse.

Synaptic delay Time required for a signal to cross a synapse between two neurons.

Synaptic vesicles Small membranous sacs containing neurotransmitter.

Synarthrosis (sin″ar-thro′sis) Immovable joint.

Synchondrosis (sin″kon-dro′sis) A joint in which the bones are united by hyaline cartilage.

Syndesmosis (sin″des-mo′sis) A joint in which the bones are united by a ligament or a sheet of fibrous tissue.

Synergist (sin′er-jist) (1) Muscle that aids the action of a prime mover by effecting the same movement or by stabilizing joints across which the prime mover acts, preventing undesirable movements. (2) Hormone that amplifies the effect of another hormone at a target cell.

Synostosis (sin″os-to′sis) A completely ossified joint; a fused joint.

Synovial fluid Fluid secreted by the synovial membrane; lubricates joint surfaces and nourishes articular cartilages.

Synovial joint Freely movable joint exhibiting a joint cavity; also called a diarthrosis.

Synthesis (combination) reaction A chemical reaction in which larger, more complex atoms or molecules are formed from simpler ones.

Systemic (sis-tem′ik) Pertaining to the whole body.

Systemic circuit System of blood vessels that serves gas exchange in the body tissues.

Systole (sis′to-le) Period when either the ventricles or the atria are contracting.

Systolic pressure (sis-tah′lik) Pressure exerted by blood on the blood vessel walls during ventricular contractions.

T cells Lymphocytes that mediate cellular immunity; include helper, cytotoxic, regulatory, and memory cells. Also called T lymphocytes.

T tubule (transverse tubule) Extension of the muscle cell plasma membrane (sarcolemma) that protrudes deeply into the muscle cell.

Tachycardia (tak″e-kar′de-ah) A heart rate over 100 beats per minute.

Taste buds Sensory receptor organs that house gustatory epithelial cells, which respond to dissolved food chemicals.

Telencephalon (tel″en-seh′fuh-lon) Anterior subdivision of the primary forebrain that develops into olfactory lobes, cerebral cortex, and basal nuclei.

Telophase The final phase of mitosis, meiosis I, and meiosis II; begins when migration of chromosomes to the poles of the cell has been completed and ends with the formation of two daughter nuclei.

Tendon (ten′dun) Cord of dense regular connective tissue attaching muscle to bone.

Tendon organ Proprioceptor located in tendon; monitors muscle tension to prevent tearing and help smooth onset and termination of muscle contraction.

Tendonitis Inflammation of tendon sheaths, typically caused by overuse.

Terminal branches Branching ends of an axon that allow it to form many axon terminals; terminal arborization.

Testis (tes′tis) Male primary reproductive organ that produces sperm; male gonad.

Testosterone (tes-tos′tĕ-rōn) Male sex hormone produced by the testes; during puberty promotes virilization, and is necessary for normal sperm production.

Tetanus (tet′ah-nus) (1) A smooth, sustained muscle contraction resulting from high-frequency stimulation; (2) an infectious disease caused by an anaerobic bacterium.

Thalamus (thal′ah-mus) A mass of gray matter in the diencephalon of the brain.

Thermogenesis (ther″mo-jen′ĕ-sis) Heat production.

Thermoreceptor (ther″mo-re-sep′ter) Receptor sensitive to temperature changes.

Third-degree burn A burn that involves the entire thickness of the skin; also called a full-thickness burn. Usually requires skin grafting.

Thoracic cage (bony thorax) Bones and costal cartilages that form the framework of the thorax; includes sternum, ribs, and thoracic vertebrae.

Thoracic duct Large lymphatic duct that receives lymph drained from the entire lower body, the left upper extremity, and the left side of the head and thorax.

Thoracic vertebrae The 12 vertebrae that are in the middle part of the vertebral column and articulate with the ribs.

Thorax (tho′raks) That portion of the body trunk above the diaphragm and below the neck.

Threshold stimulus Weakest stimulus capable of producing a response in an excitable tissue.

Thrombin (throm′bin) Enzyme that induces clotting by converting fibrinogen to fibrin.

Thrombocyte (throm′bo-sīt) Platelet; cell fragment that participates in blood coagulation.

Thrombocytopenia (throm″bo-si″to-pe′ne-ah) A reduction in the number of platelets circulating in the blood.

Thrombus (throm′bus) A clot that develops and persists in an unbroken blood vessel.

Thymine (T) (thi′mēn) Single-ring base (a pyrimidine) in DNA.

Thymus (thi′mus) Lymphoid organ active in immune response; site of maturation of T lymphocytes.

Thyroid gland (thi′roid) One of the largest of the body's endocrine glands; straddles the anterior trachea.

Thyroid hormone (TH) The major hormone secreted by thyroid follicles; stimulates production of enzymes concerned with glucose oxidation. *See also* Thyroxine, Triiodothyronine.

Thyroid-stimulating hormone (TSH) Anterior pituitary hormone that regulates secretion of thyroid hormones.

Thyroxine (T_4) (thi-rok′sin) Iodine-containing hormone secreted by the thyroid gland; accelerates cellular metabolic rate in most body tissues.

Tight junction Area where plasma membranes of adjacent cells are tightly bound together, forming an impermeable barrier.

Tissue A group of similar cells and their intercellular substance specialized to perform a specific function; primary tissue types of the body are epithelial, connective, muscle, and nervous tissue.

Tissue perfusion Blood flow through body tissues or organs.

Tonicity (to-nis′ĭ-te) A measure of the ability of a solution to cause a change in cell shape or tone by promoting osmotic flows of water.

Tonsils A ring of lymphoid tissue around the entrance to the pharynx. *See also* Adenoids.

Total peripheral resistance (TPR) A measure of the amount of friction encountered by blood as it flows through the blood vessels.

Trabecula (trah-bek′u-lah) (1) Any of the fibrous bands extending from the capsule into the interior of an organ; (2) strut or thin plate of bone in spongy bone.

Trachea (tra′ke-ah) Windpipe; cartilage-reinforced tube extending from larynx to bronchi.

Tract (1) A collection of axons in the central nervous system having the same origin, termination, and function; (2) a major anatomical passageway.

Transcription The transfer of genetic code information from a DNA base sequence to the complementary base sequence of an mRNA molecule; the first major step in polypeptide synthesis.

Transduction (trans-duk′shun) The conversion of the energy of a stimulus into an electrical event (a graded potential).

Transepithelial transport (trans-ep″ĭ-the′le-al) Movement of substances through, rather than between, adjacent epithelial cells connected by tight junctions, such as absorption of nutrients in the small intestine.

Transfer RNA (tRNA) Short-chain RNA molecules that transfer amino acids to the ribosome.

Transfusion reaction Agglutination and destruction of red blood cells following transfusion of incompatible blood.

Translation The second major step in the transfer of genetic code information, in which the information carried by mRNA is decoded and used to assemble polypeptides.

Transverse (horizontal) plane A plane running from right to left, dividing the body or an organ into superior and inferior parts.

Tricuspid valve (tri-kus′pid) The right atrioventricular valve.

Triglycerides (tri-glis′er-īdz) Fats and oils composed of fatty acids and glycerol; are the body's most concentrated source of energy fuel.

Triiodothyronine (T_3) (tri″i-o″do-thi′ro-nēn) Thyroid hormone; secretion and function similar to those of thyroxine (T_4).

Trophoblast (tro′fo-blast) Outer sphere of cells of the blastocyst.

Tropic hormone (tropin) (trōp′ik) A hormone that regulates the secretory action of another endocrine organ.

Trypsin Proteolytic enzyme secreted by the pancreas.

Tubular reabsorption The movement of filtrate components from the renal tubules into the blood.

Tubular secretion The movement of substances (such as drugs, urea, excess ions) from blood into renal filtrate.

Tumor An abnormal growth of cells; a swelling; may be cancerous.

Tunica (too′nĭ-kah) A covering or tissue coat; membrane layer.

Tympanic membrane (tim-pan′ik) Eardrum.

Ulcer (ul′ser) Lesion or erosion of the mucous or cutaneous membrane, such as a gastric ulcer of the stomach.

Umbilical cord (um-bĭ′lĭ-kul) Structure bearing arteries and a vein connecting the placenta and the fetus.

Umbilicus (um-bĭ′lĭ-kus) Navel; marks site where umbilical cord was attached in fetal stage.

Unipolar neuron Neuron in which embryological fusion of the two processes leaves only one process extending from the cell body.

Uracil (U) (u′rah-sil) A smaller, single-ring base (a pyrimidine) found in RNA.

Urea (u-re′ah) Main nitrogen-containing waste excreted in urine.

Ureter (u-re′ter) Tube that carries urine from kidney to bladder.

Urethra (u-re′thrah) Canal through which urine passes from the bladder (and semen passes from the ejaculatory duct in the male) to outside the body.

Uric acid The nitrogenous waste product of nucleic acid metabolism; component of urine.

Urinary bladder A smooth, collapsible, muscular sac that stores urine temporarily.

Urinary system System primarily responsible for water, electrolyte, and acid-base balance and removal of nitrogenous wastes.

Uterine tube (u′ter-in) Tube through which the ovum is transported to the uterus. Also called fallopian tube.

Uterus (u′ter-us) Hollow, thick-walled organ that receives, retains, and nourishes fertilized egg; site where embryo/fetus develops.

Uvula (u′vu-lah) Tissue tag hanging from soft palate.

Vaccine Preparation that provides artificially acquired active immunity.

Vagina Thin-walled tube extending from the cervix to the body exterior; often called the birth canal.

Valence shell (va′lens) Outermost electron shell (energy level) of an atom that contains electrons.

Varicosities Knoblike swellings of certain autonomic axons containing mitochondria and synaptic vesicles.

Vasa recta (va′sah rek′tah) Capillary branches that supply nephron loops in the medulla region of the kidney.

Vascular Pertaining to blood vessels or richly supplied with blood vessels.

Vascular spasm Immediate response to blood vessel injury; results in constriction.

Vasoconstriction (vas″o-kon-strik′shun) Narrowing of blood vessels.

Vasodilation (vas″o-di-la′shun) Relaxation of the smooth muscles of the blood vessels, producing dilation.

Vasomotion (vas″o-mo′shun) Oscillating constriction and dilation of blood vessels. In arterioles, this results in intermittent flow through capillary beds and matches perfusion to tissue requirements.

Vasomotor center (vas″o-mo′ter) Brain area concerned with regulation of blood vessel resistance.

Vasomotor fibers Sympathetic nerve fibers that cause the contraction of smooth muscle in the walls of blood vessels, thereby regulating blood vessel diameter.

Veins (vānz″) Blood vessels that return blood toward the heart from the circulation.

Ventral Pertaining to the front; anterior.

Ventricles (1) Paired, inferiorly located heart chambers that function as the major blood pumps; (2) cavities in the brain.

Venule (ven′ūl) A small vein.

Vertebral column (spine) (ver′tĕ-brul) Formed of a number of individual bones called vertebrae and two composite bones (sacrum and coccyx).

Vesicle (vĕ′sĭ-kul) A small liquid-filled sac or bladder.

Vesicular follicle Mature ovarian follicle.

Vesicular transport Transport of large particles and macromolecules into or out of a cell or between its compartments in membrane-bound sacs.

Vestibule An enlarged area at the beginning of a canal, i.e., inner ear, nose, larynx.

Villus (vil′us) One of the fingerlike projections of the small intestinal mucosa that tremendously increase its surface area for absorption.

Visceral (vis′er-al) Pertaining to an internal organ of the body or the inner part of a structure.

Visceral muscle Type of smooth muscle; its cells are electrically coupled by gap junctions, and so they rhythmically contract as a unit. They often exhibit spontaneous action potentials. Also called unitary smooth muscle.

Visceral organs (viscera) A group of internal organs housed in the ventral body cavity.

Visceral serosa (se-ro′sah) The part of the double-layered membrane that lines the outer surfaces of organs within the ventral body cavity.

Viscosity (vis′kos′ĭ-te) A measurement of thickness (ability to flow) of a fluid.

Visual field The field of view seen when the head and eyes are still.

Vital capacity (VC) The volume of air that can be expelled from the lungs by forcible expiration after the deepest inspiration; total exchangeable air.

Vital signs Includes pulse, blood pressure, respiratory rate, and body temperature measurements.

Vitamins Organic compounds required by the body in minute amounts.

Vocal folds Mucosal folds that function in voice production (speech); also called the true vocal cords.

Volatile acid An acid that can be eliminated by the lungs; carbonic acid is converted to CO_2, which diffuses into the alveoli.

Volkmann's canals *See* Perforating canals.

Voltage-gated channel An ion channel that opens or closes when the transmembrane voltage changes.

Voluntary muscle Muscle under strict nervous control; skeletal muscle.

Voluntary nervous system The somatic nervous system.

Vulva (vul′vuh) Female external genitalia.

Wallerian degeneration (wal-er′ē-an) A process of disintegration of an axon that occurs when it is crushed or severed and cannot receive nutrients from the cell body.

White matter White substance of the central nervous system; myelinated nerve fibers.

Xenograft Tissue graft taken from another animal species.

Yolk sac (yōk) One of the extraembryonic membranes; involved in early blood cell formation.

Zygote (zi′gōt) Fertilized egg.

Index

NOTE: Page numbers in **boldface** indicate a definition. A *t* following a page number indicates tabular material, an *f* indicates an illustration, and a *b* indicates boxed material.

A agglutinins, 664, 664*t*
A agglutinogens, 664, 664*t*, 665*f*
A bands, **284**, 285*f*, 288*f*, 289, 289*f*, 684*f*, 685
ABCD rule, for melanoma recognition, **166**
Abdomen
  arteries of, 744–747*f*, 744–747*t*
  muscles of, 330*f*, 346*t*, 347*f*
  sympathetic pathways to, 540*f*, 541
  veins of, 756–757*f*, 756–757*t*
Abdominal aorta, **738***t*, 738*f*, 739*f*, 744–747*f*, 744–747*t*, 748*f*
Abdominal aortic plexus, 537, **541**
Abdominal cavity, **18**, 18*f*
Abdominal hernia, 346*t*, **386**
Abdominal organs, arterial supply/perfusion/blood flow of, 726, 726*f*, 744–747*f*, 744–747*t*
Abdominal reflexes, **525**
Abdominal wall, innervation of, 515
Abdominal wall, muscles of, 330*f*, 346*t*, 347*f*
Abdominopelvic cavity, **18**, 18*f*, 19, 19*f*
Abdominopelvic organs, 19, 19*f*
  muscles compressing, 345*t*, 347*f*
  muscles supporting, 348*t*, 349*f*
Abducens nerve (cranial nerve VI), 450*f*, 452, 499*f*, 503*t*, **506**, 556, 557*f*
Abduction (body movement), **259**, 259*f*, 325*f*, 350*t*, 354*t*, 362*t*, 365*t*, 367*t*, 384*t*
Abductor digiti minimi muscle, **364***t*, 365*f*, **380***t*, 381*f*
Abductor hallucis muscle, **380***t*, 381*f*
Abductor muscles, of thigh, 367*t*
Abductor pollicis brevis muscle, **364***t*, 365*f*
Abductor pollicis longus muscle, **360***t*, 361*f*, 362*t*, 363*f*
ABO blood groups, **664**, 664*t*, 665–666, 665*f*, 811, 1129, 1129*t*
Abortion, **1120**
Abruptio placenta, **1120**
Abscess, 787
Absence (petit mal) seizures, 462
Absolute refractory period, **410**, 410*f*
  in cardiac muscle, 685, 689*f*, 690
Absorption (food/nutrient), **869**, 870*f*, **871**, 872, 889, 904*t*, 912
  in large intestine, 904*t*
  in small intestine, 902–903, 902*f*, 904*t*, 905–906, 913*f*
  vitamin/electrolyte/water, 917
Absorptive cells (enterocytes), of small intestine, 902*f*, 903, 903*f*
Absorptive (fed) state, 950–952, 951*f*, 952*f*
Abstinence methods, of contraception, 1118*b*
Acceleration
  crista ampullaris response to, 592, 592*f*, 593
  macular response to, 590–591, 591*f*
Accessory digestive organs, 869, 869*f*, **870**, 893–900. *See also specific structure*
Accessory hemiazygos vein, 754*f*, **755***t*, 755*f*
Accessory nerve (cranial nerve XI), 340*t*, 352*t*, 450*f*, 451*f*, 499*f*, **506**, 506*t*, 509*f*
Accessory oculomotor (Edinger-Westphal) nuclei, 536
Accessory pancreatic duct, 900, 900*f*
Accessory reproductive ducts. *See* Reproductive duct system
Accessory reproductive organs/glands/ducts, **1042**, 1047, **1050**, **1052**–1053
Acclimatization, **858**
Accommodation, gastric, **892**
Accommodation, ocular, 565, **566**–567
Accommodation pupillary reflex, **567**
ACE. *See* Angiotensin converting enzyme
Acetabular labrum, 268–269, 269*f*
Acetabulum, **236**, 237*f*, 239*t*, 268–269
Acetic acid, 39, 41, 946
Acetylcholine (ACh), 81, 421*t*, **423**, 517, **533**, 543, 544*t*
  in autonomic versus somatic nervous system, 533, 533*f*, 543, 544*t*
  in hydrochloric acid secretion control, 889
  in muscle contraction, **290**, 291, 291*f*, 292*f*, 293, 293*f*, 294*f*, 315
  in neuromuscular junction, **290**, 292*f*, 293*f*, 517
Acetylcholine (ACh) receptors, **290**, 292*f*, 421*t*, 517
Acetylcholinesterase (AChE), 292*f*, **293**, **423**, 517
Acetylcholinesterase (AChE) inhibitors, autonomic activity and, 544*t*
Acetyl coenzyme A (acetyl CoA), 934, 935*f*, 939*f*, **940**, 944*f*, 946–947, 946*f*, 947*f*
ACh. *See* Acetylcholine
Achalasia, **919**
AChE. *See* Acetylcholinesterase
Achilles (calcaneal) tendon, 244, 331*f*
  ruptured, **386**
Achondroplasia, **195**
Acid(s), **39**
  amino acid as, 48
  nonvolatile (fixed), **1029**
  pH of, 40, 40*f*
  strong, **41**, 1027, 1027*f*
  volatile, **1029**
  weak, **41**, 1027, 1027*f*
Acid-base balance, 39–40, **1026**–1035
  abnormalities of, 1033–1035, 1033*t*, 1034*b*, 1035. *See also* Acidosis; Alkalosis
  aldosterone and, 623
  blood in regulation of, 643
  chemical buffer systems in, 41, **1027**–1028, 1027*f*
  developmental aspects of, 1035–1037
  physiological buffer systems in, 1027, 1028–1032, 1030*f*, 1031*f*, 1032*f*
  renal regulation of, 992*f*, 995, 1029–1032, 1030*f*, 1031*f*, 1032*f*, 1035
  respiratory and renal compensations and, **1035**
  respiratory regulation of, 852, 856, 1035
Acidemia, **1027**. *See also* Acidosis
Acid group, amino acid, 48, 49*f*
Acid hydrolases, 86
Acidic diet, 1002
Acidic solution, 40, 40*f*
Acid mantle of skin, **163**, 783, 783*t*
Acid mantle of vagina, 783*t*, 1066
Acidosis, **56**, 1026, **1027**, 1034*b*
  in diabetes, 952
  effects of, 1035
  metabolic, 947, 1033*t*, 1034*b*, **1035**
  newborn's first breath and, 1116
  physiological, 1027
  renal tubular, **1037**
  respiratory (hypoventilation), **858**, 1029, **1033**–1034, 1033*t*, 1034*b*
  respiratory and renal compensations and, **1035**
Acinar (alveolar) glands, **125**, 125*f*
Acini/acinar cells, pancreatic, 630, 630*f*, **898**, 899*f*
Acinus (secretory unit), of multicellular exocrine gland, 125, 125*f*
Acne, 163, 169
Acoustic meatus
  external (external auditory/ear canal), 204*f*, 206*f*, **208**, 208*f*, **216***t*, 581*f*, **582**, 596
  internal, 205*f*, 207*f*, **208**, **216***t*, 503*t*
Acoustic nerve. *See* Vestibulocochlear nerve
Acquired immune deficiency syndrome (AIDS), **811**
Acquired immunodeficiencies, 811
Acquired (learned) reflex, 519
Acromegaly, 612*t*, **616**
Acromial end of clavicle, **228**, 228*f*
Acromioclavicular joint, 227*f*, **228**, 256*t*
Acromion, **228**, 229*f*, 267*f*
Acrosomal reaction, **1093**, 1095*f*
Acrosome, 1057*f*, **1058**
ACTH. *See* Adrenocorticotropic hormone
Actin, 49*f*, 88, 88*f*, 91, 95*t*, 283*t*, 286*f*, **287**, 313*t*
  clot retraction and, 660
  cross bridge activity and, 296, 297*f*
  in excitation-contraction coupling, 291*f*, 295*f*
  in sliding filament model, 289
Actin filaments. *See* Thin (actin) filaments
Action potential, 24, **290**, 396, 403, 404
  as all-or-none phenomenon, **409**, 410
  generation of, 396, 405, 406–407*f*, 408
  across sarcolemma, 293–296, 293*f*
  information processing in retina and, 572*f*, 573
  in muscle fiber contraction, 290
    cardiac muscle, 685, 686, 687*f*, 689–690, 689*f*
    skeletal muscle, 290, 291*f*, 292*f*, 293–296, 293*f*, 296*f*
  in neuron, 396, 404, **405**–412, 406–407*f*, 410*f*
    graded potential compared with, 416–417*t*
    information transfer at chemical synapse and, 414, 415*f*
  propagation of, 291, 293, 293*f*, 295*f*, **409**, 409*f*, 411*f*
  impaired, 412
Activated macrophages, 795
Activation energy, **52**, 52*f*, 938
Activation gate, 407*f*, 408
Active humoral immunity, **797**–798, 797*f*
Active hyperemia, **728**, 728*f*
Active processes/transport, **68**, 68*t*, 73–79, 74*f*, 75*f*, 76*f*, 77*f*, 78*t*, 79*f*, 912
  active transport, 74*f*, **75**–76, 75*f*, 78*t*
  electrochemical gradient/membrane potentials and, 80–81
  in tubular reabsorption, **990**
  vesicular transport, **76**–79, 76*f*, 77*f*, 78*t*, 79*f*
Active sites, **51**, 52, 53*f*, 287
Active tubular reabsorption, **990**
Acute (immediate/type I) hypersensitivity, **812**–813, 813*f*
Acute glomerulonephritis, 1008. *See also* Glomerulonephritis
Acute hypotension, 724
Acute leukemia, 654
Acute mountain sickness, 858
Adam's apple (laryngeal prominence), **824**, 825*f*
Adaptation, **494**
  dark and light, **573**
  olfactory, 577
Adaptive immune system/defenses, **782**, 782*f*, **790**–811, 809*f*, 810*t*
  antigens, 770, **791**–792, 791*f*
  cells of, 792–795, 793*f*, 794*f*, 795*t*, 795*f*, 810*t*
  cellular immune response, 782*f*, **790**, 795*t*, 801–811, 802*f*, 803*t*, 804*f*, 805*t*, 806*f*, 807*f*, 809*f*, 810*t*
  humoral immune response, 782*f*, **790**, 795*t*, 796–801, 796*f*, 797*f*, 798*f*, 799*t*, 800*f*, 809*f*
Addison's disease, **625**–626, 626*t*, 1021, 1022
Adduction (body movement), **259**, 259*f*, 325*f*
  of lower limb, 367*t*, 384*t*, 385*f*
  of upper limb, 259*f*, 350*t*, 354*t*, 365*t*
Adductor(s)/adductor muscles, of thigh, 330*f*, 331*f*, **367***t*, 368*f*, **369***t*, 385*f*
Adductor brevis muscle, 368*f*, **369***t*, 384*t*
Adductor hallucis muscle, **382***t*, 383*f*
Adductor hiatus, 748*t*, 748*f*, 749*f*
Adductor longus muscle, 330*f*, 368*f*, **369***t*, 384*t*
Adductor magnus muscle, 331*f*, 368*f*, **369***t*, 371*f*, 384*t*
Adductor pollicis muscle, **364***t*, 365*f*
Adductor tubercle, 240*f*, **241**
A delta fibers, 495
Adenine (A), 54*f*, **55**
Adenocarcinoma, 147, **860**
Adenohypophysis, **609**–610. *See also* Anterior pituitary gland
Adenoidectomy (adenotonsillectomy), **863**
Adenoids, 823. *See also* Pharyngeal tonsils
Adenoma, 144*b*, **147**
Adenosine, 422*t*, **423**, 989
Adenosine diphosphate. *See* ADP
Adenosine monophosphate. *See* AMP
Adenosine triphosphate. *See* ATP
Adenotonsillectomy (adenoidectomy), **863**
Adenylate cyclase, 577, 577*f*, **604**, 605*f*
ADH. *See* Antidiuretic hormone
Adherence, in phagocytosis, 784, 784*f*
Adhesions, 146
Adipocytes (adipose/fat cells), 127*t*, 128*f*, **129**, 130, 131*f*, 958*b*, 960
Adiponectin, 634, 635*t*
Adipose cells. *See* Adipocytes

Adipose (fat) tissue, 127*t*, **130**–133, 131*f*, 151*f*
  autonomic innervation/effects and, 546*t*
  cholesterol transport to, 955
  hormones produced by, 634, 635*t*
  lipolysis in, 953, 953*f*, 954*f*
  in postabsorptive state, 953, 953*f*, 954, 954*f*
  white and brown, 130–133
Adluminal compartment, of seminiferous tubule, 1056*f*, **1058**
ADP (adenosine diphosphate), 55*f*, 56, **658**
  phosphorylation of, 304, 304*f*, 305*f*, 936, 936*f*
Adrenal cortex, **622**, 623–626, 623*f*, 624*f*, 625*f*, 626*t*
Adrenal (suprarenal) gland(s), 602*f*, **622**–627, 623*f*, 624*f*, 625*f*, 626*t*, 628–629*f*, 976. *See also* Adrenal cortex; Adrenal medulla
  aging affecting, 636
  arteries of, 738*f*, 746*t*, 746*f*
  autonomic innervation/effects and, 534*f*, 540*f*, 542, 542*f*
  in stress response, 622, 624, 627, 628–629*f*
  veins of, 750*f*, **756***t*, 756*f*, 757*f*
Adrenal hormones, 622–627, 626*t*. *See also* Adrenal medullary hormones; Adrenocortical hormones
Adrenaline. *See* Epinephrine
Adrenal insufficiency/Addison's disease, **625**–626, 626*t*, 1021, 1022
Adrenal medulla, **622**, 623*f*, 626*t*, 627
  autonomic pathways with synapses in/autonomic innervation and, 540*f*, 542, 542*f*, 546*t*
  blood pressure control and, 721
Adrenal medullary hormones, 626*t*, 627, 628*f*
Adrenergic fibers, **543**
Adrenergic receptors, 543–545, 544*t*
Adrenocortical hormones, 623–626, 623*f*, 624*f*, 626*t*
Adrenocorticotropic hormone (ACTH/corticotropin), **610**, 611*f*, 613*t*, **616**, 620*t*, 624, 624*f*, 625, 629*f*
Adrenogenital syndrome, 626, 626*t*
Adult respiratory distress syndrome (ARDS), **863**
Adventitia, **874**
  of esophagus, 874, 882*f*, 883
  tracheal, **827**, 827*f*
  of ureter, 1002, 1002*f*
  vaginal, 1066
Aerobic cellular respiration, 84, 304, 304*f*, **305**–306, 305*f*, 313*t*, 686. *See also* Cellular respiration; Krebs cycle
Aerobic endurance, **305**
Aerobic exercise, **309**. *See also* Exercise
Aerobic pathways, **938**–939
Afferent arteriole, glomerular, 978, 978*f*, 981*f*, **982**, 982*f*
Afferent (sensory) division of peripheral nervous system, **392**, 392*f*, 497
Afferent lymphatic vessels, **772**, 772*f*
Afferent nerves/neurons/tracts. *See* Sensory (afferent) nerves; Sensory (afferent) neurons; Sensory (ascending) pathways/tracts
Afferent pathway, in homeostasis, 10, 10*f*, 11*f*
Affinity
  hemoglobin, for oxygen, 847, 849*f*
  hormone-receptor, 608
Afterbirth, **1116**
After-discharge circuit, parallel, 427, 427*f*
Afterload, **698**
Age-related macular degeneration (ARMD), **596**
Ageusia, **596**
Agglutination, 665–666, 665*f*, **800**, 800*f*, 809*f*
Agglutinins, **664**, 664*t*
Agglutinogens, **663**, 664*t*, 665*f*
Aggregated lymphoid nodules (Peyer's patches), 771, 771*f*, **775**, 775*f*, **903**
Aging, theories of cellular, 110. *See also specific structure or system*
Aging pigment (lipofuscin), 394
Agonist (muscle), **324**
Agouti-related peptides, in food intake regulation, 960, 961*f*
Agranulocytes, 652, 652*f*, **653**, 653*f*, 655*f*, 656*t*
AIDS (acquired immune deficiency syndrome), **811**
Air blood barrier. *See* Respiratory membrane
Air cells, mastoid, **209**, 582
Air flow, volume and pressure relationships and, 834–840, 835*f*, 836*f*, 837*f*, 838*f*, 839*f*. *See also* Airway resistance

Beta oxidation, **946**, 946*f*, 947*f*
Beta (β) particles, 28
Beta (β)-pleated sheet, **50**, 50*f*
Beta waves, **461**, 461*f*
Biaxial movement, **258**, 263*f*
Bicarbonate/bicarbonate ion, **39**, **850**–852
  in acid-base balance, 41, 852, 1027–1028, 1029–1032, 1030*f*, 1031*f*, 1032*f*, 1034*b*
  in acidosis/alkalosis, 1033*t*, 1034–1035, 1034*b*
  carbon dioxide transport as, **850**–852, 851*f*
  generation of, 1031–1032, 1031*f*, 1032*f*
  in mucosal barrier, 887
  in plasma/interstitial fluid/intracellular fluid, 1014*f*
  tubular reabsorption and, 992*f*, 1029, 1030–1031, 1030*f*
  tubular secretion and, 994, 995, 1029, 1030*f*, 1032
Bicarbonate buffer system, **41**, **852**, **1027**–1028, 1028*f*
  bicarbonate reabsorption and, 1029, 1030–1031, 1030*f*
  bicarbonate regeneration and, 1031–1032, 1031*f*, 1032*f*
  bicarbonate secretion and, 1029, 1032
Biceps brachii muscle, 330*f*, 355*f*, 356*f*, **357***t*, 362*t*, 363*f*
  tendon of long head of, 266, 267*f*
Biceps femoris muscle, 331*f*, 371*f*, **373***t*, 384*t*
Bicipital groove (intertubercular sulcus), 230*f*, **231**
Bicuspid (mitral) valve, 677*f*, 678*f*, **679**, 681*f*, 696*f*
Bicuspids (premolars), 879*f*, **880**
Bifid spinous process, 221, 222*f*
Bilayer, plasma membrane, 63, 64–65*f*, 66
Bile/bile salts, 47*t*, 894, 896*f*, **897**, 897*f*, 913*f*, 916, 916*f*
  secretion of, 900, 900*f*, 901*f*
  in urine, 1001*t*
Bile canaliculi, 896*f*, **897**
Bile duct, **894**, 895*f*, 896*f*, 897, 898, 900*f*
Bile pigment, 897. *See also* Bilirubin
Biliary calculi (gallstones), **898**
Bilirubin, **649**, 649*f*, **897**
Bilirubinuria, 1001*t*
Bimalleolar fracture, 242*f*, 243
Biochemistry, **38**–56
  inorganic compounds in, **38**–41
  organic compounds in, **38**, 41–56
Biogenic amines, 421*t*, **423**
Biological colloids, 38
Biopsy, in cancer diagnosis, 145*b*
Biotin (vitamin B_7), 932*t*
Biotransformation, liver in, 956*t*
Bipennate fascicle pattern/muscles, 326*f*, 327
Bipolar neurons/cells, **397**, 398–399*t*
  retinal, 560*f*, **561**, 572*f*, 573
Birth, 1114–1116, 1114*f*, 1115*f*
  adjustment to extrauterine life after, 1116
  bone development at, 194
  circulation changes at, 1107, 1109*f*, 1116
  digestive system after, 919
  oxytocin in labor and, 11, 612, **1114**–1115, 1114*f*
Birth canal. *See* Vagina
Birth control, 1118–1119*b*
Birth control pill, 1118*b*
2,3-Bisphosphoglycerate (BPG), hemoglobin saturation and, 847–850
Bisphosphonates, 193
Bitter taste, 578, 579
Blackhead, 163
Black patients, sickle-cell anemia in, 650
Bladder. *See* Urinary bladder
Bladder cancer, **1007**

Mucus
  in body defense, 783, 783*t*, 808*f*
  cervical glands producing, 1064, 1066
  in cystic fibrosis, 861
  duodenal glands secreting, 903
  in gastric mucosal barrier, 887
  mucosa of alimentary canal producing, 872, 873
  mucous neck cells producing (acidic), 886*f*, **887**
  nasal glands producing, 576, 576*f*, 822
  salivary glands producing, **878**
  submucosa of trachea producing, 827
Müllerian (paramesonephric) ducts, 1082*f*, **1083**
Multiaxial movement, **258**, 263*f*
Multicellular glands, 123, 123*f*
  exocrine, 123*f*, **125**–126, 125*f*, 126*f*
Multifidus muscle, 343*f*
Multimodal association areas, 440*f*, **443**
Multineuronal pathways, **478**–480, 479*f*, 481*t*
Multinucleate cells, **91**
Multipennate fascicle pattern/muscles, 326*f*, 327
Multiple-allele inheritance, **1129**, 1129*t*
Multiple electrolyte solution, for volume restoration, 663
Multiple motor unit summation (recruitment), **301**–302, 301*f*, 309
Multiple sclerosis, **412**, 812
Multipolar neurons, **397**, 398–399*t*
Multi unit smooth muscle, **316**
Mumps, **921**
Murmurs, heart, **696**
Muscarinic agents, autonomic activity and, 544*t*
Muscarinic receptors, 421*t*, **543**, 544*t*
Muscle(s)/muscle tissue, 116*f*, 138–139*f*, **138**–140, 279–322, 283*t*, 312–313*t*. *See also* Cardiac muscle/cardiac muscle tissue; Muscular system; Skeletal muscle(s)/skeletal muscle tissue; Smooth muscle/smooth muscle tissue
  characteristics of, 280
  developmental aspects of, 316–319, 316*f*, 317*b*
  functional classification of, 324, 325*f*
  functions of, 280–281
  homeostatic imbalances and, 287, 293, 296–298, 310
  regeneration of, 317
  types of, 280, 312–313*t*
Muscle action, 324, 325*f*, 326, 332
Muscle atrophy, disuse causing, 310
Muscle attachments, 282–284, 326
Muscle cells/fibers, 138, 138*f*, **280**, 283*t*, 312*t*. *See also* Cardiac muscle cells; Skeletal muscle fibers/cells; Smooth muscle fibers/cells
  contraction of. *See* Muscle contraction
  development of, 316–319, 316*f*
  in muscle spindle, 520–521, 520*f*, 521*f*
  naming muscles and direction of, 324
  types/classification of, 307–309, 307*f*, 308*t*
Muscle contraction, 280, 313*t*
  cardiac muscle, 313*t*, 689–690, 689*f*
  force of, 306–307, 307*f*
  graded, 299–302, **300**, 300*f*
  heat production during, 281
  muscle fatigue and, **306**
  skeletal muscle. *See under* Skeletal muscle(s)/skeletal muscle tissue
  sliding filament model of, **289**, 289*f*
  smooth muscle, 313*t*, 314–316, 315*f*
Muscle fascicles, **282**, 282*f*, 283*t*, 324, 326–327, 326*f*
Muscle fatigue, **306**
Muscle fibers/cells. *See* Muscle cells/fibers
Muscle metabolism, 303–306, 304*f*, 305*f*, 313*t*, 952, 953*f*
Muscle spasm, **319**
Muscle spindle, 477*f*, 492*t*, **493**, 520–521, 520*f*, 521*f*, 522*f*, 523–524
Muscle strain, **319**
Muscle stretch, 307, 307*f*, 313*t*, 315–316, 697–698
Muscle tension, **299**, 307, 307*f*, 316
Muscle tone, 258, 281, 302–303, 310, 314
Muscle twitch, **299**, 299*f*, 300*f*
Muscular (distributing) arteries, 707*f*, 709*t*, **710**
Muscular dystrophy, **287**, 317
Muscularis externa
  of alimentary canal, **873**, 873*f*
  of esophagus, 882*f*, 883
  of small intestine, 903
  of stomach, 885*f*, 886, 886*f*
  of ureter, 1002, 1002*f*
  of vagina, 1066
Muscularis mucosae
  of alimentary canal, **873**, 873*f*
  of small intestine, 902*f*
  of stomach, 886*f*
Muscular pump, venous return and, **717**–718, 718*f*, 723*f*
Muscular system, 6*f*, 323–389, 330*f*, 331*f*. *See also* Muscle(s)/muscle tissue; Skeletal muscle(s)
  actions of, 324, 325*f*, 326
  cardiovascular system and, 318*b*, 761*b*
  case study and, 322*b*, 388–389*b*
  digestive system and, 318*b*, 920*b*
  endocrine system and, 318*b*, 637*b*
  functions of, 6*f*, 8, 280–281
  homeostatic imbalances and, 287, 293, 296–298, 310
  homeostatic relationships of, 318*b*
  integumentary system and, 168*b*, 318*b*
  lymphatic system/immunity and, 318*b*, 778*b*
  movement and, 6*f*, 8, 280–281
  naming muscles and, 324–326
  nervous system and, 318*b*, 550*b*
  reproductive system and, 318*b*, 1085*b*
  respiratory system and, 318*b*, 862*b*
  skeletal system and, 196*b*, 318*b*
    lever systems and, **327**–328, 327–328*f*, 329*f*
  thyroid hormone affecting, 618*t*
  urinary system and, 318*b*, 1036*b*
Musculocutaneous nerve, 356*t*, 357*t*, 510*t*, 511*f*, **512**
Mutation(s), **110**, 144*b*, 1132, 1133, **1135**
Myalgia, **319**
Myasthenia gravis, 293, 812
Myelencephalon, **435**, 435*f*, 436*f*
Myelinated axons/fibers, **396**, 397*f*, 411–412, 411*f*
Myelination, 393*f*, 396–397, 397*f*, 483, 411–412, 411*f*
  multiple sclerosis and, **412**, 812
Myelin sheath(s), 393*f*, 394, **396**, 397*f*, 411–412, 411*f*, 812
Myelin sheath gaps (nodes of Ranvier), 395*f*, **396**, 397
Myelitis, **484**
Myeloblasts, **654**, 655*f*
Myelocytes, **654**, 655*f*
Myelogram, **484**
Myeloid leukemia, 654
Myeloid stem cells, **647**, **654**, 655*f*
Myelomeningocele, 483, 483*f*
Myeloproliferative disorder, **667**
Myenteric nerve plexus, 873*f*, **874**
Mylohyoid muscle, **338***t*, 339*f*
Myo (prefix), **280**
Myoblasts, **316**, 316*f*
Myocardial infarction (heart attack), **683**, 700, 760*b*
Myocarditis, **702**
Myocardium, **673**, 673*f*, 677*f*
Myoclonus, **484**
Myocytes. *See* Cardiac muscle cells/fibers
Myoepithelial cells, 161
Myofascial pain syndrome, **319**
Myofibrils, 283*t*, **284**–288, 285*f*, 286*f*, 288*f*, 312*t*, 685
Myofilaments, **138**, 283*t*, **284**–287, 285*f*, 286*f*, 311–314, 312*t*
Myogenic controls, of blood flow, 726, **727**, 727*f*, 987*t*, **988**, 988*f*
Myoglobin, **284**
Myogram, **299**, 299*f*
Myoid cells, **1055**, 1055*f*
Myomesin, 287
Myometrium, 1063*f*, **1065**, 1114
Myopathy, **319**
Myopia (nearsightedness), 566*f*, **567**
Myosin, 49*f*, 88, 283*t*, **286**–287, 286*f*
  clot retraction and, 660
  cross bridge activity and, 296, 297*f*, 298, 314*f*
  in excitation-contraction coupling, 291*f*, 295*f*
  in sliding filament model, 289
  in smooth muscle, 311, 313*t*, 314, 315*f*
Myosin ATPase, 307, 308
Myosin filaments. *See* Thick (myosin) filaments
Myosin heads, 283*t*, 286–287, 286*f*, 287, 289, 291*f*, 296, 297*f*, 311
Myosin kinase (myosin light chain kinase), **314**, 315*f*
Myosin tail, 286, 286*f*, 287
Myotome, 1105*f*, **1106**, 1106*f*
Myotonic dystrophy, **319**
Myotubes, 316, 316*f*

Right inguinal (iliac) region, **20**, 20*f*
Right lateral (lumbar) region, **20**, 20*f*
Right lobe, of liver, 894, 894*f*, 895*f*
Right lower quadrant (RLQ), **19**, 19*f*
Right lymphatic duct, 768*f*, **769**, 769*f*
Right main bronchus, 820*f*, **828**
Right marginal artery, 675*f*, **682**, 683*f*
Right posterior intercostal veins, 754*f*, **754***t*
Right pulmonary artery, 675–677*f*, **736***t*, 736*f*
Right pulmonary vein, 675–677*f*, 736*f*
Right subclavian artery, **738***t*, 738*f*, 742*f*, 743*f*
Right suprarenal vein, 750*f*, 757*f*. *See also* Suprarenal veins
Right upper quadrant (RUQ), **19**, 19*f*
Right ventricle, 671, 671*f*, 674, 681*f*, 682, 682*f*, 683*f*
Rigor mortis, 296–298, 297*f*
Ringer's solution, for volume restoration, 663
Risorius muscle, **334***t*, 335*f*
RNA (ribonucleic acid), **53**–55, 53*t*
  in chromatin, 93
  digestion/absorption of, 913*f*, 917
  messenger (mRNA), 54, **99**, 99*f*, 102–105, 102*f*, 105–108*f*
  micro (miRNAs), 54, **108**
  in protein synthesis, 54, 98–108, 99*f*, 102*f*, 105*f*, 106–107*f*, 108*f*
  ribosomal (rRNA), 54, 84, **99**
  small noncoding, 1131–1132
  small/small interfering, **108**, 1132
  transfer (tRNA), 54, **99**, 103–104, 103*f*, 106–107*f*, 108*f*
RNA polymerase, **102**, 102*f*
Rod(s), 560*f*, **561**, 564*f*, 568–571, 568*f*, 569*t*, 573, 943*f*. *See also* Photoreceptors
Rod discs, 568*f*, 569
Rod inner segments, 568, 568*f*
Rod outer segments, 560*f*, 568, 568, 568*f*, 569
Roof of nasal cavity, 215
Roof of orbit, 213*f*
Root
  of brachial plexus, **510**, 511*f*
  hair, 151*f*, 158, 158*f*
  of lung, 832*f*, **833**
  nail, 160, 160*f*
  nerve, 509. *See also* Dorsal root(s); Spinal root(s); Ventral root(s)
  of nose, 821, 821*f*
  of penis, 1051*f*
  of tongue, 877
  of tooth, **880**, 880*f*
Root canal, **880**, 880*f*
Root hair plexus (hair follicle receptor), 151*f*, **159**, 164, 491*t*, **492**
Rooting reflex, 919
Rootlets, spinal nerve, 471*f*, **508**, 508*f*
Root sheath, epithelial, 158*f*, **159**
Rosacea, **170**
Rotation (body movement), **260**, 260*f*, 350*t*, 354*t*, 362*t*, 367*t*, 384*t*
Rotational acceleration, 592, 592*f*, 593
Rotator cuff, **266**, 267*f*, 354*t*, 355–356*f*
Rotatores muscle, 343*f*
Rotator muscles of thigh, lateral, 372–373*t*
Rotor, ATP synthase, 941*f*, 943*f*
Rough endoplasmic reticulum, 62*f*, 84, 84*f*, **85**, 85*f*, 86*f*, 87*f*, 94*t*, 105, 105*f*
Round ligament (ligamentum teres), **894**, 894*f*, 895*f*, **1107**, 1107*t*, 1109*f*
Round ligament of uterus, 1061*f*, 1063*f*, **1064**, 1064*f*
Round window, 581*f*, **582**, 583*f*, 587*f*
rRNA. *See* Ribosomal RNA
Rubrospinal tract, 475*f*, **478**, 479*f*, 481*t*
Ruffini endings (bulbous corpuscles), 492*t*, **493**
Ruffled border, osteoclast, 181, 188
Rugae
  of bladder, 1003, 1003*f*
  gastric, **885**, 885*f*
  vaginal, 1066

movement and, 6*f*, 8
muscular system and, 196*b*, 318*b*
lever systems and, **327**–328, 327–328*f*, 329*f*
parathyroid hormone affecting, **189**, 189*f*
reproductive system and, 196*b*, 1085*b*
respiratory system and, 196*b*, 862*b*
thyroid hormone affecting, 188, 618, 618*t*
urinary system and, 196*b*, 1036*b*
Skills (procedural) memory, 460
Skin (cutaneous membrane/integument), 5*f*, 123, **141**, 141*f*, 150–157, 151*f*, 152*f*, 154*f*, 155*f*, 156*f*
appendages of, 151*f*, **157**–163, 158*f*, 160*f*, 161*f*. *See also specific structure*
artificial/synthetic, for burn injury, 167
autonomic innervation/effects and, 534*f*, 539*f*, 540*f*
burn injury and, **166**–167, 166*f*, 167*f*
case study and, 172*b*
color of, 156–157, 1130*f*, 1131
cutaneous sensation (receptors/sense organs) and, 151*f*, 152*f*, 154, 155, **164**
developmental aspects of, 167–169
excretion via, 165
functions of, 5*f*, 6*f*, 8, 163–165
biological barriers, 164
as blood reservoir, 165
body defense, 5*f*, 6*f*, 8, 163–164, 782–783, 782*f*, 783*t*
boundary maintenance, 5*f*, 6*f*, 8, 163–164
chemical barriers/protective secretions and, 163, 783
metabolic, 164–165
as physical barrier, 163–164
protective, 5*f*, 6*f*, 8, 163–164, 782–783, 782*f*, 783*t*
temperature regulation, 164, 728, 729
homeostatic imbalances/disorders of, 156–157, 163, 164, 165–167
homeostatic relationships of, 5*f*, 168*b*
hormones produced by, 634–635, 635*t*
innervation of (dermatomes), **516**–517, 516*f*
perfusion (blood flow) of, 164, 726*f*, 728–729
sun damage and, 153, 156, 163, 165, 169
thick, **153**
thin, 153
Skin cancer, 156, 165–166, 165*f*
Skin-fold test, **969**
Skin grafts, for burn injury, 167
Skin patch, for contraception, 1118*b*
Skin pigments, 156
Skin (decubitus) ulcers, **169**
Skull, 200, 200*f*, **201**–217, 201*f*, 202*f*, 204–207*f*, 206*f*, 207*f*, 216–217*t*, 246, 246*f*
Sleep, 461, 461*f*, 462–464, 463*f*
Sleep apnea, **860**
Sleep-wake cycles, 449, 458, 462–464
Sliding filament model of contraction, **289**, 289*f*, 314
Slipped (herniated/prolapsed) disc, **219**–220, 219*f*
Slit diaphragm, 985*f*, 986
Slow block to polyspermy (zona reaction), **1096**
Slow Ca^{2+} channels, in cardiac muscle contraction, 685, **689**, 689*f*
Slow fibers, **307**, 307*f*, 308*t*
Slow oxidative fibers, 307*f*, **308**, 308*t*
Slow waves, cyclic, of stomach, 892
Slow-wave sleep, **463**
Small cardiac vein, 675*f*, **683**, 683*f*
Small cell carcinoma, of lung, **860**
Small cell (lateral) nuclear group, 453*f*, **457**
Small intestine, 869*f*, 900–906, **901**, 901*f*, 902*f*, 903*f*
autonomic innervation/effects and, 536*f*, 540*f*
in calcium regulation, 1026
digestive processes occurring in, 870*f*, 902*f*, 904*t*, 905–906, 905*t*, 912, 913*f*, 914*f*, 915*f*
hormones produced by, 635*t*
motility of, 905–906, 905*t*
Small noncoding RNAs, 1131–1132
Small saphenous vein, 751*f*, **758***t*, 758*f*
Small/small interfering RNAs, **108**, 1132
Smell, 440*f*, 443, 457, 575–578, 576*f*, 577*f*, 580, 595. *See also under Olfactory*
Smell transduction, 577, 577*f*
Smoking, effects of, 724, 858, 858*f*, 860
Smooth endoplasmic reticulum, 62*f*, 84*f*, **85**, 87*f*, 94*t*

Visual pigments (photopigments), 568*f*, **569**–571, 570*f*, 571*f*, 573
Visual processing, 575
Visual receptor cells. *See* Photoreceptors
Vital capacity (VC), **841**, 841*f*
forced (FVC), **842**
Vital signs, **716**–717
Vitamin(s), 9, **931**, 932*t*
absorption of, 917
fat-soluble, 47*t*, 917, **931**, 932*t*
gut bacteria in synthesis of, 909
immune system and, 814
storage of in liver, 956*t*
water-soluble, 917, **931**, 932*t*
Vitamin A (retinol), 47*t*, 156, 569, 570*f*, 571, 573, 931, 932*t*
Vitamin B_1 (thiamine), 932*t*
Vitamin B_2 (riboflavin), 932*t*, 935
Vitamin B_3 (niacin), 932*t*, 935
Vitamin B_5 (pantothenic acid), 932*t*
Vitamin B_6 (pyridoxine), 932*t*
Vitamin B_7 (biotin), 932*t*
Vitamin B_9 (folic acid/folacin), 483, 649, 649*f*, 932*t*, 1112
Vitamin B_{12} (cyanocobalamin), 649, 649*f*, 932*t*
intrinsic factor and, 650, 889, 931
Vitamin C (ascorbic acid), 147, 931, 932*t*
Vitamin D, 47*t*, **917**, 931, 932*t*
calcium absorption/regulation and, 164, 917
deficiency of, osteomalacia and rickets and, 193, 932*t*
immune system and, 814
for osteoporosis, 193
parathyroid hormone affecting activation of, 622, 622*f*
synthesis of in skin, 164
Vitamin E (tocopherol), 47*t*, 931, 932*t*
Vitamin K (phylloquinone), 47*t*, 658, 662, 931, 932*t*
Vitiligo, **170**
Vitreous humor, 558*f*, **562**, 562*f*
VLDLs. *See* Very low density lipoproteins
VMN. *See* Ventromedial nucleus
V_{O_2max}, aging affecting, 861
Vocal cords
false (vestibular folds), 823*f*, 825*f*, **826**, 826*f*
true. *See* Vocal folds
Vocal folds (true vocal cords), 823*f*, 825–826, 825*f*, 826*f*
Vocal ligaments, **825**
Voice box. *See* Larynx
Voice production, 826
Voiding (micturition), **1004**–1005, 1005*f*, 1007
Volatile acid, **1029**
Volkmann's (perforating) canals, **182**, 183*f*
Volt(s), 400
Voltage, 79, **400**
Voltage-gated channel(s), **290**, **400**, 401*f*
action potential and, 406*f*, 407*f*, 408
information transfer at chemical synapse and, 414, 415*f*, 572*f*
muscle contraction and, **290**, 292*f*, 293*f*, 315*f*, **689**, 689*f*
Volume-pressure relationships, in respiratory physiology, 834–840, 835*f*, 836*f*, 837*f*, 838*f*, 839*f*
Volume replacement, 663
Voluntary muscle, **138**, **280**. *See also* Skeletal muscle(s)
Voluntary nervous system, **392**, 392*f*. *See also* Somatic nervous system
Vomer, 202*f*, 203*f*, 205*f*, 206*f*, **212**, 214*f*, **217***t*
Vomiting (emesis), **893**
von Willebrand factor, 658
V (variable) region, 798*f*, **799**
VRG. *See* Ventral respiratory group
v-SNAREs, in exocytosis, 79, 79*f*
VTA. *See* Ventral tegmental area
VT/V-tac. *See* Ventricular tachycardia
Vulva (external genitalia), **1060**, 1066*f*, **1067**, 1083–1084, 1083*f*

Wallerian degeneration, 498*f*
Walls of nasal cavity, 215
Walls of orbit, 212, 213*f*
Warfarin, **662**
Warts, genital, **1080**
Water, **9**, **38**, 39*f*, 843, 843*t*
absorption of, in digestion, 917–918
alveolar, 843*t*, 844
body, 1013, 1013*f*, 1035–1037, 1113. *See also* Water balance
exchanges of among fluid compartments, 1015, 1015*f*
hydrogen bonding and, 34–35, 35*f*
intake of, 1016–1017, 1016*f*, 1017*f*
loss of
insensible, **965**, **1016**
sensible, **1016**, 1017
metabolic (water of oxidation), **1016**
output of, 1016, 1016*f*, 1017
partial pressure of, 843, 843*t*
polarity of, 34, 34*f*, 38
as solvent, 29, **38**, 1013
as survival requirement, **9**, 38
tubular reabsorption of, 991, 991*f*, 992*f*
Water balance, 1016–1019, 1016*f*, 1018*f*, 1019*f*
antidiuretic hormone in, 449, 613, 998, 999*f*, 1000, 1017–1018, 1018*f*
developmental aspects of, 1035–1037
disorders of, 1018–1019, 1019*f*
hypothalamus in, 449
intake/intake regulation and, 1016–1017, 1017*f*
kidneys in, 974, 995
output/output regulation and, 1016, 1016*f*, 1017
sodium in, 1020*t*, 1021–1024, 1021*t*, 1022*f*, 1023*f*, 1024*f*
Water intake, 1016–1017, 1017*f*
Water on the knee, 273
Water output, 1016, 1016*f*, 1017
Water-soluble hormones, 604–605, 605*f*, 609*t*
Water-soluble vitamins, 917, **931**, 932*t*
Wavelength, 563–564
light, 564, 564*f*
sound, **586**
Wave (temporal) summation, **300**–301, 416*t*, 419*f*, 420
WBCs (white blood cells). *See* Leukocyte(s)
Weak acids, **41**, 1027, 1027*f*
Weak bases, **41**, 1027
"Wear-and-tear arthritis" (osteoarthritis/degenerative joint disease), **273**–275
Wear-and-tear theory, of aging, 110
Weber's test, **596**
Weeping lubrication, 254
Weight, regulation of, 958–959*b*, 960–962, 961*f*
Weight gain, during pregnancy, 1112
Weight-loss supplements, 959*b*
Weight training, anabolic steroid abuse and, 317*b*
Wernicke's area, 440*f*, 443, **459**
White blood cell(s). *See* Leukocyte(s)
White blood cell count, 652
differential, 652*f*, **666**
White columns/funiculi, 473*f*, **474**, 475*f*, **476**, 480*t*
White fat (white adipose tissue), 130
Whitehead, 163
White matter, **436**, 437*f*
of brain
brain stem, 437*f*
cerebellar, 437*f*, 454, 455*f*
cerebral, 435*f*, 437*f*, 439, **444**, 445*f*, 446*f*
of spinal cord, 437*f*, 473*f*, 474, 475*f*, 482, 482*f*
White pulp, 773*f*, **774**
White ramus communicans/rami communicantes, 535*t*, **538**, 538*f*, 539–541, 539*f*, 540*f*
Whole blood transfusions, **663**
Willis, circle of (cerebral arterial circle), 714, 740*f*, **741***t*, 741*f*
Window of implantation, 1099
Windpipe. *See* Trachea
Wisdom teeth, 879–880
Withdrawal (coitus interruptus), 1118*b*
Withdrawal (flexor) reflex, 8, 10, **524**, 525*f*
Wolffian (mesonephric) ducts, **1006**, 1006*f*, 1082*f*, **1083**

Wolff's law, 189–190
Working (short-term) memory, **460**, 460*f*
Wound healing/repair, 142–146, 143*f*
  by first/second intention, **147**
Wrist (carpus). *See* Carpal bones/carpus (wrist)
Wrist drop, 512
Wrist joint, 256*t*
Wrong site surgery, 20

X chromosome, **1081**, 1125, 1130, 1130*f*
Xenical. *See* Orlistat
Xenografts, **814**
Xerostomia (dry mouth), 878, 1017, 1017*f*
Xiphisternal joint, 225*f*, **226**
Xiphoid process, 225, 225*f*
X-linked inheritance, **1130**
X-ray imaging, 16*f*, 16*b*
X rays, 16*b*, 563, 564*f*

Y chromosome, **1081**, 1125, 1130, 1130*f*
Yellow bone marrow, 178, 179, 179*f*, 666
Yellow bone marrow cavity, 178
Yellowness of skin, 157
Yolk sac, 666, 1100*f*, 1101*f*, **1102**, 1103*f*, 1104*f*, 1105*f*

Z discs/lines, **284**
  in cardiac muscle, 684*f*, 685
  in skeletal muscle, **284**, 285*f*, 286*f*, 288*f*, 289, 289*f*
ZIFT. *See* Zygote intrafallopian transfer
Zinc, 26*t*, 933*t*
